W. H. Freeman and Company
New York

Publisher: Clancy Marshall
Senior Acquisitions Editor: Jessica Fiorillo
Senior Developmental Editor: Randi Rossignol
Marketing Manager: John Britch
Media and Supplements Editor: Dave Quinn
Assistant Editor: Tony Petrites
Photo Editor: Bianca Moscatelli
Cover/Text Designer: Blake Logan
Senior Project Editor: Georgia Lee Hadler
Copy Editor: Margaret Comaskey
Illustration Coordinator: Bill Page
Illustrations: Peter Atkins with Network Graphics
Production Coordinator: Paul Rohloff
Composition: MPS Limited, A Macmillan Company
Printing and Binding: Quebecor

Library of Congress Control Number:
2009936820
ISBN-13: 978-1-4292-1955-6
ISBN-10: 1-4292-1955-6

CONTENTS IN BRIEF

FUNDAMENTALS F1

Introduction and Orientation, Matter and Energy, Elements and Atoms, Compounds, The Nomenclature of Compounds, Moles and Molar Masses, Determination of Chemical Formulas, Mixtures and Solutions, Chemical Equations, Aqueous Solutions and Precipitation, Acids and Bases, Redox Reactions, Reaction Stoichiometry, Limiting Reactants

1	ATOMS: THE QUANTUM WORLD	1
2	CHEMICAL BONDS	55
	MAJOR TECHNIQUE 1: INFRARED SPECTROSCOPY	90
3	MOLECULAR SHAPE AND STRUCTURE	93
	MAJOR TECHNIQUE 2: ULTRAVIOLET AND VISIBLE SPECTROSCOPY	130
4	THE PROPERTIES OF GASES	133
5	LIQUIDS AND SOLIDS	171
	MAJOR TECHNIQUE 3: X-RAY DIFFRACTION	203
6	INORGANIC MATERIALS	205
7	THERMODYNAMICS: THE FIRST LAW	235
8	THERMODYNAMICS: THE SECOND AND THIRD LAWS	287
9	PHYSICAL EQUILIBRIA	333
	MAJOR TECHNIQUE 4: CHROMATOGRAPHY	381
10	CHEMICAL EQUILIBRIA	383
11	ACIDS AND BASES	423
12	AQUEOUS EQUILIBRIA	475
13	ELECTROCHEMISTRY	515
14	CHEMICAL KINETICS	561
	MAJOR TECHNIQUE 5: COMPUTATION	610
15	THE ELEMENTS: THE MAIN GROUP ELEMENTS	611
16	THE ELEMENTS: THE d-BLOCK	667
17	NUCLEAR CHEMISTRY	705
18	ORGANIC CHEMISTRY I: THE HYDROCARBONS	735
	MAJOR TECHNIQUE 6: MASS SPECTROMETRY	758
19	ORGANIC CHEMISTRY II: POLYMERS AND BIOLOGICAL COMPOUNDS	761
	MAJOR TECHNIQUE 7: NUCLEAR MAGNETIC RESONANCE	791

CONTENTS

Preface xv

FUNDAMENTALS F1

INTRODUCTION AND ORIENTATION F1

- Chemistry and Society F1
- Chemistry: A Science at Three Levels F2
- How Science Is Done F2
- The Branches of Chemistry F4
- Mastering Chemistry F4

A MATTER AND ENERGY F5

- A.1 Physical Properties F5
- A.2 Force F9
- A.3 Energy F10
- **Exercises F13**

B ELEMENTS AND ATOMS F15

- B.1 Atoms F15
- B.2 The Nuclear Model F16
- B.3 Isotopes F17
- B.4 The Organization of the Elements F18
- **Exercises F21**

C COMPOUNDS F22

- C.1 What Are Compounds? F22
- C.2 Molecules and Molecular Compounds F23
- C.3 Ions and Ionic Compounds F24
- **Exercises F28**

D THE NOMENCLATURE OF COMPOUNDS F29

- D.1 Names of Cations F29
- D.2 Names of Anions F29
- D.3 Names of Ionic Compounds F31

TOOLBOX D.1 HOW TO NAME IONIC COMPOUNDS F31

- D.4 Names of Inorganic Molecular Compounds F32

TOOLBOX D.2 HOW TO NAME SIMPLE INORGANIC MOLECULAR COMPOUNDS F33

- D.5 Names of Some Common Organic Compounds F35
- **Exercises F36**

E MOLES AND MOLAR MASSES F37

- E.1 The Mole F37
- E.2 Molar Mass F39
- **Exercises F44**

F DETERMINATION OF CHEMICAL FORMULAS F45

- F.1 Mass Percentage Composition F46
- F.2 Determining Empirical Formulas F47
- F.3 Determining Molecular Formulas F49
- **Exercises F50**

G MIXTURES AND SOLUTIONS F51

- G.1 Classifying Mixtures F51
- G.2 Separation Techniques F53
- G.3 Concentration F54
- G.4 Dilution F57

TOOLBOX G.1 HOW TO CALCULATE THE VOLUME OF STOCK SOLUTION REQUIRED FOR A GIVEN DILUTION F57

- **Exercises F58**

H CHEMICAL EQUATIONS F60

- H.1 Symbolizing Chemical Reactions F60
- H.2 Balancing Chemical Equations F62
- **Exercises F64**

I AQUEOUS SOLUTIONS AND PRECIPITATION F65

- I.1 Electrolytes F65
- I.2 Precipitation Reactions F67
- I.3 Ionic and Net Ionic Equations F67
- I.4 Putting Precipitation to Work F69
- **Exercises F70**

J ACIDS AND BASES F72

- J.1 Acids and Bases in Aqueous Solution F72
- J.2 Strong and Weak Acids and Bases F74
- J.3 Neutralization F75
- **Exercises F76**

K REDOX REACTIONS F77

- K.1 Oxidation and Reduction F78
- K.2 Oxidation Numbers: Keeping Track of Electrons F79

TOOLBOX K.1 HOW TO ASSIGN OXIDATION NUMBERS F80

- K.3 Oxidizing and Reducing Agents F81
- K.4 Balancing Simple Redox Equations F83
- **Exercises F84**

L REACTION STOICHIOMETRY F85
L.1 Mole-to-Mole Predictions F86
L.2 Mass-to-Mass Predictions F86
TOOLBOX L.1 HOW TO CARRY OUT MASS-TO-MASS CALCULATIONS F87
L.3 Volumetric Analysis F89
TOOLBOX L.2 HOW TO INTERPRET A TITRATION F90
Exercises **F93**
M LIMITING REACTANTS F95
M.1 Reaction Yield F95
M.2 The Limits of Reaction F96
TOOLBOX M.1 HOW TO IDENTIFY THE LIMITING REACTANT F97
M.3 Combustion Analysis F100
Exercises **F103**

Chapter 1 ATOMS: THE QUANTUM WORLD

INVESTIGATING ATOMS 1
1.1 The Nuclear Model of the Atom 2
1.2 The Characteristics of Electromagnetic Radiation 3
1.3 Atomic Spectra 6
QUANTUM THEORY 8
1.4 Radiation, Quanta, and Photons 8
1.5 The Wave–Particle Duality of Matter 13
1.6 The Uncertainty Principle 15
1.7 Wavefunctions and Energy Levels 17
THE HYDROGEN ATOM 22
1.8 The Principal Quantum Number 22
1.9 Atomic Orbitals 23
1.10 Electron Spin 30
1.11 The Electronic Structure of Hydrogen 30
Box 1.1 How Do We Know . . . That an Electron Has Spin? 31
MANY-ELECTRON ATOMS 32
1.12 Orbital Energies 32
1.13 The Building-Up Principle 33
TOOLBOX 1.1 HOW TO PREDICT THE GROUND-STATE ELECTRON CONFIGURATION OF AN ATOM 36
1.14 Electronic Structure and the Periodic Table 37
Box 1.2 The Development of the Periodic Table 38
THE PERIODICITY OF ATOMIC PROPERTIES 39
1.15 Atomic Radius 39
1.16 Ionic Radius 40
1.17 Ionization Energy 42
1.18 Electron Affinity 44
1.19 The Inert-Pair Effect 46
1.20 Diagonal Relationships 46
1.21 The General Properties of the Elements 46
Exercises **49**

Chapter 2 CHEMICAL BONDS

IONIC BONDS 55
2.1 The Ions That Elements Form 56
2.2 Lewis Symbols 58
2.3 The Energetics of Ionic Bond Formation 58
2.4 Interactions Between Ions 59
COVALENT BONDS 63
2.5 Lewis Structures 63
2.6 Lewis Structures of Polyatomic Species 64
TOOLBOX 2.1 HOW TO WRITE THE LEWIS STRUCTURE OF A POLYATOMIC SPECIES 65
2.7 Resonance 67
2.8 Formal Charge 69
TOOLBOX 2.2 HOW TO USE FORMAL CHARGE TO DETERMINE THE MOST LIKELY LEWIS STRUCTURE 70
EXCEPTIONS TO THE OCTET RULE 71
2.9 Radicals and Biradicals 72
2.10 Expanded Valence Shells 72
Box 2.1 What Has This to Do with . . . Staying Alive? 73
2.11 The Unusual Structures of Some Group 13/III Compounds 75
IONIC VERSUS COVALENT BONDS 76
2.12 Correcting the Covalent Model: Electronegativity 76
2.13 Correcting the Ionic Model: Polarizability 78
THE STRENGTHS AND LENGTHS OF COVALENT BONDS 79
2.14 Bond Strengths 79
2.15 Variation in Bond Strength 80
2.16 Bond Lengths 81

Box 2.2 How Do We Know . . . the Length of a Chemical Bond? 83
Exercises 84

MAJOR TECHNIQUE 1: INFRARED SPECTROSCOPY 90

Chapter 3 MOLECULAR SHAPE AND STRUCTURE

THE VSEPR MODEL 93
Box 3.1 Frontiers of Chemistry: Drugs by Design and Discovery 94
3.1 The Basic VSEPR Model 94
3.2 Molecules with Lone Pairs on the Central Atom 98
TOOLBOX 3.1 HOW TO USE THE VSEPR MODEL 100
3.3 Polar Molecules 101
VALENCE-BOND THEORY 104
3.4 Sigma and Pi Bonds 105
3.5 Electron Promotion and the Hybridization of Orbitals 107
3.6 Other Common Types of Hybridization 108
3.7 Characteristics of Multiple Bonds 111
MOLECULAR ORBITAL THEORY 113
3.8 The Limitations of Lewis's Theory 113
Box 3.2 How Do We Know . . . That Electrons Are Not Paired? 114
3.9 Molecular Orbitals 115
3.10 Electron Configurations of Diatomic Molecules 116
Box 3.3 How Do We Know . . . the Energies of Molecular Orbitals? 117
TOOLBOX 3.2 HOW TO DETERMINE THE ELECTRON CONFIGURATION AND BOND ORDER OF A HOMONUCLEAR DIATOMIC SPECIES 118
3.11 Bonding in Heteronuclear Diatomic Molecules 120
3.12 Orbitals in Polyatomic Molecules 121
Exercises 124

MAJOR TECHNIQUE 2: ULTRAVIOLET AND VISIBLE SPECTROSCOPY 130

Chapter 4 THE PROPERTIES OF GASES

THE NATURE OF GASES 134
4.1 Observing Gases 134
4.2 Pressure 134
4.3 Alternative Units of Pressure 136
THE GAS LAWS 138
4.4 The Experimental Observations 138
4.5 Applications of the Ideal Gas Law 141
TOOLBOX 4.1 HOW TO USE THE IDEAL GAS LAW 142
4.6 Gas Density 145
4.7 The Stoichiometry of Reacting Gases 147
4.8 Mixtures of Gases 148
MOLECULAR MOTION 152
4.9 Diffusion and Effusion 152
4.10 The Kinetic Model of Gases 153
4.11 The Maxwell Distribution of Speeds 157
Box 4.1 How Do We Know . . . the Distribution of Molecular Speeds? 158
REAL GASES 159
4.12 Deviations from Ideality 159
4.13 The Liquefaction of Gases 160
4.14 Equations of State of Real Gases 161
Exercises 163

Chapter 5 LIQUIDS AND SOLIDS

INTERMOLECULAR FORCES 171
5.1 The Origin of Intermolecular Forces 172
5.2 Ion–Dipole Forces 172
5.3 Dipole–Dipole Forces 174
5.4 London Forces 175
5.5 Hydrogen Bonding 178
5.6 Repulsions 179
LIQUID STRUCTURE 179
5.7 Order in Liquids 180
5.8 Viscosity and Surface Tension 180
SOLID STRUCTURES 182
5.9 Classification of Solids 182
Box 5.1 How Do We Know . . . What a Surface Looks Like? 183
5.10 Molecular Solids 184

5.11 Network Solids 185
5.12 Metallic Solids 186
5.13 Unit Cells 188
5.14 Ionic Structures 191
THE IMPACT ON MATERIALS 194
5.15 Liquid Crystals 194
5.16 Ionic Liquids 195
Exercises 196

MAJOR TECHNIQUE 3: X-RAY DIFFRACTION 203

Chapter 6 INORGANIC MATERIALS

METALLIC MATERIALS 205
6.1 The Properties of Metals 205
6.2 Alloys 207
6.3 Steel 208
6.4 Nonferrous Alloys 209
HARD MATERIALS 210
6.5 Diamond and Graphite 210
6.6 Calcium Carbonate 211
6.7 Silicates 212
6.8 Cement and Concrete 214
6.9 Borides, Carbides, and Nitrides 215
6.10 Glasses 216
6.11 Ceramics 217
MATERIALS FOR NEW TECHNOLOGIES 218
6.12 Bonding in the Solid State 218
6.13 Semiconductors 220
6.14 Superconductors 221
6.15 Luminescent Materials 223
6.16 Magnetic Materials 224
6.17 Composite Materials 225
NANOMATERIALS 226
6.18 The Nature and Uses of Nanomaterials 226
6.19 Nanotubes 227
6.20 Preparation of Nanomaterials 228
Exercises 231

Chapter 7 THERMODYNAMICS: THE FIRST LAW

SYSTEMS, STATES, AND ENERGY 235
7.1 Systems 236
7.2 Work and Energy 236
7.3 Expansion Work 237
7.4 Heat 243
7.5 The Measurement of Heat 243
7.6 The First Law 247
7.7 A Molecular Interlude: The Origin of Internal Energy 251
ENTHALPY 252
7.8 Heat Transfers at Constant Pressure 252
7.9 Heat Capacities at Constant Volume and Constant Pressure 254
7.10 A Molecular Interlude: The Origin of the Heat Capacities of Gases 255
7.11 The Enthalpy of Physical Change 257
7.12 Heating Curves 259
Box 7.1 How Do We Know . . . the Shape of a Heating Curve? 260
THE ENTHALPY OF CHEMICAL CHANGE 261
7.13 Reaction Enthalpies 261
7.14 The Relation Between ΔH and ΔU 263
7.15 Standard Reaction Enthalpies 264
7.16 Combining Reaction Enthalpies: Hess's Law 265
TOOLBOX 7.1 HOW TO USE HESS'S LAW 266
7.17 The Heat Output of Reactions 267
Box 7.2 What Has This to Do with . . . the Environment? 268
7.18 Standard Enthalpies of Formation 271
7.19 The Born–Haber Cycle 274
7.20 Bond Enthalpies 276
7.21 The Variation of Reaction Enthalpy with Temperature 278
Exercises 280

Chapter 8 THERMODYNAMICS: THE SECOND AND THIRD LAWS

ENTROPY 287
8.1 Spontaneous Change 287
8.2 Entropy and Disorder 288
8.3 Changes in Entropy 290

8.4 Entropy Changes Accompanying Changes in Physical State 295
8.5 A Molecular Interpretation of Entropy 298
8.6 The Equivalence of Statistical and Thermodynamic Entropies 301
8.7 Standard Molar Entropies 303
Box 8.1 Frontiers of Chemistry: The Quest for Absolute Zero 304
8.8 Standard Reaction Entropies 307
GLOBAL CHANGES IN ENTROPY 308
8.9 The Surroundings 308
8.10 The Overall Change in Entropy 310
8.11 Equilibrium 314
GIBBS FREE ENERGY 315
8.12 Focusing on the System 315
8.13 Gibbs Free Energy of Reaction 318
8.14 The Gibbs Free Energy and Nonexpansion Work 321
8.15 The Effect of Temperature 323
8.16 Impact on Biology: Gibbs Free Energy Changes in Biological Systems 325
Exercises 326

Chapter 9 PHYSICAL EQUILIBRIA

PHASES AND PHASE TRANSITIONS 333
9.1 Vapor Pressure 334
9.2 Volatility and Intermolecular Forces 335
9.3 The Variation of Vapor Pressure with Temperature 335
9.4 Boiling 338
9.5 Freezing and Melting 339
9.6 Phase Diagrams 340
9.7 Critical Properties 342
SOLUBILITY 344
9.8 The Limits of Solubility 344
9.9 The Like-Dissolves-Like Rule 345
9.10 Pressure and Gas Solubility: Henry's Law 347
9.11 Temperature and Solubility 348
9.12 The Enthalpy of Solution 349
9.13 The Gibbs Free Energy of Solution 351
COLLIGATIVE PROPERTIES 352
9.14 Molality 352
TOOLBOX 9.1 HOW TO USE THE MOLALITY 353
9.15 Vapor-Pressure Lowering 356
9.16 Boiling-Point Elevation and Freezing-Point Depression 358
9.17 Osmosis 360
TOOLBOX 9.2 HOW TO USE COLLIGATIVE PROPERTIES TO DETERMINE MOLAR MASS 362
BINARY LIQUID MIXTURES 365
9.18 The Vapor Pressure of a Binary Liquid Mixture 365
9.19 Distillation 367
9.20 Azeotropes 368
THE IMPACT ON BIOLOGY AND MATERIALS 369
9.21 Colloids 370
9.22 Bio-based and Biomimetic Materials 371
Box 9.1 Frontiers of Chemistry: Drug Delivery 372
Exercises 373
MAJOR TECHNIQUE 4: CHROMATOGRAPHY 381

Chapter 10 CHEMICAL EQUILIBRIA

REACTIONS AT EQUILIBRIUM 384
10.1 The Reversibility of Reactions 384
10.2 Equilibrium and the Law of Mass Action 385
10.3 The Thermodynamic Origin of Equilibrium Constants 390
10.4 The Extent of Reaction 395
10.5 The Direction of Reaction 396
EQUILIBRIUM CALCULATIONS 397
10.6 The Equilibrium Constant in Terms of Molar Concentrations of Gases 398
10.7 Alternative Forms of the Equilibrium Constant 400
10.8 Using Equilibrium Constants 401
TOOLBOX 10.1 HOW TO SET UP AND USE AN EQUILIBRIUM TABLE 401
THE RESPONSE OF EQUILIBRIA TO CHANGES IN CONDITIONS 405
10.9 Adding and Removing Reagents 405
10.10 Compressing a Reaction Mixture 408

10.11 Temperature and Equilibrium 410
10.12 Catalysts and Haber's Achievement 413
10.13 The Impact on Biology: Homeostasis 413
Exercises 414

Chapter 11 ACIDS AND BASES

THE NATURE OF ACIDS AND BASES 423
11.1 Brønsted–Lowry Acids and Bases 423
11.2 Lewis Acids and Bases 426
11.3 Acidic, Basic, and Amphoteric Oxides 428
11.4 Proton Exchange Between Water Molecules 429
11.5 The pH Scale 431
11.6 The pOH of Solutions 434
WEAK ACIDS AND BASES 435
11.7 Acidity and Basicity Constants 435
11.8 The Conjugate Seesaw 438
11.9 Molecular Structure and Acid Strength 440
11.10 The Strengths of Oxoacids and Carboxylic Acids 442
THE pH OF SOLUTIONS OF WEAK ACIDS AND BASES 445
11.11 Solutions of Weak Acids 445
TOOLBOX 11.1 HOW TO CALCULATE THE pH OF A SOLUTION OF A WEAK ACID 445
11.12 Solutions of Weak Bases 448
TOOLBOX 11.2 HOW TO CALCULATE THE pH OF A SOLUTION OF A WEAK BASE 448
11.13 The pH of Salt Solutions 450
POLYPROTIC ACIDS AND BASES 454
11.14 The pH of a Polyprotic Acid Solution 455
11.15 Solutions of Salts of Polyprotic Acids 456
11.16 The Concentrations of Solute Species 457
TOOLBOX 11.3 HOW TO CALCULATE THE CONCENTRATIONS OF ALL SPECIES IN A POLYPROTIC ACID SOLUTION 458
11.17 Composition and pH 461
Box 11.1 What Has This to Do with . . . the Environment? 462
AUTOPROTOLYSIS AND pH 464
11.18 Very Dilute Solutions of Strong Acids and Bases 464
11.19 Very Dilute Solutions of Weak Acids 466
Exercises 468

Chapter 12 AQUEOUS EQUILIBRIA

MIXED SOLUTIONS AND BUFFERS 475
12.1 Buffer Action 476
12.2 Designing a Buffer 477
12.3 Buffer Capacity 482
TITRATIONS 483
12.4 Strong Acid–Strong Base Titrations 483
Box 12.1 What Has This to Do with . . . Staying Alive? 484
TOOLBOX 12.1 HOW TO CALCULATE THE pH DURING A STRONG ACID–STRONG BASE TITRATION 485
12.5 Strong Acid–Weak Base and Weak Acid–Strong Base Titrations 486
TOOLBOX 12.2 HOW TO CALCULATE THE pH DURING A TITRATION OF A WEAK ACID OR A WEAK BASE 490
12.6 Acid–Base Indicators 492
12.7 Stoichiometry of Polyprotic Acid Titrations 494
SOLUBILITY EQUILIBRIA 496
12.8 The Solubility Product 497
12.9 The Common-Ion Effect 499
12.10 Predicting Precipitation 501
12.11 Selective Precipitation 502
12.12 Dissolving Precipitates 504
12.13 Complex Ion Formation 505
12.14 Qualitative Analysis 507
Exercises 509

Chapter 13 ELECTROCHEMISTRY

REPRESENTING REDOX REACTIONS 515
13.1 Half-Reactions 516
13.2 Balancing Redox Equations 516
TOOLBOX 13.1 HOW TO BALANCE COMPLICATED REDOX EQUATIONS 517

GALVANIC CELLS 522
13.3 The Structure of Galvanic Cells 522
13.4 Cell Potential and Reaction Gibbs Free Energy 524
13.5 The Notation for Cells 526
TOOLBOX 13.2 HOW TO WRITE A CELL REACTION CORRESPONDING TO A CELL DIAGRAM 528
13.6 Standard Potentials 529
13.7 The Electrochemical Series 534
13.8 Standard Potentials and Equilibrium Constants 536
TOOLBOX 13.3 HOW TO CALCULATE EQUILIBRIUM CONSTANTS FROM ELECTROCHEMICAL DATA 537
13.9 The Nernst Equation 538
13.10 Ion-Selective Electrodes 541
ELECTROLYTIC CELLS 542
13.11 Electrolysis 542
13.12 The Products of Electrolysis 544
TOOLBOX 13.4 HOW TO PREDICT THE RESULT OF ELECTROLYSIS 545
THE IMPACT ON MATERIALS 547
13.13 Applications of Electrolysis 547
13.14 Corrosion 548
13.15 Practical Cells 550
Box 13.1 Frontiers of Chemistry: Fuel Cells 552
Exercises 553

Chapter 14 CHEMICAL KINETICS

REACTION RATES 561
14.1 Concentration and Reaction Rate 561
Box 14.1 How Do We Know . . . What Happens to Atoms During a Reaction? 564
14.2 The Instantaneous Rate of Reaction 565
14.3 Rate Laws and Reaction Order 566
CONCENTRATION AND TIME 572
14.4 First-Order Integrated Rate Laws 572
14.5 Half-Lives for First-Order Reactions 576
14.6 Second-Order Integrated Rate Laws 578
REACTION MECHANISMS 580
14.7 Elementary Reactions 580
14.8 The Rate Laws of Elementary Reactions 581
14.9 Chain Reactions 585
14.10 Rates and Equilibrium 586
MODELS OF REACTIONS 587
14.11 The Effect of Temperature 587
14.12 Collision Theory 591
Box 14.2 How Do We Know . . . What Happens During a Molecular Collision? 593
14.13 Transition State Theory 594
ACCELERATING REACTIONS 595
14.14 Catalysis 595
14.15 Industrial Catalysts 597
Box14.3 What Has This to Do with . . . the Environment? 598
14.16 Living Catalysts: Enzymes 600
Exercises 602
MAJOR TECHNIQUE 5: COMPUTATION 610

Chapter 15 THE ELEMENTS: THE MAIN GROUP ELEMENTS

PERIODIC TRENDS 611
15.1 Atomic Properties 611
15.2 Bonding Trends 613
HYDROGEN 615
15.3 The Element 615
Box 15.1 What Has This to Do with . . . the Environment? 616
15.4 Compounds of Hydrogen 618
GROUP 1: THE ALKALI METALS 619
15.5 The Group 1 Elements 620
15.6 Compounds of Lithium, Sodium, and Potassium 622
GROUP 2: THE ALKALINE EARTH METALS 623
15.7 The Group 2 Elements 624
15.8 Compounds of Beryllium, Magnesium, and Calcium 625
GROUP 13/III: THE BORON FAMILY 628
15.9 The Group 13/III Elements 628
15.10 Group 13/III Oxides and Halides 630
15.11 Boranes and Borohydrides 632
GROUP 14/IV: THE CARBON FAMILY 633
15.12 The Group 14/IV Elements 633

Box 15.2 Frontiers of Chemistry: Self-Assembling Materials 636
15.13 Oxides of Carbon and Silicon 637
15.14 Other Important Group 14/IV Compounds 639
GROUP 15/V: THE NITROGEN FAMILY 640
15.15 The Group 15/V Elements 641
15.16 Compounds with Hydrogen and the Halogens 642
15.17 Nitrogen Oxides and Oxoacids 644
15.18 Phosphorus Oxides and Oxoacids 646
GROUP 16/VI: THE OXYGEN FAMILY 647
15.19 The Group 16/VI Elements 648
15.20 Compounds with Hydrogen 650
15.21 Sulfur Oxides and Oxoacids 652
GROUP 17/VII: THE HALOGENS 654
15.22 The Group 17/VII Elements 654
15.23 Compounds of the Halogens 656
GROUP 18/VIII: THE NOBLE GASES 659
15.24 The Group 18/VIII Elements 659
15.25 Compounds of the Noble Gases 660
Exercises 661

Chapter 16 THE ELEMENTS: THE d-BLOCK

THE d-BLOCK ELEMENTS AND THEIR COMPOUNDS 667
16.1 Trends in Physical Properties 668
16.2 Trends in Chemical Properties 669
SELECTED ELEMENTS: A SURVEY 671
16.3 Scandium Through Nickel 671
16.4 Groups 11 and 12 676
COORDINATION COMPOUNDS 680
16.5 Coordination Complexes 680
Box 16.1 What Has This to Do with . . . Staying Alive? 681
TOOLBOX 16.1 HOW TO NAME d-METAL COMPLEXES AND COORDINATION COMPOUNDS 683
16.6 The Shapes of Complexes 685
16.7 Isomers 686

LETTER FROM THE AUTHORS

Dear Colleagues,

It is with great pleasure that we offer the fifth edition of *Chemical Principles: The Quest for Insight*. The new edition is designed, like its predecessors, to encourage students to think and to develop a solid understanding of chemistry by first building a qualitative understanding and then showing how to express those qualitative concepts quantitatively.

Because college students often have forgotten much of their high school chemistry, the book begins with a *Fundamentals* section that reviews the basic ideas of chemistry such as nomenclature, concentration, and stoichiometry. The main part of the book starts with an investigation of the structure of the atom, goes on to show how atomic properties determine the types of bonds that atoms form, and then investigates how the properties of molecules and ions contribute to the structure, reactions, and properties of bulk matter.

We have updated much of the content and the format of the periodic table. We have also introduced a new materials chapter following the solid state chapter. This chapter serves as a review of the first five chapters and introduces students to the chemistry that is the basis of the exciting field of nanotechnology. In this chapter students also see how the chemical principles they are learning, even at an early stage in their course, apply to modern research and applications such as ceramic and magnetic materials and electronic components. In later chapters we investigate further properties of materials as new concepts are introduced.

We have enhanced our approach to problem solving to help students develop the kinds of problem-solving skills that experts use. That is, we want students to learn to solve problems as chemists do. Consequently, in the worked examples we begin, where appropriate, with an *Anticipate* section that encourages students to estimate the answer and develop their powers of insight and judgment. Then we present a general *Plan* that encourages readers to collect their thoughts and establish an approach to the problem. After the fully worked out *Solve* section, we encourage students to reflect on their original anticipation in a brief *Evaluate* section. In addition, for a number of calculations we encourage students to organize their thinking by asking *What should we assume?* before proceeding. Almost all the worked examples are accompanied by graphic thumbnail interpretations of each step, which were introduced in the fourth edition as an entirely new way to help students make connections among the different levels of chemical description. The thumbnails have been developed further for this edition.

We hope you will like the scattering of *Thinking points* throughout the text, which are intended to encourage and emphasize our underlying strategy: to get students to think as well as to learn. We have also generated a new art program for a great deal of the book, which we hope will enhance the learning experience by conveying insight into the molecular world.

We are grateful for the feedback and support we have received from those who have used the previous four editions. The suggestions readers have given us have helped us to refine the book and make it more interesting and useful for students. We hope that you and your students find the book to be a refreshing and intriguing introduction to chemistry.

Yours sincerely,

Peter Atkins

PREFACE

CHEMICAL PRINCIPLES

This text is designed for a rigorous course in introductory chemistry. Its central theme is to challenge students to think and question while providing a sound foundation in the principles of chemistry.

At the same time, students of all levels benefit from assistance in learning how to think, pose questions, and approach problems. To that end, *Chemical Principles* is organized in a logical way that builds understanding and offers students a wide array of pedagogical support.

ATOMS-FIRST ORGANIZATION

Chemical Principles presents the concepts of chemistry in a logical sequence that enhances student understanding. The **atoms-first sequence** starts with the behavior of atoms and molecules and builds to more complex properties and interactions.

- **Atoms and molecules** come first (including discussions of quantum mechanics and molecular orbitals), providing the foundation for understanding bulk properties and models of gases, liquids, and solids. Chapter 1 has been reorganized in this edition to give readers a gentler introduction to atoms and their structure.
- Next comes an exploration of **thermodynamics and equilibrium,** which builds on a conceptual understanding of entropy and free energy. This integrated presentation lays a common foundation for related concepts and provides a basis for the form of the equilibrium constant.
- **Kinetics** then shows the dynamic nature of chemistry and the crucial role of insight and model building in identifying reaction mechanisms.

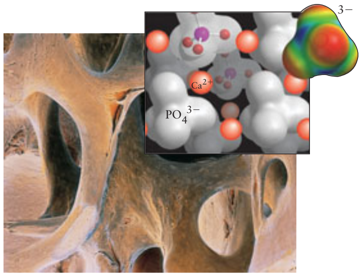

FIGURE 2.8 A micrograph of bone, which owes its rigidity to calcium phosphate. The overlay shows part of the crystal structure of calcium phosphate. Phosphate ions are polyatomic ions; however, as shown in the inset, they are nearly spherical and fit into crystal structures in much the same way as monatomic ions of charge −3.

COVERING THE BASICS

The **Fundamentals** sections, which precede Chapter 1, are identified by green-edged pages. These 13 minichapters provide a streamlined overview of the basics of chemistry. They can be used either to provide a useful, succinct review of basic material to which students can refer for extra help as they progress through the course, or as a concise, quick survey of material before starting on the main text.

Diagnostic Test for the Fundamentals Sections. This test allows instructors to determine what their students understand and where they need additional support. Instructors can then make appropriate assignments from the Fundamentals sections. The test includes 5 to 10 problems for each Fundamentals section. The diagnostic test was created by Cynthia LaBrake at the University of Texas, Austin and can be found on the Instructor's Resource CD ROM and on the Instructor pages of the Web site.

FLEXIBLE MATH COVERAGE

Optional Use of Calculus. The ***How do we do that*?** feature sets off derivations of key equations and encourages students to appreciate the power of mathematics. Almost all the calculus in the text is confined to this feature, so it can easily be avoided or emphasized as the instructor chooses.

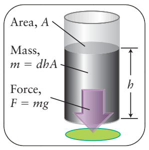
A selection of end-of-chapter exercises that make use of calculus are provided and marked with a C.

HOW DO WE DO THAT?

We want to find the relation between the height, h, of the column of mercury in a barometer and the atmospheric pressure, P. Suppose the cross-sectional area of the cylindrical column is A. The volume of mercury in the column is the height of the cylinder times this area, $V = hA$. The mass, m, of this volume of mercury is the product of mercury's density, d, and the volume; so $m = dV = dhA$. The mercury is pulled down by the force of gravity; and the total force that its mass exerts at its base is the product of the mass and the acceleration of free fall (the acceleration due to gravity), g: $F = mg$. Therefore, the pressure at the base of the column, the force divided by the area, is

From $P = F/A$ and $F = mg$:

$$P = \frac{\overbrace{F}^{mg}}{A} = \frac{mg}{A} = \frac{\overbrace{dhA}^{m}\,g}{A} = dhg$$



This equation shows that the pressure, P, exerted by a column of mercury is proportional to the height of the column. Mercury inside a tube sealed at one end and inverted in a pool of mercury will fall until the pressure exerted by the mercury balances the atmospheric pressure. Therefore, the height of the column can be used as a measure of atmospheric pressure.

EXAMPLE 4.3 **Using the combined gas law when one variable is changed**

Assume that, when you press in the piston of a bicycle pump, the volume inside the pump is decreased from about 100. cm^3 to 20. cm^3 before the air flows into the tire. Suppose that the compression is isothermal; estimate the final pressure of the compressed air in the pump, given an initial pressure of 1.00 atm.

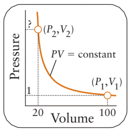
Anticipate The volume is reduced by a factor of 5, so we should expect a fivefold increase in pressure.

PLAN Follow the second procedure in Toolbox 4.1. Only the pressure and volume change, so all other variables cancel, resulting in Boyle's law.

SOLVE

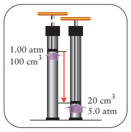
Step 1 Rearrange $P_1V_1/n_1T_1 = P_2V_2/n_2T_2$ to find P_2 by multiplying both sides by n_2T_2/V_2, and set $n_2 = n_1$ (no change in the amount) and $T_2 = T_1$ (no change in temperature):

$$P_2 = \frac{P_1V_1}{n_1T_1} \times \frac{n_2T_2}{V_2} \overset{n_2=n_1,\ T_2=T_1}{=} \frac{P_1V_1}{n_1T_1} \times \frac{n_1T_1}{V_2} = P_1 \times \frac{V_1}{V_2}$$



Step 2 Substitute the data:

$$P_2 = (1.00\ \text{atm}) \times \frac{100\ \text{cm}^3}{20\ \text{cm}^3} = 5.0\ \text{atm}$$



Evaluate The final pressure is higher by a factor of 5 (more precisely, 5.0), as expected.

Self-Test 4.8A A sample of argon gas of volume 10.0 mL at 200. Torr is allowed to expand isothermally into an evacuated tube with a volume of 0.200 L. What is the final pressure of the argon in the tube?

[*Answer:* 10.0 Torr]

EMPHASIS ON PROBLEM SOLVING

- ***NEW!*** **Anticipate/Plan/Solve/Evaluate Strategy**. This problem-solving approach encourages students to anticipate or predict what a problem's answer should be and to map out the solution before trying to solve the problem. Following the solution, the original anticipation is evaluated. The accompanying graphics provide the opportunity for visualizing and interpreting each step of the solution and the final result.

- **Self-Tests** occur as pairs throughout the book. They enable students to test their understanding of the material covered in the preceding section or Worked Example. The answer to the first self-test is provided immediately and the answer to the second can be found at the back of the book.

- ***NEW!*** **Thinking Points** encourage students to speculate about the implications of what they are learning and to transfer their knowledge to new situations.

The relative energies of the d-orbitals are different in complexes with different shapes. For example, in a tetrahedral complex, the three t_2-orbitals point more directly at the ligands than the two e-orbitals do. As a result, in a tetrahedral complex, the t_2-orbitals have a higher energy than the e-orbitals (Fig. 16.29). The ligand field splitting, Δ_T (where the T denotes tetrahedral), is generally smaller than in octahedral complexes, in part because there are fewer repelling ligands.

Thinking point: Into what groups do you think the d-orbitals are split in a square-planar complex?

- **Toolboxes** show students how to tackle *major types* of calculations, demonstrating how to connect concepts to problem solving. They are designed as learning aids and handy summaries of key material. Each Toolbox is immediately followed by a related example.

TOOLBOX 7.1 **HOW TO USE HESS'S LAW**

CONCEPTUAL BASIS
Because enthalpy is a state function, the enthalpy change of a system depends only on its initial and final states. Therefore, we can carry out a reaction in one step or, if that is not convenient, visualize it as the sum of several steps; the reaction enthalpy is the same in each case.

PROCEDURE
To use Hess's law to find the enthalpy of a given reaction, we find a sequence of reactions with known reaction enthalpies that adds up to the reaction of interest.

Step 1 Select one of the reactants in the overall reaction and write down a chemical equation in which it also appears as a reactant.
Step 2 Select one of the products in the overall reaction and write down a chemical equation in which it also appears as a product. Add this equation to the equation written in step 1 and cancel species that appear on both sides of the equation.
Step 3 Cancel unwanted species in the sum obtained in step 2 by adding an equation that has the same substance or substances on the opposite side of the arrow.
Step 4 Once the sequence is complete, combine the standard reaction enthalpies.

In each step, we may need to reverse the equation or multiply it by a factor. Recall from Eq. 16 that, if we want to reverse a chemical equation, we have to change the sign of the reaction enthalpy. If we multiply the stoichiometric coefficients by a factor, we must multiply the reaction enthalpy by the same factor.

This procedure is illustrated in Example 7.9.

CUTTING EDGE CHEMISTRY FOR ALL STUDENTS

Of special interest to **Engineering students:**

- Liquid Crystals (Section 5.15)
- Colloids (Section 9.21)
- Applications of Electrolysis (Section 13.13)
- Fuels (Section 18.9 and Box 7.2)
- Polymerization and Polymers (Sections 19.9–19.12)
- Corrosion (Section 13.14)
- Fuel Cells (Box 13.1 Frontiers of Chemistry)
- Industrial Catalysts (Section 14.15)
- Self Assembling Materials (Box 15.2 Frontiers of Chemistry)
- The whole of Chapter 6, Inorganic Materials

Of special interest to **Biology students:**

- Drugs by Design and Discovery (Box 3.1 Frontiers of Chemistry)
- Gibbs Free Energy Changes in Biological Systems (Section 8.16)
- Colloids (Section 9.21)
- Bio-based and Biomimetic Materials (Section 9.22)
- Homeostasis (Section 10.13)
- Physiological Buffers (Box 12.1 What Has This to Do with . . . Staying Alive?)
- Living Catalysts: Enzymes (Section 14.16)
- Why We Need to Eat d-Metals (Box 16.1 What Has This to Do with . . . Staying Alive?)
- Nuclear Medicine (Box 17.1 What Has This to Do with . . . Staying Alive?)
- The Biological Effects of Radiation (Section 17.6)
- Proteins (Section 19.13)
- Carbohydrates (Section 19.14)
- Nucleic Acids (Section 19.15)

Of special interest to **Environmental Science students:**

- Green Chemistry promotes environmentally sound chemistry. Green chemistry passages in the text and green chemistry end-of-chapter exercises are accompanied by an icon.
- Alternative Fuels (Box 7.2 What Has This to Do with . . . the Environment?)
- Acid Rain and the Gene Pool (Box 11.1 What Has This to Do with . . . the Environment?)
- Protecting the Ozone Layer (Box 14.3 What Has This to Do with . . . the Environment?)
- The Greenhouse Effect (Box 15.1. What Has This to Do with . . . the Environment?)
- Coal (Section 18.10)

dense materials. Branched polymer chains cannot fit together as closely and form weaker, less dense materials (Fig. 19.15). A soft, lightweight body armor has been developed by creating arrays of long polyethylene chains that are closely aligned in the same direction, giving rise to very strong intermolecular forces. This body armor is reported to be 15 times stronger than steel, yet has such a low density that it floats on water. It is also soft and flexible, so it is comfortable to wear (Fig. 19.16).

FIGURE 19.16 Recruits at the New York Police Academy are issued bullet-proof vests. The high-density polyethylene body armor protects law enforcement personnel without restricting movement because it is soft and flexible.

- ***NEW!*** **Chapter 6, Inorganic Materials.** This new chapter reviews the first five chapters and introduces students to the chemistry that is the basis of the exciting new field of nanotechnology. In this chapter students also see how the chemical principles they are learning apply to cutting edge research and applications such as ceramic and magnetic materials and electronic components.

6.11 Ceramics

Many of the materials used in the most advanced technologies are based on a material characteristic of one of the oldest technologies: common clay. Most clays used commercially are oxides of silicon, aluminum, and magnesium. *China clay* contains primarily *kaolinite*, a form of aluminum aluminosilicate that can be obtained reasonably free of the iron impurities that make many clays look reddish brown, and so it is white. However, other clays contain the iron oxides that cause the orange color of terra cotta tiles and flower pots.

The appearance of a flake of clay reflects its internal structure, which is something like an untidy stack of papers (Fig. 6.23). Sheets of tetrahedral silicate units or octahedral units of aluminum or magnesium oxides are separated by layers of water molecules that serve to bind the layers of the flake together. Each flake of clay is surrounded by a double layer of ions that separates the flakes by repelling the like charges on the other flakes. This repulsion allows the flakes to slide past one another and gives the clay the ability to flow in response to stress. As a result, clays can be easily molded.

When clay is baked in a kiln, it forms the hard, tough *ceramic* materials used in firebricks, tiles, and pots as the water is driven out and strong chemical bonds form between the flakes. Large amounts of china clay, which is used to make ceramics such as porcelain and china, are applied in the coating of paper (such as this page) to give a smooth, nonabsorbent surface. Clay was the first substance to be made into a **ceramic,** an inorganic material that has been hardened by heating to a high temperature. Today a wide variety of compounds, often oxides, are used to create ceramics with specific properties.

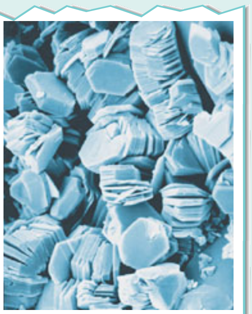


FIGURE 6.23 The layers of clay particles can be seen in this micrograph. Because the surfaces of these layers have like charges, they repel one another and easily slide past one another, making clay soft and malleable.

MEDIA INTEGRATION

Selected figures and exercises throughout the book are accompanied by **media link icons** that direct students to Web-based resources. These integrated links to the companion Web site are designed to make the text more dynamic and interactive. *Chemical Principles* contains media links to:

- **Living Graphs.** Selected graphs in the text are available in interactive form on the Web site. Students can manipulate parameters and see cause and effect relationships.

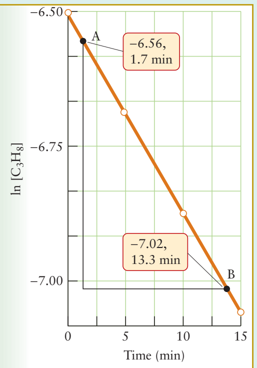

FIGURE 14.11 We can test for a first-order reaction by plotting the natural logarithm of the reactant concentration against time. The graph is linear if the reaction is first order. The slope of the line, which is calculated here for the system in Example 14.4 by using the points A and B, is equal to the negative of the rate constant.

Living Graph 14.11

- **Animations.** Selected art in the text is supported by media. Students can view motion, three dimensions, and atomic and molecular interactions and learn to visualize like chemists—at a molecular level. To focus their attention, questions on each animation have been added in this edition.

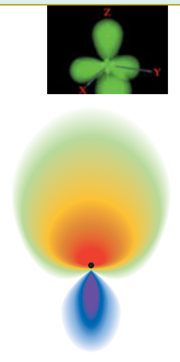

FIGURE 3.13 These contours indicate the amplitude of the sp^3 hybrid orbital wavefunction in a plane that bisects it and passes through the nucleus. The colors indicate the variation of electron density in the orbital: regions of high electron density are red and regions of low electron density blue. Each sp^3 hybrid orbital points toward the corner of a tetrahedron.

Animation 3.13

- **Lab Videos.** Video clips of many of the reactions described in the book are provided on the book's Web site.

(a) (b) (c)

FIGURE 15.48 Sulfuric acid is a dehydrating agent. When concentrated sulfuric acid is poured on to sucrose (a), the sucrose, a carbohydrate, is dehydrated (b), leaving a frothy black mass of carbon (c).

Lab Video 15.48

- **Tools.** Tools on the book's Web site allow the study of chemical calculations, graphing, and exploration of periodic properties from different points of view.

- **End-of-Chapter Exercises.** Selected exercises direct students to use media to solve problems.

> **16.98** *cis*-Platin is an anticancer drug with a structure that can be viewed on the Web site. (a) What is the formula and systematic name for the compound *cis*-Platin? (b) Draw any isomers that are possible for this compound. Label any isomers that are optically active. (c) What is the coordination geometry of the platinum atom?

INSTRUCTOR AND STUDENT SUPPORT

We believe a student needs to interact with a concept several times in a variety of scenarios in order to obtain a thorough understanding. With that in mind, W. H. Freeman and Company has developed the most comprehensive student learning package available.

FOR THE INSTRUCTOR

Instructor's Solutions Manual by Carl Hoeger, University of California, San Diego, Laurence Lavelle, University of California, Los Angeles, and Yinfa Ma, University of Missouri-Rolla ISBN: 1-4292-3892-5

The *Instructor's Solutions Manual* contains full, worked-out solutions to all even-numbered exercises. Worked-out solutions for odd-numbered exercises can be found in the *Student Study Guide and Solutions Manual*.

Test Bank by Robert Balahura, University of Guelph, and Mark Benvenuto, University of Detroit Mercy

The *Test Bank* offers over 1400 multiple-choice, fill-in-the-blank, and essay questions, and is available exclusively on the *Instructor's Resource CD*.

Instructor's Resource CD ISBN: 1-4292-5808-X

To help instructors create their own Web sites and prepare dynamic lectures, the CD contains:

- All the illustrations from the text in .jpg files and preformatted PowerPoint slides
- All animations, lab videos, and living graphs from the Book Companion Site
- All solutions to the end-of-chapter exercises, in editable Microsoft Word files
- Diagnostic Test for the Fundamentals sections
- The electronic *Test Bank*, which includes over 1400 multiple-choice, fill-in-the-blank, and essay questions

Electronic Instructor Resources

Instructors can access valuable teaching tools through www.whfreeman.com/chemicalprinciples5e. These password-protected resources are designed to enhance lecture presentations, and include all the illustrations from the textbook (in .jpg and PowerPoint format), Lecture PowerPoint slides, Clicker Questions, and more. There's also a Diagnostic Test for the Fundamentals sections, which allows instructors to determine what their students understand and where they need additional support. Instructors can then make appropriate assignments from the Fundamentals sections. This test includes 5 to 10 problems for each Fundamentals section.

WebAssign Premium

For instructors interested in online homework management, W. H. Freeman and WebAssign have partnered to deliver WebAssign Premium—a comprehensive and flexible suite of resources. Combining the most widely used online homework platform with a wealth of visualization and tutorial resources, WebAssign Premium extends and enhances the classroom experience for instructors and students by combining algorithmically generated versions of selected end-of-chapter questions with a fully interactive eBook at an affordable price. See below for more details, or visit www.webassign.net to sign up for a faculty demo account.

LabPartner Chemistry

W. H. Freeman's latest offering in custom lab manuals provides instructors with a diverse and extensive database of experiments published by W. H. Freeman and Hayden-McNeil Publishing—all in an easy-to-use, searchable online system. With the click of a button, instructors can choose from a variety of traditional and inquiry-based labs. LabPartner Chemistry sorts labs in a number of ways, from topic, title, and author, to page count, estimated completion time, and prerequisite knowledge level. Add content on lab techniques and safety, reorder the labs to fit your syllabus, and include your original experiments with ease. Wrap it all up in an array of bindings, formats, and designs. It's the next step in custom lab publishing—the perfect partner for your course.

FOR THE STUDENT

Student Study Guide and Solutions Manual by John Krenos and Joseph Potenza, Rutgers University, Laurence Lavelle, University of California, Los Angeles, Yinfa Ma, University of Missouri Rolla, and Carl Hoeger, University of California, San Diego ISBN: 1-4292-3135-1

The Student Study Guide and Solutions Manual provides students with a combined manual designed to help them to improve their problem-solving skills, avoid common mistakes, and understand key concepts. After a brief review of each section's critical ideas, students are taken through worked-out examples, try-it-yourself examples, and chapter quizzes, all structured to reinforce chapter objectives and build problem-solving techniques. The solutions manual includes detailed solutions to all odd-numbered exercises in the text.

ACS Molecular Structure Model Set by Maruzen Company, Ltd. ISBN: 0-7167-4822-3

Molecular modeling helps students understand physical and chemical properties by providing a way to visualize the three-dimensional arrangement of atoms. This model set uses polyhedra to represent atoms, and plastic connectors to represent bonds (scaled to correct bond length). Plastic plates representing orbital lobes are included for indicating lone pairs of electrons, radicals, and multiple bonds—a feature unique to this set.

Bridging to the Lab by Loretta Jones, University of Northern Colorado, and Roy Tasker, University of Western Sydney ISBN: 0-7167-4746-4

The *Bridging to the Lab* modules are computer-based laboratory simulations with engaging activities that emphasize experimental design and visualization of structures and processes at the molecular level. The modules are designed to help students connect chemical principles from lecture with their practical applications in the lab. Every module has a built-in accountability feature that

records section completion for use in setting grades and a workbook for recording student work.

Used either as pre-laboratory preparation for related laboratory activities or to expose students to additional laboratory activities not available in their program, these modules motivate students to learn by proposing real-life problems in a virtual environment. Students make decisions on experimental design, observe reactions, record data, interpret these data, perform calculations, and draw conclusions from their results. Following a summary of the module, students test their understanding by applying what they have learned to new situations or by analyzing the effect of experimental errors.

For more information, visit www.whfreeman.com/bridgingtothelab

Chemistry Laboratory Student Notebook, Second Edition
ISBN: 0-7167-3900-3

A convenient $8\frac{1}{2} \times 11$, 3-hole-punched format contains 114 pages of graph paper, carbon included. The new edition adds tables and graphs that make the *Notebook* a handy reference as well.

PREMIUM MULTIMEDIA RESOURCES

The *Chemical Principles* Book Companion Site, which can be accessed at www.whfreeman.com/chemicalprinciples5e, also contains a plethora of Premium Student Resources. Students can unlock these resources with the click of a button, putting extensive concept and problem-solving support at their fingertips. Some of the resources available are:

Toolbox Tutorials present major types of calculations, in an interactive format. They demonstrate the connections between concepts and problem solving and are designed as hands-on learning aids and handy summaries of key materials:

ChemCasts replicate the face-to-face experience of watching an instructor work a problem. Using a virtual whiteboard, these video tutors show students the steps involved in solving key worked examples, while explaining the concepts along the way. They are easy to view on a computer screen or download to an iPod.

ChemNews from *Scientific American* provides a streaming newsfeed of the latest articles from *Scientific American*.

The multimedia-enhanced eBook contains the complete text with a wealth of helpful functions. All student multimedia, including the Toolbox Tutorials, ChemCasts, and ChemNews, are linked directly from the eBook pages. Students are thus able to access supporting resources when they need them—taking advantage of the "teachable moment" as they read. Customization functions include instructor and student notes, document linking, and editing capabilities.

Online Learning Environments

The above resources are available in two platforms. WebAssign Premium offers the most effective and widely used online homework system in the sciences, and is designed specifically for those instructors seeking graded homework management. The Student Companion Web site provides student-oriented support materials independent of any homework system.

WEBASSIGN PREMIUM

For instructors interested in online homework management, WebAssign Premium features a time-tested, secure online environment already used by millions of students worldwide. Featuring algorithmic problem generation and supported by a

wealth of chemistry-specific learning tools, WebAssign Premium for *Chemical Principles, Fifth Edition* presents instructors with a powerful assignment manager and study environment. WebAssign Premium provides the following resources:

- Algorithmically generated problems: Students receive homework problems containing unique values for computation, encouraging them to work out the problems on their own.
- Complete access to the interactive eBook, from a live table of contents, as well as from relevant problem statements.
- Links to Toolbox Tutorials, ChemCasts, and other interactive tools are provided as hints and feedback to ensure a clearer understanding of the problems and the concepts they reinforce.

STUDENT COMPANION WEB SITE

The *Chemical Principles* Book Companion Site, www.whfreeman.com/chemicalprinciples5e, provides a range of tools for problem solving and chemical explorations. They include:

- An interactive Periodic Table of the Elements
- A calculator adapted for solving equilibrium calculations
- Two- and three-dimensional curve plotters
- "Living Graphs," which allow the user to control the parameters
- Animations that allow students to visualize chemical events on a molecular level
- Diagnostic Test for the Fundamentals sections
- Web-based Assessment. An excellent online quizzing bank of multiple-choice questions for each text chapter (not from the test bank). Students receive instant feedback and can take the quizzes multiple times. Instructors can go into a protected Web site to view results by quiz, student, or question, or can get weekly results via e-mail. Excellent for practice testing and/or homework.

ACKNOWLEDGMENTS

We are grateful to the many instructors, colleagues, and students who have contributed their expertise to this edition. We would like above all to thank those who carefully evaluated the fourth edition and commented on drafts of the fifth edition:

Yiyan Bai, *Houston Community College System Central Campus*

Some contributed in substantial ways. Leroy Laverman, University of California at Santa Barbara, carefully reviewed the entire text and all the art, leading to considerable improvements. Roy Tasker, University of Western Sydney, contributed to the Web site for this book, designed related animations, and selected the icons for the animation media links. Michael Cann, University of Scranton, opened our eyes to the world of green chemistry in a way that has greatly enriched this book. We would also like to thank Nathan Barrows, Arizona State University, for contributing to the Self-Test answers. The supplements authors, especially John Krenos, Joseph Potenza, Laurence Lavelle, Yinfa Ma, and Carl Hoeger, have offered us

much useful advice. Laurence Lavelle, UCLA, and Danielle Scheuhler, Wagner College, provided careful checking of all the solutions. This book also benefited from suggestions made by Dennis Kohl, University of Texas at Austin, Randall Shirts, Brigham Young University, Catherine Murphy, University of South Carolina, Michael Sailor, University of California at San Diego, Matt Miller and Jay Shore, South Dakota State University, and Peter Garik, Rosina Georgiadis, Mort Hoffman, and Dan Dill, Boston University.

We are grateful to the staff members at W. H. Freeman and Company, who understood our vision and helped to bring it to fruition. In particular, we would like to acknowledge Jessica Fiorillo, senior chemistry editor, who organized us and the entire project; Randi Rossignol, our developmental editor, who guided us toward important improvements in this edition; Georgia Lee Hadler, senior project editor, who once again took on the awesome task of overseeing the transformation of our files into paper; Margaret Comaskey, our copy editor, who organized and coordinated those files with great care; Bianca Moscatelli, who found exactly the right new photographs; and Dave Quinn, who directed the development and production of the substantial array of print and media supplements. We also thank Jenness Crawford for her help with the supplements and Anthony Petrites and Brittany Murphy for their help shepherding the manuscript into production. The authors could not have wished for a better or more committed team.

FUNDAMENTALS

WELCOME to chemistry! You are about to embark on a remarkable journey that will take you to the center of science. Looking in one direction, toward physics, you will see how the principles of chemistry are based on the behavior of atoms and molecules. Looking in another direction, toward biology, you will see how chemists contribute to an understanding of that most awesome property of matter, life. Eventually, you will be able to look at an everyday object, see in your mind's eye its composition in terms of atoms, and understand how that composition determines its properties.

INTRODUCTION AND ORIENTATION

Chemistry is the science of matter and the changes it can undergo. The world of chemistry therefore embraces everything material around us—the stones we stand on, the food we eat, the flesh we are made of, and the silicon in our computers. There is nothing material beyond the reach of chemistry, be it living or dead, vegetable or mineral, on Earth or in a distant star.

Chemistry and Society

Today's chemistry is built on centuries of exploration and discovery. In the earliest days of civilization, when the Stone Age gave way to the Bronze Age and then to the Iron Age, people did not realize that they were doing chemistry when they changed the material they found as stones—we would now call them *minerals*—into metals (Fig. 1). The possession of metals gave them a new power over their environment, and treacherous nature became less brutal. Civilization emerged as skills in transforming materials grew: glass, jewels, coins, ceramics, and, inevitably, weapons became more varied and effective. Art, agriculture, and warfare became more sophisticated. None of this would have happened without chemistry.

The development of steel accelerated the profound impact of chemistry on society. Better steel led to the Industrial Revolution, when muscles gave way to steam and giant enterprises could be contemplated. With improved transport and greater output from

FIGURE 1 Copper is easily extracted from its ores and was one of the first metals worked. The Bronze Age followed the discovery that adding some tin to copper made the metal harder and stronger. These four bronze swords date from 1250 to 850 BCE, the Late Bronze Age, and are from a collection in the Naturhistorisches Museum, Vienna, Austria. From bottom to top, they are a short sword, an antenna-type sword, a tongue-shaped sword, and a Liptau-type sword.

FIGURE 2 Cold weather triggers chemical processes that reduce the amount of the green chlorophyll in leaves, allowing the colors of various other pigments to show.

factories came more extensive trade, and the world became simultaneously a smaller but busier place. None of this would have happened without chemistry.

With the twentieth century, and now the twenty-first, came enormous progress in the development of the chemical industry. Chemistry transformed agriculture. Synthetic fertilizers provided the means of feeding the enormous, growing population of the world. Chemistry transformed communication and transportation. Today chemistry provides advanced materials, such as polymers for fabrics, ultrapure silicon for computers, and glass for optical fibers. It is producing more efficient renewable fuels and the tough, light alloys that are needed for modern aircraft and space travel. Chemistry has transformed medicine, substantially extended life expectancy, and has provided the foundations of genetic engineering. The deep understanding of life that we are developing through molecular biology is currently one of the most vibrant areas of science. None of this progress would have been achieved without chemistry.

However, the price of all these benefits has been high. The rapid growth of industry and agriculture, for instance, has stressed the Earth and damaged our inheritance. There is now widespread concern about the preservation of our extraordinary planet. It will be up to you and your contemporaries to draw on chemistry—in whatever career you choose—to build on what has already been achieved. Perhaps you will help to start a new phase of civilization based on new materials, just as semiconductors transformed society in the twentieth century. Perhaps you will help to reduce the harshness of the impact of progress on our environment. To do that, you will need chemistry.

Chemistry: A Science at Three Levels

Chemistry can be understood at three levels. At one level, chemistry is about matter and its transformations. This is the level at which we can actually see the changes, as when a fuel burns, a leaf changes color in the fall (Fig. 2), or magnesium burns brightly in air (Fig. 3). This level is the **macroscopic level**, the level dealing with the properties of large, visible objects. However, there is an underworld of change, a world that we cannot see directly. At this deeper **microscopic level**, chemistry interprets these phenomena in terms of the rearrangements of atoms (Fig. 4). The third level is the **symbolic level**, the expression of chemical phenomena in terms of chemical symbols and mathematical equations. This level ties the other two levels together. A chemist thinks at the microscopic level, conducts experiments at the macroscopic level, and represents both symbolically. We can map these three aspects of chemistry as a triangle (Fig. 5). As you read further in this text, you will find that sometimes the topics and explanations are close to one vertex of the triangle, sometimes to another. Because it is helpful in understanding chemistry to make connections among these levels, in the worked examples in this book you will find drawings of the molecular level as well as graphical interpretations of equations. As your understanding of chemistry grows so will your ability to travel easily within the triangle as you connect, for example, a laboratory observation to the symbols on a page and to mental images of atoms and molecules.

FIGURE 3 When magnesium burns in air, it gives off a lot of heat and light. The gray-white powdery product looks like smoke.

Lab Video 3

How Science Is Done

Scientists pursue ideas in an ill-defined but effective way often called the **scientific method**. There is no strict rule of procedure that leads you from a good idea to a Nobel prize or even to a publishable discovery. Some scientists are meticulously careful, others are highly creative. The best scientists are probably both careful and creative. Although there are various scientific methods in use, a typical approach consists of a series of steps (Fig. 6). The first step is often to collect **data** by making observations and measurements. These measurements are usually made on small **samples** of matter, representative pieces of the material that we want to study.

Scientists are always on the lookout for patterns. When a pattern is observed in the data, it can be stated as a scientific **law**, a succinct summary of a wide range of observations. For example, water was found to have eight times the mass of oxygen as it has of hydrogen, regardless of the source of the water or the size of the sample. One

of the earliest laws of chemistry summarized those types of observations as the "law of constant composition," which states that a compound has the same composition regardless of the source of the sample.

Formulating a law is just one way, not the only way, of summarizing data. There are many properties of matter (such as superconductivity, the ability of a few cold solids to conduct electricity without any resistance) that are currently at the forefront of research but are not described by grand "laws" that embrace hundreds of different compounds. A major current puzzle, which might be resolved in the future either by finding the appropriate law or by detailed individual computation, is what determines the shapes of protein molecules such as those that govern almost every aspect of life, including serious diseases such as Alzheimer's, Parkinson's, and cancer.

Once they have detected patterns, scientists may develop **hypotheses**, possible explanations of the laws—or the observations—in terms of more fundamental concepts. Observation requires careful attention to detail, but the development of a hypothesis requires insight, imagination, and creativity. In 1807, John Dalton interpreted experimental results to propose the hypothesis that matter consists of atoms. Although Dalton could not see individual atoms, he was able to imagine them and formulate his *atomic hypothesis*. Dalton's hypothesis was a monumental insight that helped others understand the world in a new way. The process of scientific discovery never stops. With luck and application, you may acquire that kind of insight as you read through this text, and one day you may make your own extraordinary and significant hypotheses.

After formulating a hypothesis, scientists design further **experiments**—carefully controlled tests—to verify it. Designing and conducting good experiments often requires ingenuity and sometimes good luck. If the results of repeated experiments—often in other laboratories and sometimes by skeptical coworkers—support the hypothesis, scientists may go on to formulate a **theory,** a formal explanation of a law. Quite often the theory is expressed mathematically. A theory originally envisioned as a **qualitative** concept, a concept expressed in words or pictures, is converted into a **quantitative** form, the same concept expressed in terms of mathematics. After a concept has been expressed quantitatively, it can be used to make numerical predictions and is subjected to rigorous experimental confirmation. You will have plenty of practice with the quantitative aspect of chemistry while working through this text.

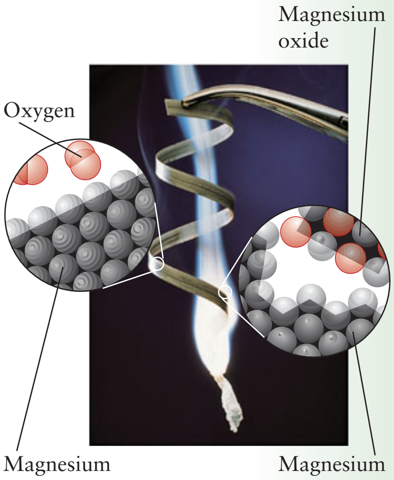

FIGURE 4 When a chemical reaction takes place, atoms exchange partners, as in Fig. 3 where magnesium and oxygen atoms form magnesium oxide. As a result, two forms of matter (left inset) are changed into another form of matter (right inset). Atoms are neither created nor destroyed in chemical reactions.

The postulates of Dalton's atomic hypothesis are described in Section B.

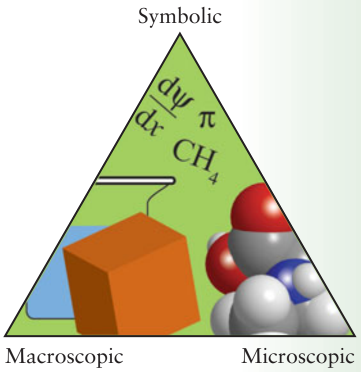

FIGURE 5 This triangle illustrates the three modes of scientific inquiry used in chemistry: macroscopic, microscopic, and symbolic. Sometimes we work more at one corner than at the others, but it is important to be able to move from one approach to another inside the triangle.

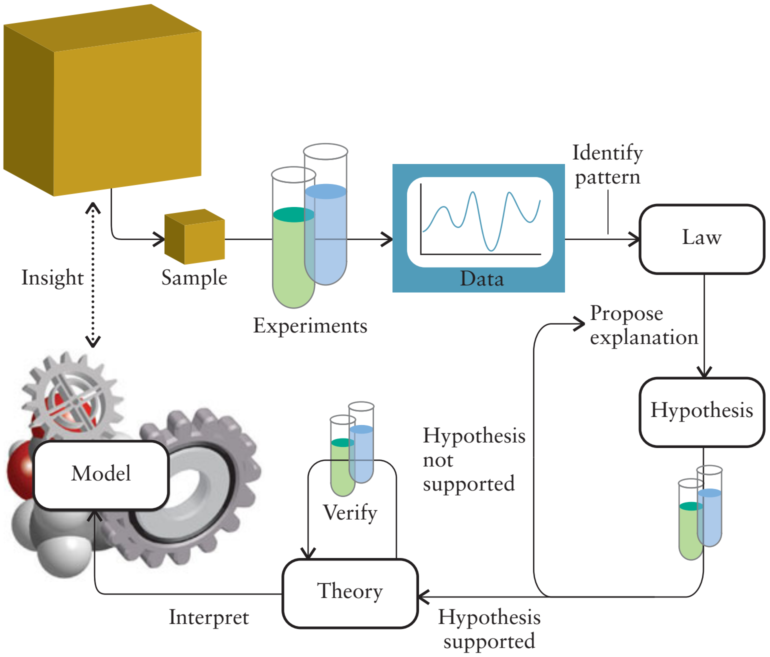

FIGURE 6 A summary of the principal activities in a common version of the scientific method. The ideas proposed must be tested and possibly revised at each stage.

Scientists commonly interpret a theory in terms of a **model,** a simplified version of the object of study that they can use to make predictions. Like hypotheses, theories and models must be subjected to experiment and revised if experimental results do not support them. For example, our current model of the atom has gone through many formulations and progressive revisions, starting from Dalton's vision of an atom as an uncuttable solid sphere to our current much more detailed model, which is described in Chapter 1. One of the main goals of this text is to show you how to build models, turn them into a testable form, and then refine them in the light of additional evidence.

The Branches of Chemistry

Chemistry is more than test tubes and beakers. New technologies have transformed chemistry dramatically in the past 50 years, and new areas of research have emerged (Fig. 7). Traditionally, the field of chemistry has been organized into three main branches:

organic chemistry, the study of compounds of carbon;
inorganic chemistry, the study of all the other elements and their compounds; and
physical chemistry, the study of the principles of chemistry.

New regions of study have developed as information has been acquired in specialized areas or as a result of the use of particular techniques. It is the nature of a vigorously developing science that the distinctions between its branches are not clear-cut, but nevertheless we still speak of

biochemistry, the study of the chemical compounds, reactions, and other processes in living systems;
analytical chemistry, the study of techniques for identifying substances and measuring their amounts;
theoretical chemistry, the study of molecular structure and properties in terms of mathematical models;
computational chemistry, the computation of molecular properties;
chemical engineering, the study and design of industrial chemical processes, including the fabrication of manufacturing plants and their operation;
medicinal chemistry, the application of chemical principles to the development of pharmaceuticals; and
biological chemistry, the application of chemical principles to biological structures and processes.

FIGURE 7 Scientific research today often requires sophisticated equipment and computers. This chemist is using an Auger electron spectrometer to probe the surface of a crystal. The data collected will allow the chemist to determine which elements are present in the surface.

Various interdisciplinary branches of knowledge with roots in chemistry have arisen, including:

molecular biology, the study of the chemical and physical basis of biological function and diversity, especially in relation to genes and proteins;
materials science, the study of the chemical structure and composition of materials; and
nanotechnology, the study of matter at the nanometer level, where structures consisting of small number of atoms can be manipulated.

A newly emerging concern of chemistry is **sustainable development,** the economical utilization and renewal of resources coupled with hazardous waste reduction and concern for the environment. This sensitive approach to the environment and our planetary inheritance is known colloquially as **green chemistry.** Where we think it is appropriate to draw your attention to this important development, we display the small icon shown here.

All sciences, medicine, and many fields of commercial activity draw on chemistry. You can be confident that whatever career you choose in a scientific or technical field, it will make use of the concepts discussed in this text. Chemistry is truly central to science.

Mastering Chemistry

The following lettered sections summarize the basic information that you need to begin your chemistry course. You might already have a strong background in chemistry.

These green-bordered introductory pages will provide you with a summary of a number of basic concepts and techniques. Your instructor will advise you on how to use these sections to prepare yourself for the chapters in the text itself.

If you have done little chemistry before, these pages are for you, too. They contain a brief but systematic summary of the basic concepts and calculations of chemistry that you should know before studying the chapters in the text. You can return to them as needed. If you need to review the mathematics required for chemistry, especially algebra and logarithms, Appendix 1 has a brief review of the important procedures.

A MATTER AND ENERGY

A.1 Physical Properties
A.2 Force
A.3 Energy

Whenever we touch, pour, or weigh something, we are working with matter. Chemistry is concerned with the properties of matter and particularly the conversion of one form of matter into another kind. But what is matter? Matter is in fact difficult to define precisely without drawing on advanced ideas from elementary particle physics, but a straightforward working definition is that **matter** is anything that has mass and takes up space. Thus, gold, water, and flesh are forms of matter; electromagnetic radiation (which includes light) and justice are not.

One characteristic of science is that it uses common words from our everyday language but gives them a precise meaning. In everyday language, a "substance" is just another name for matter. However, in chemistry, a **substance** is a *single, pure form of matter*. Thus, gold and water are distinct substances. Flesh is a mixture of many different substances, and, in the technical sense used in chemistry, it is not a "substance." Air is matter; but, being a mixture of several gases, it is not a single substance.

Substances, and matter in general, come in different forms, called **states of matter.** The three most common states of matter are solid, liquid, and gas:

A **solid** is a form of matter that retains its shape and does not flow.
A **liquid** is a fluid form of matter that has a well-defined surface; it takes the shape of the part of the container it occupies.
A **gas** is a fluid form of matter that fills any vessel containing it.

The term **vapor** denotes the gaseous form of a substance that is normally a solid or liquid. Thus, we speak of ice (the solid form of water), liquid water, and water vapor (steam).

Figure A.1 shows how the states of matter can be distinguished by the arrangements and motions of atoms and molecules. In a solid, such as ice or copper metal, the atoms are packed together closely, and the solid is rigid because the atoms cannot move past one another. However, the atoms in a solid are not motionless: they oscillate around their average locations, and the oscillation becomes more vigorous as the temperature is raised. The atoms (and molecules) of a liquid are packed together about as closely as they are in a solid, but they have enough energy to move past one another. As a result, a liquid, such as water or molten copper, flows in response to a force, such as gravity. In a gas, such as air (which is mostly nitrogen and oxygen) and water vapor, the molecules have achieved almost complete freedom from one another: they fly through empty space at close to the speed of sound, colliding when they meet and immediately flying off in another direction.

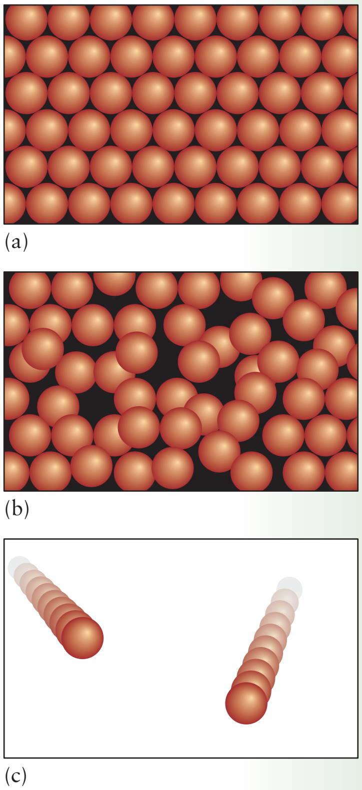

FIGURE A.1 A molecular representation of the three states of matter. In each case, the spheres represent particles that may be atoms, molecules, or ions. (a) In a solid, the particles are packed tightly together and held in place, but continue to oscillate. (b) In a liquid, the particles are in contact, but have enough energy to move past one another. (c) In a gas, the particles are far apart, move almost completely freely, and are in ceaseless random motion.

A.1 Physical Properties

Chemistry is concerned with the **properties** of matter, its distinguishing characteristics. A **physical property** of a substance is a characteristic that we can observe or measure without changing the identity of the substance. For example, a physical property of a sample of water is its mass; another is its temperature. Physical properties include characteristics such as melting point (the temperature at which a solid turns into a liquid), hardness, color, state of matter (solid, liquid, or gas), and density. A **chemical property**

refers to the ability of a substance to be changed into another substance. For example, a chemical property of the gas hydrogen is that it reacts with (burns in) oxygen to produce water; a chemical property of the metal zinc is that it reacts with acids to produce hydrogen gas. When a substance undergoes a **physical change,** the identity of the substance does not change, only its physical properties are different. For example, when water freezes, the solid ice is still water. However, when a substance undergoes a **chemical change,** it is transformed into a different substance altogether. In this section we review some important physical properties of matter.

Each physical quantity is represented by an italic or sloping Greek symbol (thus, *m* for mass, not m). The results of a measurement, the "value" of a physical quantity, is reported as a multiple of a **unit,** such as reporting a mass as 15 kilograms, which is understood to be 15 times the unit "1 kilogram." Scientists have reached international agreement on the units to use when reporting measurements, so their results can be used with confidence and checked by people anywhere in the world. You will find most of the symbols used in this textbook together with their units in Appendix 1.

A note on good practice: All units are denoted by Roman letters, such as m for meter and s for second, that distinguish them from the physical quantity to which they refer (such as *l* for length and *t* for time).

The **Système International** (SI) is the internationally accepted form and elaboration of the metric system. It defines seven base units in terms of which all physical quantities can be expressed. At this stage all we need are:

meter, m	The **meter,** the unit of length
kilogram, kg	The **kilogram,** the unit of mass
second, s	The **second,** the unit of time

All the units are defined in Appendix 1B. Each unit may be modified by a prefix. The full set is given in Appendix 1B; some common examples are:

Prefix	Symbol	Factor	Example
centi-	c	1/100	1 cm = 1/100 m (1 centimeter)
milli-	m	1/1000	1 ms = 1/1000 s (1 millisecond)
kilo-	k	1000	1 km = 1000 m (1 kilometer)

Units may be combined together into **derived units** to express a property more complicated than mass, length, or time. For example, **volume,** *V*, the amount of space occupied by a substance, is the product of three lengths; therefore, the derived unit of volume is $(\text{meter})^3$, denoted m^3. Similarly, **density,** the mass of a sample divided by its volume, is a derived unit expressed in terms of the base unit for mass divided by the derived unit for volume—namely, $\text{kilogram}/(\text{meter})^3$, denoted kg/m^3 or, equivalently, $kg{\cdot}m^{-3}$.

A note on good practice: The SI convention is that a power, such as the 3 in cm^3, refers to the unit and its multiple. That is, cm^3 should be interpreted as $(cm)^3$ or $10^{-6}\ m^3$ *not* as $c(m^3)$, or $10^{-2}\ m^3$.

It is often necessary to convert measurements from another set of units into SI units. For example, we may need to convert a length measured in inches into centimeters. To convert these units, we use the relation 1 in. = 2.54 cm, and in general,

$$\text{Units given} = \text{unit required}$$

Relations between common units can be found in Table 5 of Appendix 1B. We use these relations to construct a **conversion factor** of the form

$$\text{Conversion factor} = \frac{\text{units required}}{\text{units given}}$$

Then we use it as follows:

Information required = information given × conversion factor

When using a conversion factor, we treat the units just like algebraic quantities: they are multiplied or canceled in the normal way.

EXAMPLE A.1 Converting units

Suppose you are in a store—perhaps in Canada or Europe—where paint is sold only in liters. You know you need 1.7 qt of a particular paint. What is that volume in liters?

Anticipate It is useful to remember that 1 L is slightly more than 1 qt, so we should expect a volume of slightly less than 1.7 L.

PLAN Identify the relation between the two units from Table 5 of Appendix 1B:

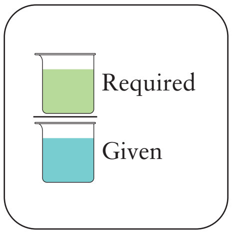
$$1\ \text{qt} = 0.946\ 352\ 5\ \text{L}$$

Then set up the conversion factor from the units given (qt) to the units required (L).

SOLVE

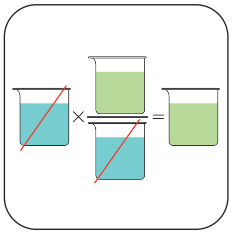
Form the conversion factor as (units required)/(units given).

$$\text{Conversion factor} = \frac{0.946\ 352\ 5\ \text{L}}{1\ \text{qt}}$$



Convert the measurement into the required units.

$$\text{Volume(L)} = (1.7\ \text{qt}) \times \frac{0.946\ 352\ 5\ \text{L}}{1\ \text{qt}} = 1.6\ \text{L}$$



Evaluate As expected, we need slightly less than 1.7 L. We have rounded the answer to two significant figures, as explained below.

Self-Test A.1A Express the height of a person 6.00 ft tall in centimeters.

[***Answer:*** 183 cm]

Self-Test A.1B Express the mass in ounces of a 250.-g package of breakfast cereal.

Answers to all B self-tests are in the back of this book.

It is often necessary to convert a unit that is raised to a power (including negative powers). In such cases, the conversion factor is raised to the same power. For example, to convert a density of 11 700 $\text{kg}\cdot\text{m}^{-3}$ into grams per centimeter cubed ($\text{g}\cdot\text{cm}^{-3}$), we use the two relations

$$1\ \text{kg} = 10^3\ \text{g} \quad \text{and} \quad 1\ \text{cm} = 10^{-2}\ \text{m}$$

as follows:

$$\begin{aligned}\text{Density}\ (\text{g}\cdot\text{cm}^{-3}) &= (11\ 700\ \text{kg}\cdot\text{m}^{-3}) \times \frac{10^3\ \text{g}}{1\ \text{kg}} \times \left(\frac{1\ \text{cm}}{10^{-2}\ \text{m}}\right)^{-3} \\ &= (11\ 700\ \text{kg}\cdot\text{m}^{-3}) \times \frac{10^3\ \text{g}}{1\ \text{kg}} \times \frac{10^{-6}\ \text{m}^3}{1\ \text{cm}^3} \\ &= 11.7\frac{\text{g}}{\text{cm}^3} = 11.7\ \text{g}\cdot\text{cm}^{-3}\end{aligned}$$

A note on good practice: Units are treated like algebraic quantities and are multiplied and canceled just like numbers. For example, in the second line of this calculation we used the relation

$$\left(\frac{1\ \text{cm}}{10^{-2}\ \text{m}}\right)^{-3} = \left(\frac{10^{-2}\ \text{m}}{1\ \text{cm}}\right)^{3} = \frac{10^{-6}\ \text{m}^3}{1\ \text{cm}^3}$$

Self-Test A.2A Express a density of 6.5 $\text{g}\cdot\text{mm}^{-3}$ in micrograms per nanometer cubed ($\mu\text{g}\cdot\text{nm}^{-3}$).

[***Answer:*** $6.5 \times 10^{-12}\ \mu\text{g}\cdot\text{nm}^{-3}$]

Self-Test A.2B Express an acceleration of 9.81 $\text{m}\cdot\text{s}^{-2}$ in kilometers per hour squared.

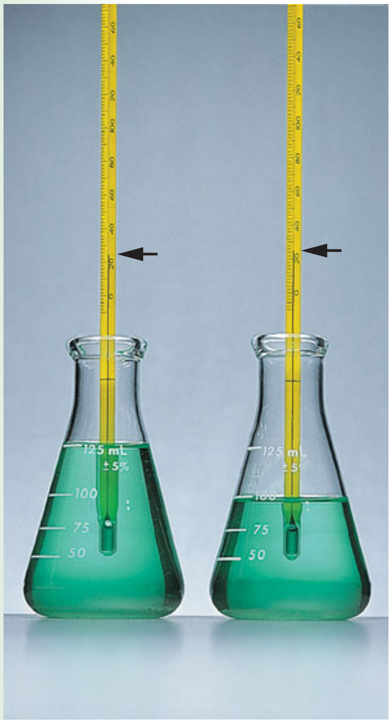


FIGURE A.2 Mass is an extensive property, but temperature is intensive. These two samples of iron(II) sulfate solution were taken from the same well-mixed supply: they have different masses but the same temperature.

Properties can be classified according to their dependence on the size of a sample. An **extensive property** is a property that does depend on the size ("extent") of the sample. More precisely, if a system is divided into parts and it is found that the property of the complete system has a value that is the sum of the values of the property of all the parts, then that property is extensive. If that is not the case, then the property is intensive. In short, an **intensive property** is independent of the size of the sample. Volume is an extensive property: 2 kg of water occupies twice the volume of 1 kg of water. Temperature is an intensive property, because we can take a sample of any size from a uniform bath of water and measure the same temperature (Fig. A.2). The importance of the distinction is that we identify different substances by their intensive properties. Thus, we might recognize a sample as water by noting its color, density (1.00 $\text{g}\cdot\text{cm}^{-3}$), melting point (0°C), boiling point (100°C), and the fact that it is a liquid.

Some intensive properties are ratios of two extensive properties. For example, the density, d, mentioned above, is a ratio of the mass, m, of a sample divided by its volume, V:

$$\text{Density} = \frac{\text{mass}}{\text{volume}} \quad \text{or} \quad d = \frac{m}{V} \tag{1}$$

The density of a substance is independent of the size of the sample because doubling the volume also doubles the mass; so the ratio of mass to volume remains the same. Density is therefore an intensive property.

We have to be aware that most properties depend on the state of matter and the conditions, such as the temperature and pressure. For example, the density of water at 0°C is 1.00 $\text{g}\cdot\text{cm}^{-3}$ but at 100°C it is 0.96 $\text{g}\cdot\text{cm}^{-3}$. The density of ice at 0°C is 0.92 $\text{g}\cdot\text{cm}^{-3}$ and the density of water vapor at 100°C and atmospheric pressure is nearly 2000 times less, at 0.59 $\text{g}\cdot\text{L}^{-1}$. Water is unusual in expanding slightly when it freezes to ice, so ice is less dense than water at 0°C: most substances contract slightly and become more dense as they freeze.

Units for physical quantities and temperature scales are discussed in Appendix 1B.

EXAMPLE A.2 Calculating the volume of a sample

What is the volume occupied by 5.0 g of solid silver, given the density listed in Appendix 2D?

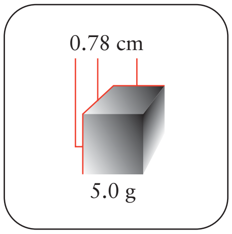
Anticipate In Appendix 2D, we see that most metals have densities in the range 5 to 20 $\text{g}\cdot\text{cm}^{-3}$, with many close to 10 $\text{g}\cdot\text{cm}^{-3}$. Therefore, we should expect a mass of 1 g to correspond to a volume of about 0.1 cm^3. For 5 g, we should expect an answer close to 0.5 cm^3.

PLAN We rearrange Eq. 1 into $V = m/d$, and then substitute the data.

SOLVE The density of silver is listed in Appendix 2D as 10.50 $\text{g}\cdot\text{cm}^{-3}$; so the volume of 5.0 g of solid silver is

From $V = m/d$,

$$V = \frac{5.0\ \text{g}}{10.50\ \text{g}\cdot\text{cm}^{-3}} = \frac{5.0}{10.50}\ \text{cm}^3 = 0.48\ \text{cm}^3$$



Evaluate The volume calculated, 0.48 cm^3, is close to what we expected.

Self-Test A.3A The density of selenium is 4.79 $g \cdot cm^{-3}$. What is the mass of 6.5 cm^3 of selenium?

[***Answer:*** 31 g]

Self-Test A.3B The density of helium gas at 0°C and 1.00 atm is 0.176 85 $g \cdot L^{-1}$. What is the volume of a balloon containing 10.0 g of helium under the same conditions?

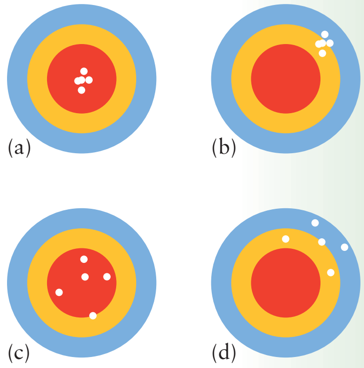


FIGURE A.3 The holes in these targets represent measurements that are (a) precise and accurate, (b) precise but inaccurate, (c) imprecise but accurate on average, and (d) both imprecise and inaccurate.

All measured quantities have some uncertainty associated with them; in science it is important to convey the degree to which we are certain of not only the values we report but also the results of calculations using those values. Notice that in Example A.2 we wrote the result of dividing 5.0 by 10.50 as 0.48, not 0.47619. The number of digits reported in the result of a calculation must reflect the number of digits in the data provided.

The number of **significant figures** in a numerical value is the number of digits that can be justified by the data. Thus, the measurement 5.0 g has two significant figures (2 sf) and 10.50 $g \cdot cm^{-3}$ has four (4 sf). The number of significant figures in the result of a calculation cannot exceed the number in the data (you can't generate reliability on a calculator!), so in Example A.2 we limited the result to 2 sf, the lower number of significant figures in the data. The full rules for counting the number of significant figures and determining the number of significant figures in the result of a calculation are given in Appendix 1C, together with the rules for rounding numerical values.

An ambiguity may arise when dealing with a whole number ending in a zero, because the number of significant figures in the number may be less than the number of digits. For example, 400 could have 1, 2, or 3 sf. To avoid ambiguity, in this book when all the digits in a number ending in zero are significant, the number is followed by a decimal point. Thus, the number 400. has 3 sf.

When scientists measure the properties of a substance, they monitor and report the accuracy and precision of the data. To make sure of their data, scientists usually repeat their measurements several times. The **precision** of a measurement is reflected in the number of significant figures justified by the procedure and depends on how close repeated measurements are to one another. The **accuracy** of a series of measurements is the closeness of their average value to the true value. The illustration in Fig. A.3 distinguishes precision from accuracy. As the illustration suggests, even precise measurements can give inaccurate values. For instance, if there is an unnoticed speck of dust on the pan of a chemical balance that we are using to measure the mass of a sample of silver, then even though we might be justified in reporting our measurements to five significant figures (such as 5.0450 g), the reported mass of the sample will be inaccurate.

More often than not, measurements are accompanied by two kinds of error. A **systematic error** is an error present in every one of a series of repeated measurements. An example is the effect of a speck of dust on a pan, which distorts the mass of each sample in the same direction (the speck makes each sample appear heavier than it is). A **random error** is an error that varies at random and can average to zero over a series of observations. An example is the effect of drafts of air from an open window moving a balance pan either up or down a little, decreasing or increasing the mass measurements randomly. Scientists attempt to minimize random error by making many observations and taking the average of the results. Systematic errors are much harder to identify.

Thinking point: What are some means that scientists can use to identify and eliminate systematic errors?

Physical properties are those that do not involve changing the identity of a substance. Chemical properties are those that involve changing the identity of a substance. Extensive properties depend on the mass of the sample; intensive properties do not. The precision of a measurement is an indication of how close together repeated measurements are; the accuracy of a measurement is its closeness to the true value.

A.2 Force

A **force,** F, is an influence that changes the state of motion of an object. For instance, we exert a force to open a door—to start the door swinging open—and we exert a force

FUNDAMENTALS

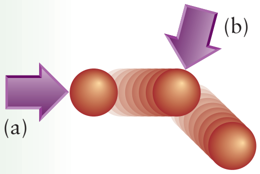

FIGURE A.4 (a) When a force acts along the direction of travel, the speed (the magnitude of the velocity) changes, but the direction of motion does not. (b) The direction of travel can be changed without affecting the speed if the force is applied in an appropriate direction. Both changes in velocity correspond to acceleration.

on a ball when we hit it with a bat. According to Newton's second law of motion, when an object experiences a force, it is accelerated. The **acceleration,** a, of the object, the rate of change of its velocity, is proportional to the force that it experiences:

Acceleration $\propto$ force, or $a \propto F$

The constant of proportionality between the force and the acceleration it produces is the mass, m, of the object experiencing the force:

$$\text{Force} = \text{mass} \times \text{acceleration, or } F = ma \qquad (2)$$

This expression, in the form $a = F/m$, tells us that a stronger force is required to accelerate a heavy object by a given amount than to accelerate a lighter object by the same amount.

Velocity, the rate of change of position, has both magnitude and direction; so, when a force acts, it can change the magnitude alone, the direction alone, or both simultaneously (Fig. A.4). The magnitude of the velocity of an object—the rate of change of position regardless of the direction of the motion—is called its **speed,** v. When we accelerate a car in a straight line, we change its speed, but not its direction, by applying a force through the rotation of the wheels and their contact with the road. To stop a car, we apply a force that opposes the motion. However, a force can also act without changing the speed: if a body is forced to travel in a different direction at the same speed, it undergoes acceleration because velocity includes direction as well as magnitude. For example, when a ball bounces on the floor, the force exerted by the floor reverses the ball's direction of travel without affecting its speed very much.

Forces important in chemistry include the electrostatic forces of attraction and repulsion between charged particles and the weaker forces between molecules. Atomic nuclei exert forces on the electrons that surround them, and it takes energy to move those electrons from one place to another in a molecule. Rather than considering the forces directly, chemists normally focus on the energy needed to overcome them. One major exception, discussed in Major Technique 1, following Chapter 2, is in the vibrations of molecules, where atoms in bonds behave as though they are joined by springs that exert forces when the bonds are stretched and compressed.

Acceleration, the rate of change of velocity, is proportional to applied force.

The joule is named for James Joule, the nineteenth-century English scientist who made many contributions to the study of heat.

A.3 Energy

Some chemical changes give off a lot of energy (Fig. A.5); others absorb energy. An understanding of the role of energy is the key to understanding chemical phenomena and the structures of atoms and molecules. But just what is energy?

The word *energy* is so common in everyday language that most people have a general sense of what it means; however, to get a technical answer to this question, we would have to delve into the theory of relativity, which is far beyond the scope of this book. In chemistry, we use a practical definition of **energy** as the capacity to do work, with **work** defined as motion against an opposing force,

Energy = force × distance

Thus, energy is needed to do the work of raising a weight a given height or the work of forcing an electric current through a circuit. The greater the energy of an object, the greater its capacity to do work.

The SI unit for energy is the **joule** (J). As explained in Appendix 1B,

$$1\ \text{J} = 1\ \text{kg}\cdot\text{m}^2\cdot\text{s}^{-2}$$

Each beat of the human heart uses about 1 J of energy, and to raise this book (of mass close to 2.0 kg) from the floor to a tabletop about 0.97 m above the floor requires about 19 J (Fig. A.6). Because energy changes in chemical reactions tend to be of the order of thousands of joules for the amounts usually studied, it is more common in chemistry to use the kilojoule (kJ, where 1 kJ = 10^3 J).

Lab Video A.5

FIGURE A.5 When bromine is poured on red phosphorus, a chemical change takes place in which a lot of energy is released as heat and light.

A note on good practice: Names of units derived from the names of people are always lower case (as for joule, named for the scientist J. P. Joule), but their abbreviations are always uppercase (as in J for joule).

There are three contributions to energy: kinetic energy, potential energy, and electromagnetic energy. **Kinetic energy,** E_k, is the energy that a body possesses due to its motion. For a body of mass m traveling at a speed v, the kinetic energy is

$$E_k = \frac{1}{2}mv^2 \qquad (3)^*$$

A heavy body traveling rapidly has a high kinetic energy. A body at rest (stationary, $v = 0$) has zero kinetic energy.

A star next to an equation number signals that it appears in the list of Key Equations on the Web site for this book: www.whfreeman.com/chemicalprinciples5e.

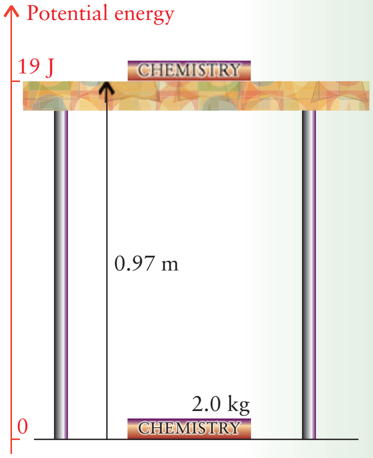

FIGURE A.6 The energy required to raise the book that you are now reading from floor to tabletop is approximately 19 J. The same energy would be released if the book fell from tabletop to floor.

EXAMPLE A.3 Calculating kinetic energy

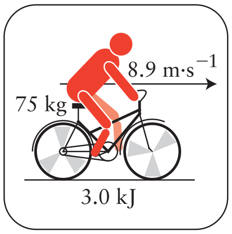
How much energy does it take to accelerate a person and a bicycle of total mass 75 kg to 20. mph (8.9 m·s^{-1}), starting from rest and ignoring friction and wind resistance?

PLAN We need to decide how much energy must be supplied to reach the kinetic energy of the cyclist corresponding to the final speed.

SOLVE

From $E_k = \frac{1}{2}mv^2$,

$$E_k = \frac{1}{2} \times (75\ \text{kg}) \times (8.9\ \text{m·s}^{-1})^2$$
$$= 3.0 \underbrace{\times 10^3}_{\text{k}} \underbrace{\text{kg·m}^2\text{·s}^{-2}}_{\text{J}} = 3.0\ \text{kJ}$$



Evaluate We see that a minimum of 3.0 kJ is needed. More energy is needed to achieve that speed when friction and wind resistance are taken into account.

Self-Test A.4A Calculate the kinetic energy of a ball of mass 0.050 kg traveling at 25 m·s^{-1}.

[***Answer:*** 16 J]

Self-Test A.4B Calculate the kinetic energy of a 1.5-kg book just before it lands on your foot after falling off a table, when it is traveling at 3.0 m·s^{-1}.

The **potential energy,** E_p, of an object is the energy that it possesses on account of its position in a field of force. There is no single formula for the potential energy of an object, because the potential energy depends on the nature of the forces that it experiences. However, two simple cases are important in chemistry: gravitational potential energy (for a particle in a gravitational field) and Coulomb potential energy (for a charged particle in an electrostatic field).

Potential energy is also commonly denoted V. A field is a region where a force acts.

A body of mass m at a height h above the surface of the Earth has a gravitational potential energy

$$E_p = mgh \qquad (4)^*$$

This formula applies only to objects close to the surface of the Earth.

relative to its potential energy on the surface itself (Fig. A.7), where g is the *acceleration of free fall* (and, commonly, the "acceleration of gravity"). The value of g depends on where we are on the Earth, but in most typical locations g has close to its "standard value" of 9.81 m·s^{-2}, and we shall use this value in all calculations. Equation 4 shows that the greater the altitude of an object, the greater is its gravitational potential energy. For instance, when we raise this book from the floor to the table against the opposing force of gravity, we have done work on the book and its potential energy is increased.

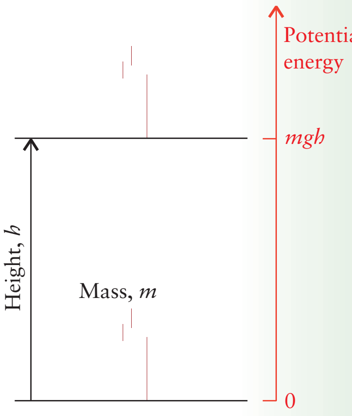


FIGURE A.7 The potential energy of a mass m in a gravitational field is proportional to its height h above a point (here, the surface of the Earth), which is taken to correspond to zero potential energy.

A note on good practice: You will sometimes see kinetic energy denoted KE and potential energy denoted PE. Modern practice is to denote all physical quantities by a single letter (accompanied, if necessary, by subscripts).

EXAMPLE A.4 Calculating the gravitational potential energy

Someone of mass 65 kg walks up a flight of stairs between two floors of a building that are separated by 3.0 m. What is the change in potential energy of the person?

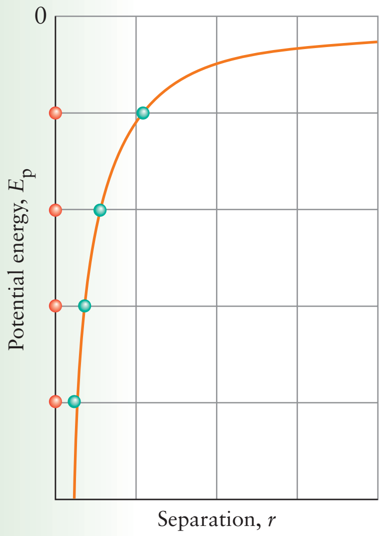

FIGURE A.8 The variation of the Coulomb potential energy of two opposite charges (one represented by the red circle, the other by the green circle) with their separation. Notice that the potential energy decreases as the charges approach each other.

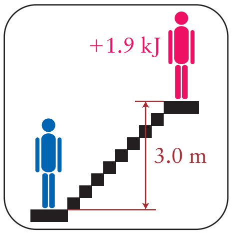
PLAN To calculate the change, we suppose that the potential energy of the person on the lower floor is zero, then calculate the potential energy at the height of the upper floor.

SOLVE The potential energy of the person on the upper floor relative to that on the lower floor is

From $E_p = mgh$,

$$E_p = (65\ \text{kg}) \times (9.81\ \text{m·s}^{-2}) \times (3.0\ \text{m})$$
$$= 1.9 \times 10^3\ \text{kg·m}^2\text{·s}^{-2} = 1.9\ \text{kJ}$$



Self-Test A.5A What is the gravitational potential energy of this book (mass 1.5 kg) when it is on a table of height 0.82 m relative to its potential energy when it is on the floor?

[*Answer:* 12 J]

Self-Test A.5B How much energy has to be expended to raise a can of soda (mass 0.350 kg) to the top of the Sears Tower in Chicago (height 443 m)?

The energy due to attractions and repulsions between electric charges is of great importance in chemistry, which deals with electrons, atomic nuclei, and ions, all of which are charged. The **Coulomb potential energy** of a particle of charge Q_1 at a distance r from another particle of charge Q_2 is proportional to the two charges and inversely proportional to the distance between them:

$$E_p = \frac{Q_1 Q_2}{4\pi\varepsilon_0 r} \qquad (5)^*$$

In this expression, which applies when the two charges are separated by a vacuum, ε_0 (epsilon zero) is a fundamental constant called the "vacuum permittivity"; its value is $8.854 \times 10^{-12}\ \text{J}^{-1}\text{·C}^2\text{·m}^{-1}$. The Coulomb potential energy is obtained in joules when the charges are in coulombs (C, the SI unit of charge) and their separation is in meters (m). The charge on an electron is $-e$, with $e = 1.602 \times 10^{-19}$ C, the "fundamental charge."

What does this equation tell us? The Coulomb potential energy approaches zero as the distance between two particles approaches infinity. If the particles have the same charge—if they are two electrons, for instance—then the numerator Q_1Q_2, and therefore E_p itself, is positive, and the potential energy *rises* (becomes more strongly positive) as the particles approach each other (r decreases). If the particles have opposite charges—an electron and an atomic nucleus, for instance—then the numerator, and therefore E_p, is negative and the potential energy *decreases* (in this case, becomes more negative) as the separation of the particles decreases (Fig. A.8).

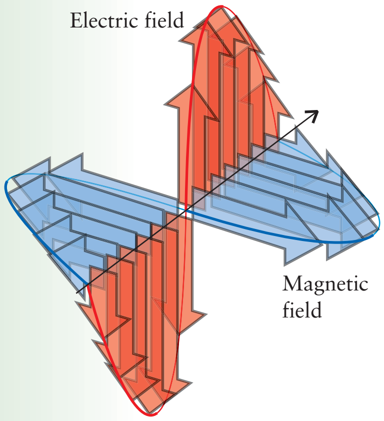


FIGURE A.9 An electromagnetic field oscillates in time and space. The magnetic field (shown in blue) is perpendicular to the electric field (shown in red). The length of an arrow at any point represents the strength of the field at that point, and its orientation denotes its direction. Both fields are perpendicular to the direction of travel of the radiation.

What we have termed "electromagnetic energy" is the energy of the **electromagnetic field**, such as the energy carried through space by radio waves, light waves, and x-rays (very high energy electromagnetic radiation). An electromagnetic field is generated by the acceleration of charged particles and consists of an oscillating **electric field** and an oscillating **magnetic field** (Fig. A.9). The crucial distinction is that an electric field affects charged particles whether they are still or moving, whereas a magnetic field affects only moving charged particles.

The **total energy,** E, of a particle is the sum of its kinetic and potential energies:

$$\text{Total energy} = \text{kinetic energy} + \text{potential energy, or } E = E_k + E_p \qquad (6)^*$$

A very important feature of the total energy of an object is that, provided there are no outside influences, it is constant. We summarize this observation by saying that *energy is conserved*. Kinetic energy and potential energy can change into each other, but their sum for a given object, whether as large as a planet or as tiny as an atom, is constant.

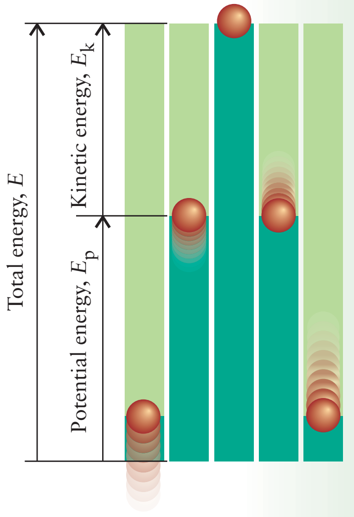

FIGURE A.10 Kinetic energy (represented by the height of the light green bar) and potential energy (the dark blue-green bar) are interconvertible, but their sum (the total height of the bar) is a constant in the absence of external influences, such as air resistance. A ball thrown up from the ground loses kinetic energy as it slows, but gains potential energy. The reverse happens as it falls back to Earth.

For instance, a ball thrown up into the air initially has high kinetic energy and zero potential energy. At the top of its flight, it has zero kinetic energy and high potential energy. However, as it returns to Earth, its kinetic energy rises and its potential energy approaches zero again. At each stage, its *total* energy is the same as it was when it was initially launched (Fig. A.10). When it strikes the Earth, the ball is no longer isolated, and its energy is dissipated as **thermal motion**, the chaotic, random motion of atoms and molecules. If we added up all the kinetic and potential energies, we would find that the total energy of the Earth had increased by exactly the same amount as that lost by the ball. No one has ever observed any exception to the **law of conservation of energy**, the observation that energy can be neither created nor destroyed. One region of the universe—an individual atom, for instance—can lose energy, but another region must gain that energy.

Chemists often refer to two other kinds of energy. The term **chemical energy** is used to refer to the change in energy when a chemical reaction takes place, as in the combustion of a fuel. "Chemical energy" is not a special form of energy: it is simply a shorthand name for the sum of the potential and kinetic energies of the substances participating in the reaction, including the potential and kinetic energies of their electrons. The term **thermal energy** is another shorthand term. In this case it is shorthand for the sum of the potential and kinetic energies arising from the thermal motion of atoms, ions, and molecules.

Energy and mass are equivalent and can be interconverted; Einstein deduced that $E = mc^2$, where c is the speed of light.

Kinetic energy results from motion, potential energy from position. An electromagnetic field carries energy through space; work is motion against an opposing force.

FUNDAMENTALS

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Identify properties as chemical or physical, intensive or extensive.

❑ 2 Use the density of a substance in calculations (Example A.1).

❑ 3 Calculate the kinetic energy of an object (Example A.2).

❑ 4 Calculate the gravitational potential energy of an object (Example A.3).

❑ 5 Distinguish the different forms of energy described in this section.

EXERCISES

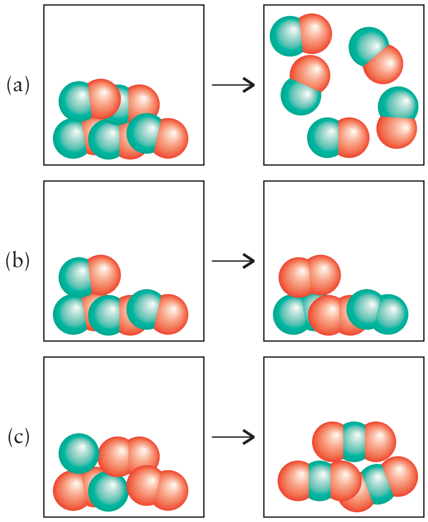
A.1 Classify the following properties as chemical or physical: (a) objects made of silver become tarnished; (b) the red color of rubies is due to the presence of chromium ions; (c) the boiling point of ethanol is 78°C.

A.2 A chemist investigates the density, melting point, and flammability of acetone, a component of fingernail polish remover. Which of these properties are physical properties and which are chemical properties?

A.3 Identify all the physical properties and changes in the following statement: "The camp nurse measured the temperature of the injured camper and ignited a propane burner; when the water began to boil some of the water vapor condensed on the cold window."

A.4 Identify all the chemical properties and changes in the following statement: "Copper is a red-brown element obtained from copper sulfide ores by heating them in air, which forms copper oxide. Heating the copper oxide with carbon produces impure copper, which is purified by electrolysis."

A.5 In the containers below, the green spheres represent atoms of one element, the red spheres the atoms of a second element. In each case, the pictures show either a physical or chemical change; identify the type of change.



A.6 Which of the containers in Exercise A.5 shows a substance that could be a gas?

A.7 State whether the following properties are extensive or intensive: (a) the temperature at which ice melts; (b) the color of nickel chloride; (c) the energy produced when gasoline burns; (d) the cost of gasoline.

A.8 State whether the following properties are extensive or intensive: (a) the price of platinum; (b) the humidity of the atmosphere; (c) the air pressure in a tire; (d) the hardness of concrete.

A.9 The following units may sound strange, but were actually used in ancient times. Suppose that they have been adopted into the SI system. Rewrite each value with the appropriate SI prefix. (a) 1000 grain; (b) 0.01 batman; (c) 1×10^6 mutchkin.

A.10 The following units may sound strange, but were actually used in ancient times. Suppose that they have been adopted into the SI system. Rewrite each value with the appropriate SI prefix. (a) 1×10^{12} scantling; (b) 1×10^{-15} palm; (c) 1×10^{-9} catty.

A.11 Express the volume in milliliters of a 1.00-cup sample of milk, given that 2 cups = 1 pint, 2 pints = 1 quart.

A.12 The ångström unit ($1\ \text{Å} = 10^{-10}$ m) is still widely used to report measurements of the dimensions of atoms and molecules. Express the following data in ångströms: (a) the radius of a sodium atom, 180 pm (2 sf); (b) the wavelength of yellow light, 550 nm (2 sf). (c) Write a (single) conversion factor between ångströms and nanometers.

A.13 When a piece of unreactive metal of mass 112.32 g is dropped into a graduated cylinder containing 23.45 mL of water, the water level rises to 29.27 mL. What is the density of the metal (in grams per cubic centimeter)?

A.14 When a piece of unreactive metal of mass 156.77 g is dropped into a graduated cylinder containing 30.21 mL of water, the water level rises to 48.95 mL. What is the density of the metal (in grams per cubic centimeter)?

A.15 The density of diamond is $3.51\ \text{g·cm}^{-3}$. The international (but non-SI) unit for weighing diamonds is the "carat" (1 carat = 200 mg exactly). What is the volume of a 0.750-carat diamond?

A.16 Use data from Appendix D to calculate the volume of 1.00 ounce of gold.

A.17 A flask weighs 43.50 g when it is empty and 105.50 g when filled with water. When the same flask is filled with another liquid, the mass is 96.75 g. What is the density of the second liquid?

A.18 What volume (in cubic centimeters) of lead (of density $11.3\ \text{g·cm}^{-3}$) has the same mass as $215\ \text{cm}^3$ of a piece of redwood (of density $0.38\ \text{g·cm}^{-3}$)?

A.19 Spacecraft are commonly clad with aluminum to provide shielding from radiation. Adequate shielding requires that the cladding provide 20. g of aluminum per square centimeter. Use data from Appendix D to calculate how thick the aluminum cladding must be to provide adequate shielding.

A.20 Assume that the entire mass of an atom is concentrated in its nucleus, a sphere of radius 1.5×10^{-5} pm. (a) If the mass of a carbon atom is 2.0×10^{-23} g, what is the density of a carbon nucleus? The volume of a sphere of radius r is $\frac{4}{3}\pi r^3$. (b) What would the radius of the Earth be if its matter were compressed to the same density as that of a carbon nucleus? (The Earth's average radius is 6.4×10^3 km, and its average density is $5.5\ \text{g·cm}^{-3}$.)

A.21 To how many significant figures should the result of the following calculation be reported?

$$\frac{0.082\,06 \times (273.15 + 1.2)}{3.25 \times 7.006}$$

A.22 To how many significant figures should the result of the following calculation be reported?

$$\frac{(604.01 + 0.53) \times 321.81 \times 0.001\,80}{3.530 \times 10^{-3}}$$

A.23 Use the conversion factors in Appendix 1B and inside the back cover to express the following measurements in the designated units: (a) 4.82 nm to pm; (b) $1.83\ \text{mL·min}^{-1}$ to $\text{mm}^3\text{·s}^{-1}$; (c) 1.88 ng to kg; (d) $2.66\ \text{g·cm}^{-3}$ to kg·m^{-3}; (e) $0.044\ \text{g·L}^{-1}$ to mg·cm^{-3}.

A.24 Use the conversion factors in Appendix 1B and inside the back cover to express the following measurements in the designated units: (a) 36 L to m^3; (b) $45\ \text{g·L}^{-1}$ to mg·mL^{-1}; (c) $1.54\ \text{mm·s}^{-1}$ to $\text{nm·}\mu\text{s}^{-1}$; (d) $7.01\ \text{cm·s}^{-1}$ to km·h^{-1}; (e) \$3.50/gallon to peso/liter (assume 1 dollar ≈ 13.1 peso).

A.25 The density of a metal was measured by two different methods. In each case, calculate the density. Indicate which measurement is more precise. (a) The dimensions of a rectangular block of the metal were measured as 1.10 cm × 0.531 cm × 0.212 cm. Its mass was found to be 0.213 g. (b) The mass of a cylinder of water filled to the 19.65-mL mark was found to be 39.753 g. When a piece of the metal was immersed in the water, the level of the water rose to 20.37 mL and the mass of the cylinder with the metal was found to be 41.003 g.

A.26 A chemist at Trustworthy Labs determined in a set of four experiments that the density of magnesium metal was $1.68\ \text{g·cm}^{-3}$, $1.67\ \text{g·cm}^{-3}$, $1.69\ \text{g·cm}^{-3}$, $1.69\ \text{g·cm}^{-3}$. A chemist at Righton Labs repeated the measurements but found the following values: $1.72\ \text{g·cm}^{-3}$, $1.63\ \text{g·cm}^{-3}$, $1.74\ \text{g·cm}^{-3}$, $1.86\ \text{g·cm}^{-3}$. The accepted value for its density is $1.74\ \text{g·cm}^{-3}$. Compare the precision and accuracy of the two chemists' data.

A.27 The reference points on a newly proposed temperature scale expressed in °X are the freezing and boiling points of water, set equal to 50.°X and 250.°X, respectively. (a) Derive a formula for converting temperatures on the Celsius scale to the new scale. (b) Comfortable room temperature is 22°C. What is that temperature in °X?

A.28 When Anders Celsius first proposed his scale, he took 100 as the freezing point of water and 0 as the boiling point. (a) To what temperature would 25°C correspond on that proposed scale? (b) To what temperature would 98.6°F correspond on the proposed scale?

A.29 The maximum ground speed of a chicken is $14\ \text{km·h}^{-1}$. Calculate the kinetic energy of a chicken of mass 4.2 kg crossing a road at its maximum speed.

A.30 Mars orbits the Sun at $25\ \text{km·s}^{-1}$. A spaceship attempting to land on Mars must match its orbital speed. If the mass of the spaceship is 3.6×10^5 kg, what is its kinetic energy when its speed has matched that of Mars?

A.31 A vehicle of mass 2.8 t slows from $100.\ \text{km·h}^{-1}$ to $50.\ \text{km·h}^{-1}$ as it enters a city. How much energy could have been recovered instead of being dissipated as heat? To what height, neglecting friction and other losses, could that energy have been used to drive the vehicle up a hill?

A.32 What is the minimum energy that a football player must expend to kick a football of mass 0.51 kg over a goalpost of height 3.0 m?

A.33 It has been said in jest that the only exercise some people get is raising a fork to their lips. How much energy do we expend to raise a loaded fork of mass 40.0 g a height of 0.50 m 30 times in the course of a meal?

A.34 Calculate the energy released when an electron is brought from infinity to a distance of 53 pm from a proton. (That distance is the most probable distance of an electron from the nucleus in a hydrogen atom.) The actual energy released when an electron and a proton form a hydrogen atom is 13.6 electronvolts (eV; 1 eV = 1.602×10^{-19} J). Account for the difference.

A.35 The expression $E_p = mgh$ applies only close to the surface of the Earth. The general expression for the potential energy of a mass m at a distance R from the center of the Earth (of mass m_E) is $E_p = -Gm_Em/R$. Write $R = R_E + h$, where R_E is the radius of the Earth; and show that, when $h \ll R_E$, this general expression reduces to the special case, and find an expression for g. You will need the expansion $(1 + x)^{-1} = 1 - x + \cdots\cdot$

A.36 The expression for the Coulomb potential energy is very similar to the expression for the general gravitational potential energy given in Exercise A.35. Is there an expression resembling $E_p = mgh$ for the change in potential energy when an electron a long way from a proton is moved through a small distance h? Find the expression of the form $E_p = egh$, with an appropriate expression for g, using the same procedure as in Exercise A.35.

B ELEMENTS AND ATOMS

B.1 Atoms
B.2 The Nuclear Model
B.3 Isotopes
B.4 The Organization of the Elements

Science is a quest for simplicity. Although the complexity of the world appears boundless, this complexity springs from an underlying simplicity that science attempts to discover. Chemistry's contribution to this quest is to show how everything around us—mountains, trees, people, computers, brains, concrete, oceans—is in fact made up of a handful of simple entities.

The ancient Greeks had much the same idea. They supposed that there were four elements—earth, air, fire, and water—that could produce all other substances when combined in the right proportions. Their concept of an element is similar to our own; but, on the basis of experiments, we now know that there are actually more than 100 elements, which—in various combinations—make up all the matter on Earth (Fig. B.1).

Appendix 2D lists the names and chemical symbols of the elements and gives the origins of their names.

FIGURE B.1 Samples of common elements. Clockwise from the red-brown liquid bromine are the silvery liquid mercury and the solids iodine, cadmium, red phosphorus, and copper.

The name *atom* comes from the Greek word for "not cuttable."

B.1 Atoms

The Greeks asked what would happen if they continued to cut matter into ever smaller pieces. Is there a point at which they would have to stop because the pieces no longer had the same properties as the whole or could they go on cutting forever? We now know that there is a point at which we have to stop. That is, matter consists of almost unimaginably tiny particles. The smallest particle of an element that can exist is called an **atom**. The story of the development of the modern model of the atom is an excellent illustration of how scientific models are developed and is continued in Chapter 1.

The first convincing argument for atoms was made in 1807 by the English schoolteacher and chemist John Dalton (Fig. B.2). He made many measurements of the ratios of the masses of elements that combine together to form the substances we call "compounds" (see Section C) and found that the ratios formed patterns. For example, he found that, in every sample of water, there was 8 g of oxygen for every 1 g of hydrogen and that, in another compound of the two elements (hydrogen peroxide),

FIGURE B.2 John Dalton (1766–1844), the English schoolteacher who used experimental measurements to argue that matter consists of atoms.

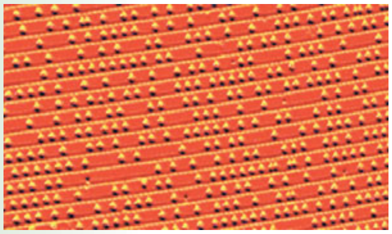


FIGURE B.3 Individual atoms can be seen as bumps on the surface of a solid by the technique called scanning tunneling microscopy (STM). This image shows how information can be stored in individual atoms. The yellow spheres are silicon atoms arranged on a surface of gold and silicon atoms in an arrangement that can be read by an STM microscope. These tiny arrays can lead to very high density storage media.

there was 16 g of oxygen for every 1 g of hydrogen. These and related data led Dalton to develop his **atomic hypothesis:**

1 All the atoms of a given element are identical.

2 The atoms of different elements have different masses.

3 A compound is a specific combination of atoms of more than one element.

4 In a chemical reaction, atoms are neither created nor destroyed; they exchange partners to produce new substances.

As we shall see in Section B.3, Dalton's first assumption has to be modified because it is now known that the atoms of an element are not all exactly the same, for they can differ slightly in mass.

Modern instrumentation provides much more direct evidence of atoms than was available to Dalton (Fig. B.3). There is no longer any doubt that atoms exist and that they are the units that make up the elements. In fact, chemists use the existence of atoms as the definition of an element: an **element** is a substance composed of only one kind of atom. By 2008, 112 elements had been discovered or created, but in some cases in only very small amounts. For instance, when element 110 was made, only two atoms were produced and they lasted less than a millisecond before disintegrating.

All matter is made up of various combinations of the simple forms of matter called the chemical elements. An element is a substance that consists of only one kind of atom.

B.2 The Nuclear Model

We develop the modern model of an atom in Chapter 1. At this stage, all we need to know is that, according to the current **nuclear model** of the atom, an atom consists of a small positively charged **nucleus,** which is responsible for almost all its mass, surrounded by negatively charged **electrons** (denoted e^-). Compared with the size of the nucleus (about 10^{-14} m in diameter), the space occupied by the electrons is enormous (about 10^{-9} m in diameter; a hundred thousand times as great). If the nucleus of an atom were the size of a fly at the center of a baseball field, then the space occupied by the surrounding electrons would be about the size of the entire stadium (Fig. B.4).

The positive charge of the nucleus exactly cancels the negative charge of the surrounding electrons. As a result, an atom is electrically neutral (uncharged). Because each electron has a single negative charge, for each electron in an atom there is a particle inside the nucleus having a single positive charge. These positively charged particles are called **protons** (denoted p); their properties are given in Table B.1. A proton is nearly 2000 times as heavy as an electron.

The number of protons in an element's atomic nucleus is called the **atomic number,** Z, of that element. For example, hydrogen has $Z = 1$; and so we know that the nucleus of a hydrogen atom has one proton; helium has $Z = 2$, and so its nucleus contains two protons. Henry Moseley, a young British scientist, was the first to determine atomic numbers unambiguously, shortly before he was killed in action in World War I. Moseley knew that when elements are bombarded with rapidly moving electrons they emit x-rays. He found that the properties of the x-rays emitted by an element depend on its atomic number; and, by studying the x-rays of many elements, he was able to determine the values of Z for them. Scientists have since determined the atomic numbers of all the known elements (see the list of elements inside the back cover).

Technological advances in electronics early in the twentieth century led to the invention of the **mass spectrometer,** a device for determining the mass of an atom (Fig. B.5). Mass spectrometers are described more fully in Major Technique 6 after Chapter 18. Mass spectrometry has been used to determine the masses of the atoms of all the elements. We now know, for example, that the mass of a hydrogen atom is 1.67×10^{-27} kg and that of a carbon atom is 1.99×10^{-26} kg. Even the heaviest atoms have masses of only about 5×10^{-25} kg. Once we know the mass of an individual atom, we can determine the number of those atoms in a given mass of element simply by dividing the mass of the sample by the mass of one atom.

FIGURE B.4 Think of a fly at the center of this stadium: that is the relative size of the nucleus of an atom if the atom were magnified to the size of the stadium.

EXAMPLE B.1 **Calculating the number of atoms in a sample**

How many atoms are there in a sample of carbon of mass 10.0 g?

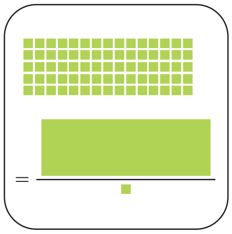
Anticipate Because atoms are very tiny, we should expect a very large number.

PLAN We need to divide the mass of the sample by the mass of one atom.

SOLVE The mass of one carbon atom is 1.99×10^{-26} kg (given in the text).

From N = (mass of sample)/(mass of one atom),

$$N = \frac{\overbrace{1.00 \times 10^{-1}\,\text{kg}}^{10.0\text{ g}}}{1.99 \times 10^{-26}\,\text{kg}} = 5.03 \times 10^{23}$$



Evaluate As anticipated, the number of atoms, 5.03×10^{23}, is very large.

A note on good practice: Notice how we have converted the units that were given (grams, for the mass of this sample) into units that cancel (here, kilograms). It is often prudent to convert all units to SI base units.

Self-Test B.1A The mass of an iron atom is 9.29×10^{-26} kg. How many iron atoms are present in an iron magnet of mass 25.0 g?

[***Answer:*** 2.69×10^{23}]

Self-Test B.1B A miner panning for gold in an Alaskan creek collects 12.3 g of the fine pieces of gold known as "gold dust." The mass of one gold atom is 3.27×10^{-25} kg. How many gold atoms has the miner collected?

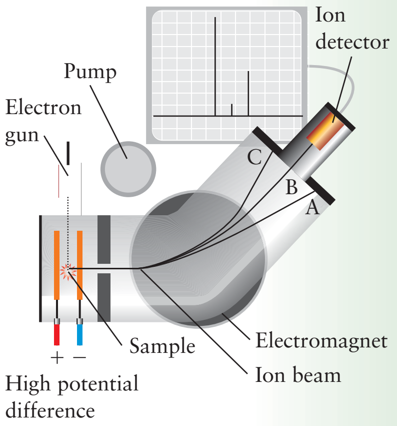


FIGURE B.5 A mass spectrometer is used to measure the masses of atoms. Electrons emerge from the electron gun and are accelerated through a magnetic field by a potential difference. A pump is used to remove air. As the strength of the magnetic field is changed, the path of the accelerated ions moves from A to C. When the path is at B, the ion detector sends a signal to the recorder. The mass of the ion is proportional to the strength of the magnetic field needed to move the beam into position to strike the detector.

In the nuclear model of the atom, the positive charge and almost all of the mass is concentrated in the tiny nucleus, and the surrounding negatively charged electrons take up most of the space. The atomic number is the number of protons in the nucleus.

B.3 Isotopes

As happens so often in science, a new and more precise technique of measurement led to a major discovery. When scientists first used mass spectrometers they found—much to their surprise—that not all the atoms of a single element have the same mass. In a sample of perfectly pure neon, for example, most of the atoms have mass 3.32×10^{-26} kg, which is about 20 times as great as the mass of a hydrogen atom. Some neon atoms, however, are found to be about 22 times as heavy as hydrogen. Others are about 21 times as heavy (Fig. B.6). All three types of atoms have the same atomic number; so they are definitely atoms of neon.

The observation that atoms of a single element can have different masses helped scientists refine the nuclear model still further. They realized that an atomic nucleus must contain subatomic particles other than protons and proposed that it also contains electrically neutral particles called **neutrons** (denoted n). Because neutrons have no electric charge, their presence does not affect the nuclear charge or the number of electrons in the atom. However, they have approximately the same mass as protons, and so add substantially to the mass of the nucleus. Therefore, different numbers of neutrons in a nucleus give rise to atoms of different masses, even though the atoms belong to the same element. As we can see from Table B.1, neutrons and protons are very similar apart from their charge; they are jointly known as **nucleons**.

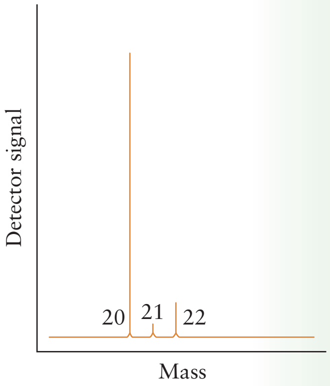

FIGURE B.6 The mass spectrum of neon. The locations of the peaks on the *x*-axis tell us the relative masses of the atoms, and the intensities tell us the relative numbers of atoms having each mass.

TABLE B.1 Properties of Subatomic Particles

Particle	Symbol	Charge*	Mass, kg
electron	e^-	−1	9.109×10^{-31}
proton	p	+1	1.673×10^{-27}
neutron	n	0	1.675×10^{-27}

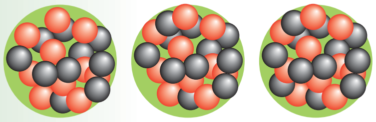
*Charges are given as multiples of the fundamental charge, which in SI units is 1.602×10^{-19} C (see Appendix 1B).

Another, better, name for the mass number is *nucleon number*.

The total number of protons and neutrons in a nucleus is called the **mass number,** A, of the atom. A nucleus of mass number A is about A times as heavy as a hydrogen atom, which has a nucleus that consists of a single proton. Therefore, if we know that an atom is a certain number of times as heavy as a hydrogen atom, then we can infer the mass number of the atom. For example, because mass spectrometry shows that the three varieties of neon atoms are 20, 21, and 22 times as heavy as a hydrogen atom, we know that the mass numbers of the three types of neon atoms are 20, 21, and 22. Because for each of them $Z = 10$, these neon atoms must contain 10, 11, and 12 neutrons, respectively (Fig. B.7).

The name *isotope* comes from the Greek words for "equal place."

Atoms with the same atomic number (belonging to the same element) but with different mass numbers are called **isotopes** of the element. All isotopes of an element have exactly the same atomic number; hence they have the same number of protons and electrons. An isotope is named by writing its mass number after the name of the element, as in neon-20, neon-21, and neon-22. Its symbol is obtained by writing the mass number as a superscript to the left of the chemical symbol of the element, as in ^{20}Ne, ^{21}Ne, and ^{22}Ne. You will occasionally see the atomic number included as a subscript on the lower left, as in the symbol $^{22}_{10}Ne$ used in Fig. B.7.



Neon-20 ($^{20}_{10}Ne$) Neon-21 ($^{21}_{10}Ne$) Neon-22 ($^{22}_{10}Ne$)

FIGURE B.7 The nuclei of different isotopes of the same element have the same number of protons but different numbers of neutrons. These three diagrams show the composition of the nuclei of the three isotopes of neon. On this scale, the atom itself would be about 1 km in diameter. These diagrams make no attempt to show how the protons and neutrons are arranged inside the nucleus.

Because isotopes of the same element have the same number of protons and the same number of electrons, they have essentially the same chemical and physical properties. However, the mass differences between isotopes of hydrogen are comparable to the masses of the atoms themselves, leading to noticeable differences in some physical properties and slight variations in some of their chemical properties. Hydrogen has three isotopes (Table B.2). The most common (^1H) has no neutrons; its nucleus is a lone proton. The other two isotopes are less common but nevertheless so important in chemistry and nuclear physics that they are given special names and symbols. The isotope with one neutron (^2H) is called *deuterium* (D) and the one with two neutrons (^3H) is called *tritium* (T).

Self-Test B.2A How many protons, neutrons, and electrons are present in (a) an atom of nitrogen-15; (b) an atom of iron-56?

[***Answer:*** (a) 7, 8, 7; (b) 26, 30, 26]

Self-Test B.2B How many protons, neutrons, and electrons are present in (a) an atom of oxygen-16; (b) an atom of uranium-236?

Isotopes of an element have the same atomic number but different mass numbers. Their nuclei have the same number of protons but different numbers of neutrons.

B.4 The Organization of the Elements

There are 112 known elements, of which only 88 occur in significant quantities on Earth and are considered to be naturally occurring. At first sight the prospect of learning their

TABLE B.2 Some Isotopes of Common Elements

Element	Symbol	Atomic number, Z	Mass number, A	Abundance, %
hydrogen	^1H	1	1	99.985
deuterium	^2H or D	1	2	0.015
tritium	^3H or T	1	3	—*
carbon-12	^{12}C	6	12	98.90
carbon-13	^{13}C	6	13	1.10
oxygen-16	^{16}O	8	16	99.76

*Radioactive, short-lived.

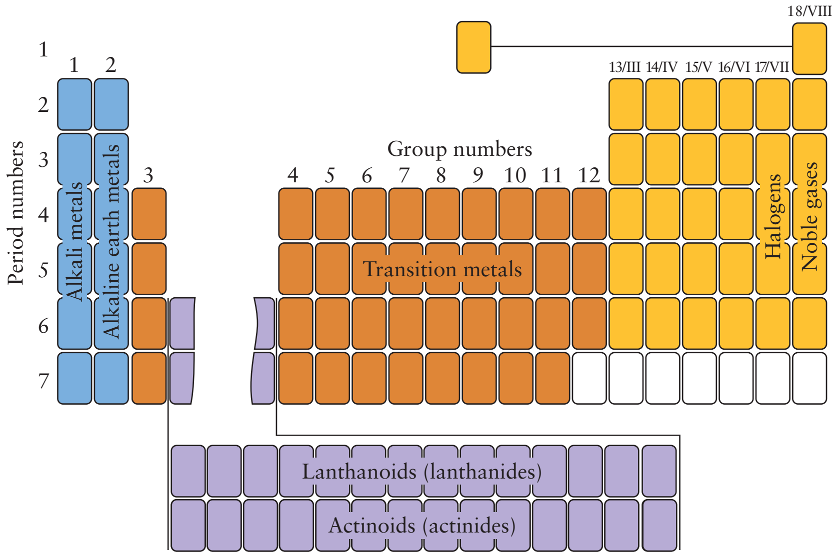


FIGURE B.8 The structure of the periodic table, showing the names of some regions and groups. The groups are the vertical columns, numbered 1 through 18. The periods are the horizontal rows, numbered 1 through 7 (Period 1 is the top row—hydrogen and helium—and is not numbered in the figure). The main-group elements are those in Groups 1, 2, and 13 through 18, together with hydrogen. Groups 1 and 2 make up the s block, 3–12 the d block, and 13–18 the p block.

properties might seem overwhelming. The task is made much easier—and more interesting—by one of the most important discoveries in the history of chemistry. Chemists have found that when the elements are listed in order of their atomic number and arranged in rows of certain lengths, they form families that show regular trends in properties. The arrangement of elements that shows their family relationships is called the **periodic table** (it is printed inside the front cover of this book and repeated schematically in Fig. B.8).

The story of the discovery of periodic relationships by Dmitri Mendeleev can be found in Box 1.2 in Chapter 1.

The vertical columns of the periodic table are called **groups.** These groups identify the principal families of elements. The taller columns (Groups 1, 2, and 13/III through 18/VIII) are called the **main groups** of the table. The horizontal rows are called **periods** and are numbered from the top down. The four rectangular regions of the periodic table are called **blocks** and, for reasons related to atomic structure (Section 1.13), are labeled s, p, d, and f. The members of the d block, with the exception of the elements in Group 12 (the zinc group) are called **transition metals.** As we shall see, these elements are transitional in character between the vigorously reactive metals in the s block and the less reactive metals on the left of the p block. The members of the f block, which is shown below the main table (to save space), are the **inner transition metals.** The upper row of this block, following lanthanum (element 57) in Period 6, consists of the **lanthanoids** (more commonly and traditionally, the "lanthanides"), and the lower row, following actinium (element 89) in Period 7, consists of the **actinoids** (more commonly, the "actinides").

In some versions of the periodic table, you will see a different notation for groups, with the noble gases belonging to Group VIII, VIIIA, or VIIIB. These alternatives are given in the table printed inside the front cover.

In some versions of the periodic table, the lanthanoids begin with lanthanum (element 57) and the actinoids begin with actinium (element 89).

Some of the main groups have special names that reflect the common properties of the elements in that group. The elements in Group 1 are called the **alkali metals.** All of them are soft, lustrous metals that melt at low temperatures. They all produce hydrogen when they come in contact with water (Fig. B.9)—lithium gently, but with increasing violence down the group. The elements calcium (Ca), strontium (Sr), and barium (Ba) in Group 2 are called the **alkaline earth metals,** but the name is often extended to all the members of the group. The Group 2 metals have many properties in common with the Group 1 metals, but their reactions are less vigorous.

On the far right of the table, in Group 18/VIII, are the elements known as the **noble gases.** They are so called because they combine with very few elements—they are chemically aloof. In fact, until the 1960s, they were called the "inert gases" because they were thought not to combine with any elements at all. All the Group 18/VIII elements are colorless, odorless gases. Next to the noble gases are the **halogens** of Group 17/VII. Many of the properties of the halogens vary in a regular fashion from fluorine (F) through chlorine (Cl) and bromine (Br) to iodine (I). Fluorine, for instance, is a very pale yellow, almost colorless gas, chlorine a yellow-green gas, bromine a red-brown liquid, and iodine a purple-black solid (Fig. B.10). All the halogens occur as diatomic molecules in elemental form: F_2, Cl_2, Br_2, and I_2.

FIGURE B.9 The alkali metals react with water, producing gaseous hydrogen and heat. Potassium, as shown here, reacts vigorously, producing so much heat that the hydrogen produced is ignited.

Lab Video B.9

FIGURE B.10 The halogens are colored elements. From left to right, chlorine is a yellow-green gas, bromine is a red-brown liquid (its vapor fills the flask), and iodine is a dark purple-black solid (note the small crystals).

At the head of the periodic table, standing alone, is hydrogen. Some tables place hydrogen in Group 1, others place it in Group 17/VII, and yet others place it in both groups. We treat it as a very special element and place it in none of the groups.

Most of the elements are solid metals. Only two elements (mercury and bromine) are liquids at ordinary temperatures, and only 11 are gaseous. The elements are classified as metals, nonmetals, and metalloids:

A **metal** conducts electricity, has a luster, and is malleable and ductile.
A **nonmetal** does not conduct electricity and is neither malleable nor ductile.
A **metalloid** has the appearance of a metal but can behave chemically like a metal or a nonmetal, depending on conditions.

A "malleable" substance (from the Latin word for "hammer") is one that can be hammered into thin sheets (Fig. B.11). A "ductile" substance (from the Latin word for "drawing out") is one that can be drawn out into wires. Copper, for example, is a metal. It conducts electricity, has a luster when polished, and is malleable. It is so ductile that it is readily drawn out to form electrical wires. Sulfur, on the other hand, is a nonmetal. This brittle yellow solid does not conduct electricity, cannot be hammered into thin sheets, and cannot be drawn out into wires. The distinctions between metals and metalloids and between metalloids and nonmetals are not very precise (and not always made), but the metalloids are often taken to be the seven elements shown in Fig. B.12 on a diagonal band between the metals on the left and the nonmetals on the right.

The periodic table is a very useful summary of the properties of the elements. Even if we have never heard of osmium (Os), we can glance at the periodic table and see that it is a metal because it lies to the left of the metalloids (all the d-block elements are metals). Similarly, even though chemists might not have investigated the reactions of radon (Rn)—it is a dangerously radioactive gas—we can expect it to resemble the other noble gases, particularly its immediate neighbor in Group 18/VIII, xenon (Xe), and to form very few compounds. As you work through this text and encounter a new element, it is

FIGURE B.11 All metals can be deformed by hammering. Gold can be hammered into a sheet so thin that light can pass through it. Here, it is possible to see the light of a flame through the sheet of gold.

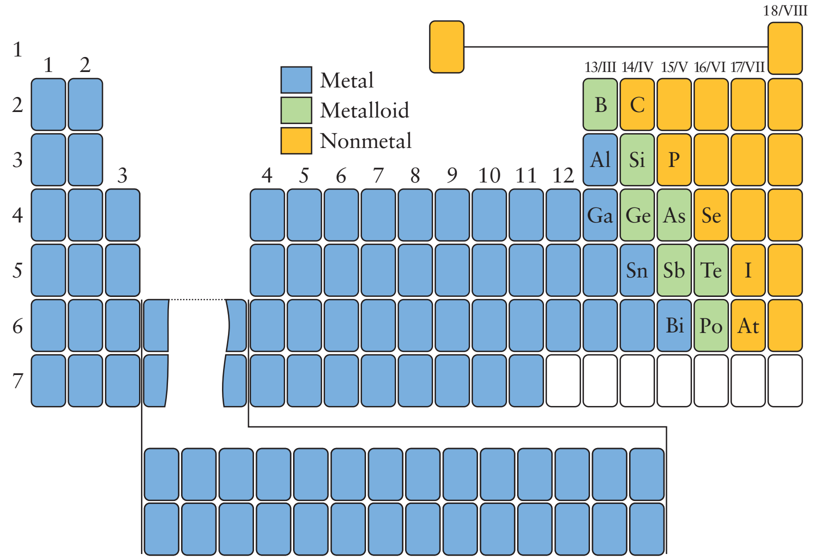

FIGURE B.12 The location of the seven elements commonly regarded as metalloids: these elements have characteristics of both metals and nonmetals. Other elements, notably beryllium and bismuth, are sometimes included in the classification. Boron (B), although not resembling a metal in appearance, is included because it resembles silicon (Si) chemically.

a good idea to refer to the periodic table, identify the neighbors of the element, and try to predict its properties.

The periodic table is an arrangement of the elements by atomic number that reflects their family relationships; members of the same group typically show a smooth trend in properties.

SKILLS YOU SHOULD HAVE MASTERED

- ❑ 1 Describe the structure of an atom.
- ❑ 2 Find the number of atoms in a given mass of an element (Example B.1).
- ❑ 3 Find the numbers of neutrons, protons, and electrons in an isotope (Self-Test B.2).
- ❑ 4 Describe the organization of the periodic table and the characteristics of elements in different regions of the table.

EXERCISES

B.1 The mass of an atom of beryllium is 1.50×10^{-26} kg. How many beryllium atoms are present in a beryllium film of mass 0.210 g used as a window on an x-ray tube?

B.2 The mass of an atom of fluorine is 3.16×10^{-26} kg. How many fluorine atoms are present in a 3.50-L tank of fluorine gas? The density of the fluorine gas in the tank is $0.777\ g \cdot L^{-1}$.

B.3 Give the number of protons, neutrons, and electrons in an atom of (a) boron-11; (b) ^{10}B; (c) phosphorus-31; (d) ^{238}U.

B.4 Give the number of protons, neutrons, and electrons in an atom of (a) tritium, ^{3}H; (b) ^{69}Ga; (c) selenium-79; (d) ^{247}Cm.

B.5 Identify the isotope that has atoms with (a) 117 neutrons, 77 protons, and 77 electrons; (b) 12 neutrons, 10 protons, and 10 electrons; (c) 28 neutrons, 23 protons, and 23 electrons.

B.6 Identify the isotope that has atoms with (a) 106 neutrons, 76 protons, and 76 electrons; (b) 30 neutrons, 28 protons, and 28 electrons; (c) 21 neutrons, 20 protons, and 20 electrons.

B.7 Complete the following table:

Element	Symbol	Protons	Neutrons	Electrons	Mass number
	^{36}Cl				
		30			65
			20	20	
lanthanum			80		

B.8 Complete the following table:

Element	Symbol	Protons	Neutrons	Electrons	Mass number
osmium					190
	^{120}Sn				
		74			184
			30	25	

B.9 (a) What characteristics do atoms of argon-40, potassium-40, and calcium-40 have in common? (b) In what ways are they different? (Consider the numbers and types of subatomic particles.)

B.10 (a) What characteristics do atoms of manganese-55, iron-56, and nickel-58 have in common? (b) In what ways are they different? (Consider the numbers and types of subatomic particles.)

B.11 Determine the fraction of the total mass of a ^{58}Fe atom that is due to (a) neutrons; (b) protons; (c) electrons. (d) What is the mass of neutrons in an automobile of mass 1.000 t? Assume that the total mass of the vehicle is due to ^{56}Fe.

B.12 (a) Determine the total number of protons, neutrons, and electrons in one carbon tetrafluoride molecule, CF_4, assuming that all atoms are the most common isotopes of that element. (b) What is the total mass of protons, of neutrons, and of electrons in one carbon tetrafluoride molecule? Calculate three masses.

B.13 Name each of the following elements: (a) Sc; (b) Sr; (c) S; (d) Sb. List their group numbers in the periodic table. Identify each as a metal, a nonmetal, or a metalloid.

B.14 Name each of the following elements: (a) P; (b) Pr; (c) Po; (d) Pd. List their group numbers in the periodic table, and identify each as a metal, a nonmetal, or a metalloid.

B.15 Write the symbol of (a) strontium; (b) xenon; (c) silicon. Classify each as a metal, a nonmetal, or a metalloid.

B.16 Write the symbol of (a) thallium; (b) europium; (c) cadmium. Classify each as a metal, a nonmetal, or a metalloid.

B.17 List the names, symbols, and atomic numbers of the halogens. Identify the normal physical state of each.

B.18 List the names, symbols, and atomic numbers of the alkali metals. Characterize their reactions with water and describe their trend in melting points.

B.19 Identify the periodic table block to which each of the following elements belongs: (a) zirconium; (b) As; (c) Ta; (d) barium; (e) Si; (f) cobalt.

B.20 State three physical properties that are typical of (a) metals; (b) nonmetals.

B.21 Identify the element having atoms with 118 neutrons and mass number 200 and state its group number in the periodic table. Is this element a metal, a nonmetal, or a metalloid?

B.22 Identify the element having atoms with 74 neutrons and mass number 127 and state its group number in the periodic table. Is this element a metal, a nonmetal, or a metalloid?

C.1 What Are Compounds?
C.2 Molecules and Molecular Compounds
C.3 Ions and Ionic Compounds

C COMPOUNDS

The small number of elements that make up our world combine to produce matter in a seemingly limitless variety of forms. We have only to look at the vegetation, flesh, landscapes, fabrics, building materials, and other things around us to appreciate the wonderful variety of the material world. A part of chemistry is **analysis**: the discovery of which elements have combined together to form a substance. Another aspect of chemistry is **synthesis**: the process of combining elements to produce compounds or converting one compound into another. If the elements are the alphabet of chemistry, then the compounds are its plays, its poems, and its novels.

C.1 What Are Compounds?

A **compound** is an electrically neutral substance that consists of two or more different elements with their atoms present in a definite ratio. A **binary compound** consists of only two elements. For example, water is a binary compound of hydrogen and oxygen, with two hydrogen atoms for each oxygen atom. Whatever the source of the water, it has exactly the same composition; indeed, a substance with a different ratio of atoms would not be water. Hydrogen peroxide (H_2O_2), for instance, has one hydrogen atom for every oxygen atom.

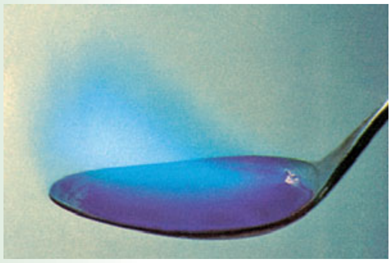

FIGURE C.1 Elemental sulfur burns in air with a blue flame and produces the dense gas sulfur dioxide, a compound of sulfur and oxygen.

Compounds are classified as either organic or inorganic. **Organic compounds** contain the element carbon and usually hydrogen, too. There are millions of organic compounds, including fuels such as methane and propane, sugars such as glucose and sucrose, and most medicines. These compounds are called organic because it was once believed, incorrectly, that they could be formed only by living organisms. **Inorganic compounds** are all the other compounds; they include water, calcium sulfate, ammonia, silica, hydrochloric acid, and many, many more. In addition, some very simple carbon compounds, particularly carbon dioxide and the carbonates, which include chalk (calcium carbonate), are treated as inorganic compounds. **Intermetallic compounds** are inorganic compounds that are formed when the atoms of two metals bond in specific proportions. Examples are nitinol, NiTi, which is used in orthodontic wires, flexible eyeglass frames, and stents that increase blood flow in arteries; Ag_3Sn, which is found in "silver" dental fillings; and FeCo, which is used in magnets.

Bonding is discussed in more detail in Chapters 2 and 3.

The elements in a compound are not just mixed together. Their atoms are actually joined, or *bonded*, to one another in a specific way due to a chemical change (see Section A). The result is a substance with chemical and physical properties different from those of the elements that form it. For example, when sulfur is ignited in air, it combines with oxygen from the air to form the compound sulfur dioxide. Solid yellow sulfur and odorless oxygen gas produce a colorless, pungent, and poisonous gas (Fig. C.1).

Chemists have found that atoms can bond together to form molecules or can be present in compounds as ions:

The name *ion* comes from the Greek word for "go," because charged particles go either toward or away from a charged electrode.

A **molecule** is a discrete group of atoms bonded together in a specific arrangement.
An **ion** is a positively or negatively charged atom or molecule.

The prefixes *cat-* and *an-* come from the Greek words for "down" and "up." Oppositely charged ions travel in opposite directions in an electric field.

A positively charged ion is called a **cation,** and a negatively charged ion is called an **anion.** For instance, a positively charged sodium atom is a cation and is denoted Na^+; a negatively charged chlorine atom is an anion and is denoted Cl^-. An example of a "polyatomic" (many-atom) cation is the ammonium ion, NH_4^+, and an example of a polyatomic anion is the carbonate ion, CO_3^{2-}; note that the latter has two negative charges. An **ionic compound** consists of ions in a ratio that results in overall electrical neutrality; a **molecular compound** consists of electrically neutral molecules.

In general, binary compounds of two nonmetals are molecular, whereas binary compounds formed by a metal and a nonmetal are ionic. Water (H_2O) is an example of a binary molecular compound, and sodium chloride (NaCl) is an example of a binary ionic compound. As we shall see, these two types of compounds have characteristic

properties, and knowing the type of compound that we are studying can be a source of insight into its properties.

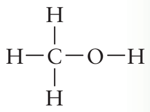
Compounds are combinations of elements in which the atoms of the different elements are present in a characteristic, constant ratio. A compound is classified as molecular if it consists of molecules and as ionic if it consists of ions.

C.2 Molecules and Molecular Compounds

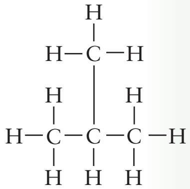
The **chemical formula** of a compound represents its composition in terms of chemical symbols. Subscripts show the numbers of atoms of each element present in the smallest unit that is representative of the compound. For molecular compounds, it is common to give the **molecular formula**, a chemical formula that shows how many atoms of each type of element are present in a single molecule of the compound. For instance, the molecular formula for water is H_2O: each molecule contains one O atom and two H atoms. The molecular formula for estrone, a female sex hormone, is $C_{18}H_{22}O_2$, showing that a single molecule of estrone consists of 18 C atoms, 22 H atoms, and 2 O atoms. A molecule of a male sex hormone, testosterone, differs by only a few atoms: its molecular formula is $C_{19}H_{28}O_2$. Think of the consequences of that tiny difference!

Some elements also exist in molecular form. Except for the noble gases, all the elements that are gases at ordinary temperatures are found as **diatomic molecules,** molecules that consist of two atoms. For example, molecules of hydrogen gas contain two hydrogen atoms bonded together and are represented as H_2. The most common form of oxygen consists of diatomic molecules and is known formally as dioxygen, O_2. Solid sulfur exists as S_8 molecules and phosphorus as P_4 molecules. Nitrogen and all the halogens exist as diatomic molecules: N_2, F_2, Cl_2, Br_2, and I_2.

A **structural formula** indicates how the atoms are linked together, but not their actual three-dimensional arrangement in space. For instance, the molecular formula of methanol (wood spirit or wood alcohol) is CH_4O, and its structural formula is shown in (**1**): each line represents a chemical bond (the link between two atoms) and each symbol an atom. Structural formulas contain more information than the chemical formula, but they are cumbersome. So chemists condense them and write, for instance, CH_3OH to represent the structure of methanol. This "condensed" structural formula indicates the groupings of the atoms and summarizes the full structural formula. In most cases, symbols with subscripts represent atoms connected to the preceding element in the formula. A group of atoms attached to another atom in the molecule is set off with parentheses. For example, methylpropane (**2**) has a *methyl* group (—CH_3) attached to the central atom in a chain of three carbon atoms, and the condensed version of its structural formula is written $CH_3CH(CH_3)CH_3$ or $HC(CH_3)_3$.



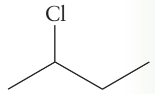
1 Methanol, CH_3OH



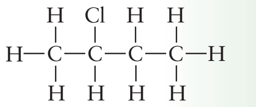
2 Methylpropane, $CH_3CH(CH_3)CH_3$

The richness of organic chemistry arises in part from the fact that, although carbon atoms nearly always form four bonds, they can form chains and rings of almost limitless variety. Another source of its richness is that the carbon atoms can be linked together by different kinds of chemical bonds. In Chapter 2, we shall see that atoms can be joined by single bonds, indicated by a single line (C—C); double bonds, represented by a double line (C=C); and triple bonds, represented by a triple line (C≡C). A carbon atom can form four single bonds, two double bonds, or any combination that results in four bonds, such as one single and one triple bond.

(**a**)

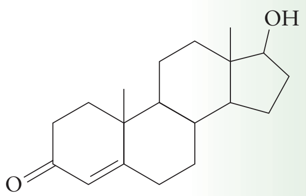


(**b**)



3 2-Chlorobutane, $CH_3CHClCH_2CH_3$

Organic chemists have found a way to draw complex molecular structures in a very simple way, by not showing the C and H atoms explicitly. A **line structure** represents a chain of carbon atoms by a zigzag line, where each short line indicates a bond and the end of each line represents a carbon atom. Atoms other than C and H are shown by their symbols. Double bonds are represented by a double line and triple bonds by a triple line. Because carbon almost always forms four bonds in organic compounds, there is no need to show the C—H bonds explicitly. We just fill in the correct number of hydrogen atoms mentally: compare the line structure of 2-chlorobutane, $CH_3CHClCH_2CH_3$ (**3a**), with its structural form (**3b**). Line structures are particularly useful for complex molecules, such as testosterone (**4**). They are used occasionally in the early chapters of this text and are explained in more detail in Chapter 18. At this



4 Testosterone, $C_{19}H_{28}O_2$

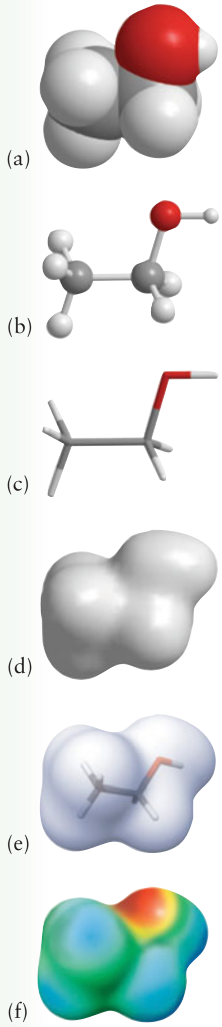


FIGURE C.2 Representations of an ethanol molecule: (a) space-filling, (b) ball-and-stick, (c) tube, (d) density isosurface, (e) transparent density isosurface, (f) electrostatic potential (elpot) surface.

stage, you need only know that a line structure is a display of the "connectivity" of a molecule, a portrayal of which atom is linked to which and by how many bonds.

Another important aspect of a molecular compound is its shape. The pictorial representations of molecules that most accurately show their shapes are images based on computation or software that represents atoms by spheres of various sizes. An example is the **space-filling model** of an ethanol molecule shown in Fig. C.2a. The atoms are represented by colored spheres (they are not the actual colors of the atoms) that fit into one another. The radii of the atoms are determined by calculation; because atoms do not have hard surfaces, the surface shown uses a chosen cut-off limit of electron density, usually 90 or 95%. Another representation of the same molecule, called a **ball-and-stick model,** is shown in Fig. C.2b. Each ball represents the location of an atom, and the sticks represent the bonds. Although this kind of model does not represent the actual molecular shape as well as a space-filling model does, it shows bond lengths and angles more clearly. It is also easier to draw and interpret.

Chemists use several other kinds of images to depict molecular structure. The **tube structure** is like a ball-and-stick structure without the balls (Fig. C.2c): different atoms are depicted by different colors at the ends of the tube that represents the link between them. Tube structures and line structures (recall **4**) are useful for showing the structures of complicated molecules. More sophisticated than any of these representations are images that show the distribution of electrons in the molecule. The cloud in Fig. C.2d, for instance, indicates how the electrons are spread throughout an ethanol molecule: it is an example of a **density isosurface** and gives a very real sense of the shape of the molecule (but it is hard to interpret in terms of the location of the atoms). Figure C.2e shows the same diagram with the density isosurface made transparent and a tube structure inside, which helps to clarify the significance of the isosurface.

Chemists also need to know the distribution of electric charge in a molecule, because that distribution affects its physical and chemical properties. To do so, they sometimes use an **electrostatic potential surface** (an "elpot" surface), in which the net electric potential is calculated at each point of the density isosurface and depicted by different colors, as in Fig. C.2f. A blue tint at a point indicates that the positive potential at that point due to the positively charged nuclei outweighs the negative potential due to the negatively charged electrons; a red tint indicates the opposite.

Thinking point: Which type of molecular representation would you use to study bond lengths? Molecular volume?

A molecular formula shows the composition of a molecule in terms of the numbers of atoms of each element present. Different styles of molecular models are used to emphasize different molecular characteristics.

C.3 Ions and Ionic Compounds

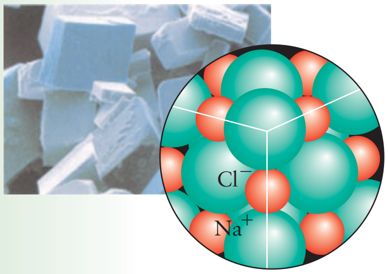

FIGURE C.3 An ionic solid consists of an array of cations and anions stacked together. This illustration shows the arrangement of sodium cations (Na^+) and chlorine anions (chloride ions, Cl^-) in a crystal of sodium chloride (common table salt). The faces of the crystal are where the stacks of ions come to an end.

To imagine what ionic compounds look like, we have to visualize a huge number of cations and anions stacked together in a regular three-dimensional formation. The ions bond together by the attraction between their opposite charges. Each crystal of sodium chloride, for example, consists of an orderly array of a vast number of alternating Na^+ and Cl^- ions (Fig. C.3). When you take a pinch of salt, each crystal that you are picking up consists of more ions than there are stars in the visible universe.

The nuclear model of the atom readily explains the existence of **monatomic ions** (single-atom ions). When an electron is removed from a neutral atom, the charge of the remaining electrons no longer fully cancels the positive charge of the nucleus (Fig. C.4). Because an electron has one unit of negative charge, each electron removed from a neutral atom leaves behind a cation with one additional unit of positive charge. For example, a sodium cation, Na^+, is a sodium atom that has lost one electron. When a calcium atom loses two electrons, it becomes the doubly positively charged calcium ion, Ca^{2+}.

Each electron gained by an atom increases the negative charge by one unit (Fig. C.5). So, when a fluorine atom gains an electron, it becomes the singly negatively

charged fluoride ion, F^-. When an oxygen atom gains two electrons, it becomes the doubly charged oxide ion, O^{2-}. When a nitrogen atom gains three electrons, it becomes the triply charged nitride ion, N^{3-}.

The periodic table can help us decide what type of ion an element forms and what charge to expect the ion to have. Fuller details will be given in Chapter 2, but we can begin to see the patterns. One major pattern is that metallic elements—those toward the left of the periodic table—typically form cations by electron loss. Nonmetallic elements—those toward the right of the table—typically form anions by gaining electrons. Thus, the alkali metals form cations, and the halogens form anions.

Figure C.6 shows another pattern in the charges of monatomic cations. For elements in Groups 1 and 2, for instance, the charge of the ion is equal to the group number. Thus, cesium in Group 1 forms Cs^+ ions; barium in Group 2 forms Ba^{2+} ions. Figure C.6 also shows that atoms of the d-block elements and some of the heavier metals of Groups 13/III and 14/IV can form cations with different charges. An iron atom, for instance, can lose two electrons to become Fe^{2+} or three electrons to become Fe^{3+}. Copper can lose either one electron to form Cu^+ or two electrons to become Cu^{2+}.

Some of the anions present in compounds are listed in Fig. C.7. We see another pattern emerging: a main-group element on the right side of the table forms an anion with a negative charge equal to its distance from the noble-gas group. Oxygen is two groups away from the noble gases and forms the oxide ion, O^{2-}; phosphorus, which is three groups away, forms the phosphide ion, P^{3-}. In general, if the group number of a main-group element is N (in the 1 to 18 system), the charge of the anions that it forms is $N - 18$.

The pattern of ion formation by main-group elements can be summarized by a single rule: For atoms toward the left or right of the periodic table, atoms lose or gain electrons until they have the same number of electrons as the nearest noble-gas atom.

Thus, a magnesium atom can lose two electrons and become Mg^{2+}, which has the same number of electrons as an atom of neon. A selenium atom can gain two electrons and become Se^{2-}, which has the same number of electrons as a krypton atom.

Metallic elements typically form cations, and nonmetallic elements typically form anions; the charge of a monatomic ion of a main group element is related to its group in the periodic table.

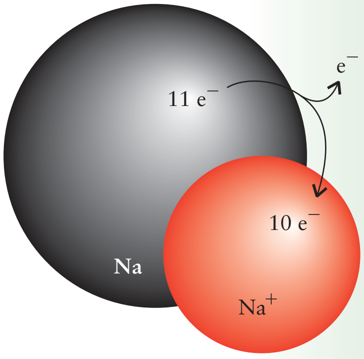

FIGURE C.4 A neutral sodium atom (left) consists of a nucleus that contains 11 protons and is surrounded by 11 electrons. When 1 electron is lost, the remaining 10 electrons cancel only 10 of the proton charges, and the resulting ion (right) has one overall positive charge.

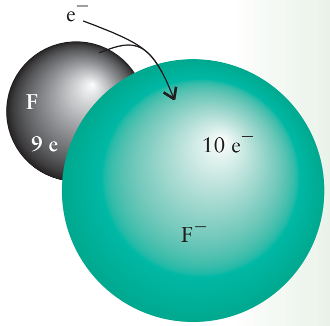

FIGURE C.5 A neutral fluorine atom (left) consists of a nucleus that contains 9 protons and is surrounded by 9 electrons. When the atom gains 1 electron, the 9 proton charges cancel all but 1 of the 10 electron charges, and the resulting ion (right) has one overall negative charge.

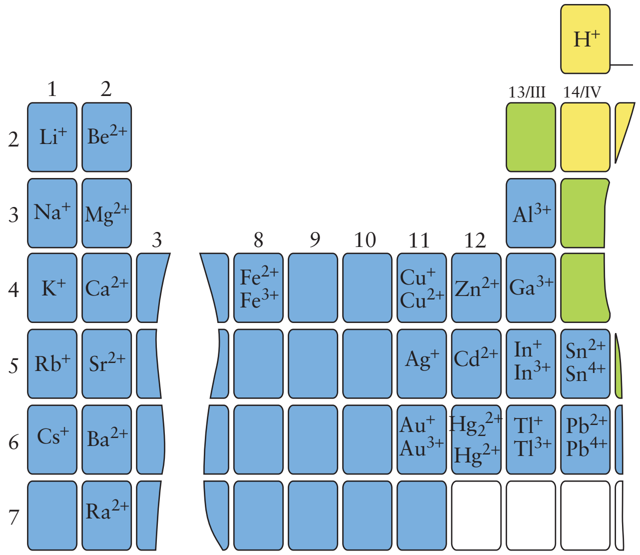

FIGURE C.6 The typical cations formed by a selection of elements in the periodic table. The transition metals (Groups 3–11) form a wide variety of cations; we have shown only a few.

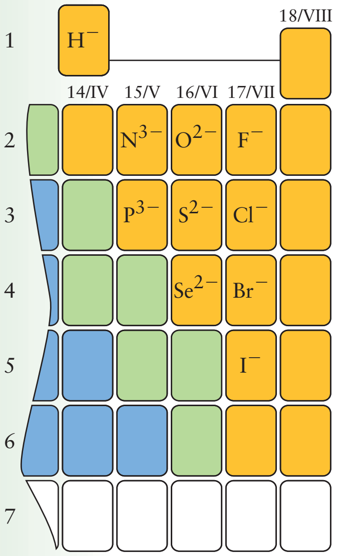

FIGURE C.7 The typical monatomic anions formed by a selection of elements in the periodic table. Notice how the charge on each ion depends on its group number. Only the nonmetals form monatomic anions under common conditions.

EXAMPLE C.1 Identifying the likely charge of a monatomic ion

What ions are (a) nitrogen and (b) calcium likely to form?

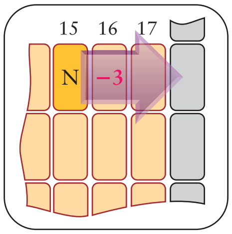
Anticipate Nitrogen is a nonmetal so we expect it to form an anion; calcium is a metal so we expect it to form a cation.

PLAN Identify the group to which each element belongs and decide whether it is likely to lose or gain electrons in order to reach a nearby noble-gas electron count. Typically, a nonmetal forms an anion of charge $N - 18$ and a metal in Group 1 or 2 forms a cation of charge N, where N is the group number.

SOLVE

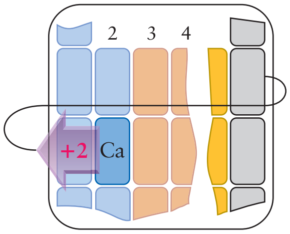
(a) Nitrogen (N) is in Group 15/V and a nonmetal.

$N = 15$; so $N - 18 = 15 - 18 = -3$; nitrogen forms N^{3-}



(b) Calcium (Ca) is in Group 2 and a metal.

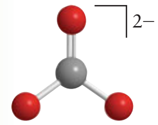
$N = 2$, so calcium forms Ca^{2+}



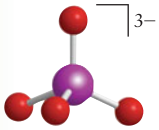
Self-Test C.1A What ions are (a) iodine and (b) aluminum likely to form?

[***Answer:*** (a) I^-; (b) Al^{3+}]

Self-Test C.1B What ions are (a) potassium and (b) sulfur likely to form?



5 Carbonate ion, CO_3^{2-}



6 Phosphate ion, PO_4^{3-}

Many ions are **diatomic,** meaning that they consist of two atoms bonded together, or **polyatomic,** meaning that they consist of three or more atoms bonded together. In each case, the ions have an overall positive or negative charge. For example, the cyanide ion, CN^-, is diatomic, and the ammonium ion, NH_4^+, is polyatomic. The most common polyatomic anions are the **oxoanions,** polyatomic anions that contain oxygen. They include the carbonate, CO_3^{2-}; nitrate NO_3^-; phosphate, PO_4^{3-}; and sulfate, SO_4^{2-}, anions. A carbonate ion (**5**), for example, has three O atoms bonded to a C atom and has two additional electrons. Similarly, a phosphate ion (**6**) consists of four O atoms bonded to a P atom, with three additional electrons. In Chapter 2, we shall see why we have drawn some of these structures with double bonds: for now, we take it as a way of making sure that each atom forms its correct number of bonds.

The formulas of ionic compounds have a different meaning from those of molecular compounds. Each crystal of sodium chloride may have a different total number of cations and anions from any other crystal. We cannot simply specify the numbers of ions present as the formula of this ionic compound, because each crystal would have a different formula and the subscripts would be enormous numbers. However, the *ratio* of the number of cations to the number of anions is the same in all the crystals, and the chemical formula shows this ratio. In sodium chloride, there is one Na^+ ion for each Cl^- ion; so its formula is NaCl. Sodium chloride is an example of a **binary ionic compound,** a compound formed from the ions of two elements. Another binary ionic compound, $CaCl_2$, is formed from Ca^{2+} and Cl^- ions in the ratio 1:2, which is required for electrical neutrality.

The formulas of compounds containing polyatomic ions follow similar rules. In sodium carbonate there are two Na^+ (sodium) ions per CO_3^{2-} (carbonate) ion; so its formula is Na_2CO_3. When a subscript has to be added to a polyatomic ion, the ion is written within parentheses, as in $(NH_4)_2SO_4$, where $(NH_4)_2$ means that there are two NH_4^+ (ammonium) ions for each SO_4^{2-} (sulfate) ion in ammonium sulfate. In each case, the ions combine in such a way that the positive and negative charges cancel: *all compounds are electrically neutral overall*.

We do not usually speak of a "molecule" of an ionic compound. However, it is useful to be able to refer to a group of ions having the number of atoms given by the formula. This group of ions is called a **formula unit.** For example, the formula unit of sodium chloride, NaCl, consists of one Na^+ ion and one Cl^- ion; and the formula unit of ammonium sulfate, $(NH_4)_2SO_4$, consists of two NH_4^+ ions and one SO_4^{2-} ion.

Clusters of ions, such as Na^+Cl^-, do exist in the gas phase and in concentrated aqueous solutions, in which case they are commonly termed ion pairs rather than molecules.

We can often decide whether a substance is an ionic compound or a molecular compound by examining its formula. Binary molecular compounds are typically formed from two nonmetals (such as hydrogen and oxygen, the elements in water). Ionic compounds are typically formed from the combination of a metallic element with nonmetallic elements (such as the combination of potassium with sulfur and oxygen to form potassium sulfate, K_2SO_4). Ionic compounds typically contain one metallic element; the principal exceptions are compounds containing the ammonium ion, such as ammonium nitrate, which are ionic even though all the elements present are nonmetallic.

EXAMPLE C.2 Writing the likely formula of a binary ionic compound

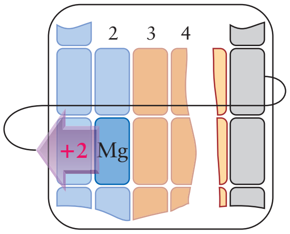
Write the formula of the binary ionic compound formed by magnesium and phosphorus.

PLAN Identify the charges of the cation and anion, then choose numbers of each so that the total charge is zero.

SOLVE

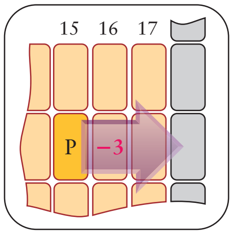
Find the charge on the cation from the periodic table.

Mg is in Group 2; so it forms ions with charge +2.



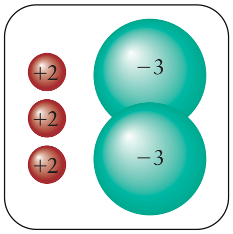
Find the charge on the anion from the periodic table.

P is in Group 15/V and forms ions with charge $15 - 18 = -3$.



Combine the ions so that their charges cancel.

3 Mg^{2+} ions have a charge of +6.
2 P^{3-} ions have a charge of −6.
The formula is Mg_3P_2.



Self-Test C.2A Write the formula of the binary ionic compound formed by (a) barium and bromine; (b) aluminum and oxygen.

[*Answer:* (a) $BaBr_2$; (b) Al_2O_3]

Self-Test C.2B Write the formula of the binary ionic compound formed by (a) lithium and nitrogen; (b) strontium and bromine.

The chemical formula of an ionic compound shows the ratio of the numbers of atoms of each element present in one formula unit. A formula unit of an ionic compound is a group of ions with the same number of atoms of each element as appears in its formula.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Distinguish between molecules, ions, and atoms.

❑ 2 Identify compounds as organic or inorganic and as molecular or ionic.

❑ 3 Use various means of representing molecules.

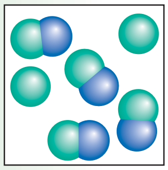
❑ 4 Predict the anion or cation that a main-group element is likely to form (Example C.1).

❑ 5 Interpret chemical formulas in reference to the number of each type of atom present.

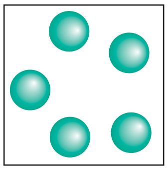
❑ 6 Predict the formulas of binary ionic compounds (Example C.2).

EXERCISES

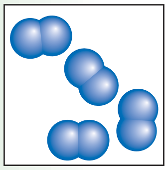
C.1 Each of the containers pictured below holds either a mixture, a single compound, or a single element. The blue spheres represent atoms of one element, the green spheres the atoms of a second element. In each case, identify the type of contents.

(a)


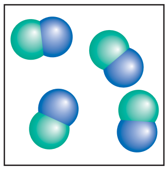
(b)



C.2 Each of the containers pictured below holds either a mixture, a single compound, or a single element. The blue spheres represent atoms of one element, the green spheres the atoms of a second element. In each case, identify the type of contents.

(a)


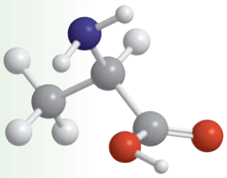
(b)



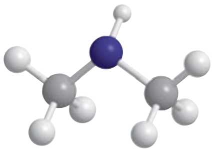
C.3 The compound xanthophyll is a yellow compound found in bird feathers and flowers. Xanthophyll contains atoms of carbon, hydrogen, and oxygen in the ratio 20:28:1. Its molecules each have six oxygen atoms. Write the molecular formula of xanthophyll.

C.4 Valinomycin is an antibiotic that has been used to treat tuberculosis. Valinomycin contains atoms of carbon, hydrogen, nitrogen, and oxygen in the ratio 9:15:1:3. Its molecules each have 18 oxygen atoms. Write the molecular formula of valinomycin.

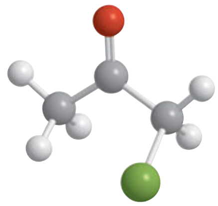
C.5 In the following ball-and-stick molecular structures, gray indicates carbon, red oxygen, white hydrogen, blue nitrogen, and green chlorine. Write the chemical formula of each structure.

(a)


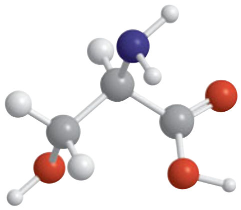
(b)



C.6 Write the chemical formula of each ball-and-stick structure. See Exercise C.5 for the color code.

(a)


(b)



C.7 State whether each of the following elements is more likely to form a cation or an anion, and write the formula for the ion most likely to be formed: (a) cesium; (b) iodine; (c) selenium; (d) calcium.

C.8 State whether each of the following elements is more likely to form a cation or an anion, and write the formula for the ion most likely to be formed: (a) tellurium; (b) barium; (c) rubidium; (d) bromine.

C.9 How many protons, neutrons, and electrons are present in (a) $^{10}Be^{2+}$; (b) $^{17}O^{2-}$; (c) $^{80}Br^{-}$; (d) $^{75}As^{3-}$?

C.10 How many protons, neutrons, and electrons are present in (a) $^{64}Cu^{2+}$; (b) $^{138}La^{3+}$; (c) $^{12}C^{2-}$; (d) $^{39}K^{+}$?

C.11 Write the symbol of the ion that has (a) 9 protons, 10 neutrons, and 10 electrons; (b) 12 protons, 12 neutrons, and 10 electrons; (c) 52 protons, 76 neutrons, and 54 electrons; (d) 37 protons, 49 neutrons, and 36 electrons.

C.12 Write the symbol of the ion that has (a) 11 protons, 13 neutrons, and 10 electrons; (b) 13 protons, 14 neutrons, and 10 electrons; (c) 34 protons, 45 neutrons, and 36 electrons; (d) 24 protons, 28 neutrons, and 22 electrons.

C.13 Write the formula of a compound formed by combining (a) Al and Te; (b) Mg and O; (c) Na and S; (d) Rb and I.

C.14 Write the formula of a compound formed by combining (a) Mg and N; (b) Ga and S; (c) Ba and Cl; (d) K and Se.

C.15 A main-group element in Period 3 forms the following ionic compounds: EBr_3 and E_2O_3. (a) To which group does the element E belong? (b) Write the name and symbol of element E.

C.16 A main-group element in Period 3 forms the molecular compound H_2E and the ionic compound Na_2E. (a) To which group does the element E belong? (b) Write the name and symbol of element E.

C.17 Determine the fraction of the total mass of a ^{48}Ti atom that is due to (a) neutrons; (b) protons; (c) electrons. (d) What is the mass of protons in a titanium bicycle frame of mass 30. kg? Assume the total mass of the bicycle frame is due to ^{48}Ti. *Note:* The masses of free protons and neutrons are slightly higher than the masses of these particles in atoms, so the answer is only an approximation.

C.18 (a) Determine the total number of protons, neutrons, and electrons in one water molecule, H_2O, assuming that only the most common isotopes, ^{1}H and ^{16}O, are present. (b) What are the total masses of protons, neutrons, and electrons in this water molecule? (c) What fraction of your own mass is due solely to the electrons in your body, assuming that you consist primarily of water made from this type of molecule? *Note:* The masses of free protons and neutrons are slightly higher than the masses of these particles in atoms; so the answer is only an approximation.

C.19 The following compounds contain polyatomic ions. (a) Write the formula for the compound formed from sodium ions and hydrogen phosphite ions (HPO_3^{2-}). (b) Write the formula for ammonium carbonate, which is formed from ammonium ions (NH_4^+) and carbonate ions (CO_3^{2-}). (c) The formula for magnesium sulfate is $MgSO_4$; what is the charge of the cation in $CuSO_4$? (d) The formula for potassium phosphate is K_3PO_4; what is the charge of the cation in $Sn_3(PO_4)_2$?

C.20 The following compounds contain polyatomic ions. (a) Write the formula for the compound formed from sodium ions and chromate ions (CrO_4^{2-}). (b) Write the formula for ammonium sulfite, which is formed from ammonium ions (NH_4^+) and sulfite ions (SO_3^{2-}). (c) The formula for manganese(II) sulfate is $MnSO_4$; what is the charge of the cation in $Co_2(SO_4)_3$? (d) The formula for potassium hydrogen phosphate is K_2HPO_4; what is the charge of the cation in $Pb_3(PO_4)_4$?

C.21 Identify the following substances as elements, molecular compounds, or ionic compounds: (a) HCl; (b) S_8; (c) CoS; (d) Ar; (e) CS_2; (f) $SrBr_2$.

C.22 Identify the following substances as elements, molecular compounds, or ionic compounds: (a) NiO_2; (b) NaF; (c) Xe; (d) P_4; (e) NH_3; (f) CO.

D THE NOMENCLATURE OF COMPOUNDS

D.1 Names of Cations
D.2 Names of Anions
D.3 Names of Ionic Compounds
D.4 Names of Inorganic Molecular Compounds
D.5 Names of Some Common Organic Compounds

Many compounds were given informal, **common names** before their compositions were known. Common names include water, salt, sugar, ammonia, and quartz. A **systematic name,** on the other hand, reveals which elements are present and, in some cases, the arrangement of atoms. The systemic naming of compounds, which is called **chemical nomenclature,** follows the simple rules described in this section.

D.1 Names of Cations

The name of a monatomic cation is the same as the name of the element forming it, with the addition of the word ion, as in "sodium ion" for Na^+. When an element can form more than one kind of cation, such as Cu^+ and Cu^{2+} from copper, we use the **oxidation number,** the charge of the cation, written as a Roman numeral in parentheses immediately following the name of the element. Thus, Cu^+ is a copper(I) ion and Cu^{2+} is a copper(II) ion. Similarly, Fe^{2+} is an iron(II) ion and Fe^{3+} is an iron(III) ion. As shown in Fig. C.6, most transition metals form more than one kind of ion; so unless we are given other information we need to include the oxidation number in the names of their compounds.

In chemical nomenclature, the oxidation number is sometimes called the *Stock number* for the German chemist Alfred Stock, who devised this numbering system. Oxidation numbers are discussed in more detail in Sections K and 2.8.

Some older systems of nomenclature are still in use. For example, some cations were once denoted by the endings *-ous* and *-ic* for the ions with lower and higher charges, respectively. To make matters worse, these endings were in some cases added to the Latin form of the element's name. Thus, iron(II) ions were called ferrous ions and iron(III) ions were called ferric ions (see Appendix 3C). We do not use this system in this text, but you will sometimes come across it and should be aware of it.

The name of a monatomic cation is the name of the element plus the word ion; for elements that can form more than one type of cation, the oxidation number, a Roman numeral indicating the charge, is included.

D.2 Names of Anions

Monatomic anions, such as the Cl^- ions in sodium chloride and the O^{2-} ions in *quicklime* (CaO), are named by adding the suffix *-ide* and the word ion to the first part of the name of the element (the "stem" of its name), as shown in Table D.1; thus, S^{2-} is a sulfide ion and O^{2-} is an oxide ion. There is usually no need to specify the charge,

TABLE D.1 Common Anions and Their Parent Acids

Anion	Parent acid	Anion	Parent acid
fluoride ion, F^-	hydrofluoric acid,* HF (hydrogen fluoride)	nitrite ion, NO_2^-	nitrous acid, HNO_2
chloride ion, Cl^-	hydrochloric acid,* HCl (hydrogen chloride)	nitrate ion, NO_3^-	nitric acid, HNO_3
bromide ion, Br^-	hydrobromic acid,* HBr (hydrogen bromide)	phosphate ion, PO_4^{3-} hydrogen phosphate ion, HPO_4^{2-} dihydrogen phosphate ion, $H_2PO_4^-$	phosphoric acid, H_3PO_4
iodide ion, I^-	hydroiodic acid,* HI (hydrogen iodide)	sulfite ion, SO_3^{2-} hydrogen sulfite ion, HSO_3^-	sulfurous acid, H_2SO_3
oxide ion, O^{2-} hydroxide ion, OH^-	water, H_2O	sulfate ion, SO_4^{2-} hydrogen sulfate ion, HSO_4^-	sulfuric acid, H_2SO_4
sulfide ion, S^{2-} hydrogen sulfide ion, HS^-	hydrosulfuric acid,* H_2S (hydrogen sulfide)	hypochlorite ion, ClO^-	hypochlorous acid, HClO
cyanide ion, CN^-	hydrocyanic acid,* HCN (hydrogen cyanide)	chlorite ion, ClO_2^-	chlorous acid, $HClO_2$
acetate ion, $CH_3CO_2^-$	acetic acid, CH_3COOH	chlorate ion, ClO_3^-	chloric acid, $HClO_3$
carbonate ion, CO_3^{2-} hydrogen carbonate (bicarbonate) ion, HCO_3^-	carbonic acid, H_2CO_3	perchlorate ion, ClO_4^-	perchloric acid, $HClO_4$

*The name of the aqueous solution of the compound. The name of the compound itself is in parentheses.

because most elements that form monatomic anions form only one kind of ion. The ions formed by the halogens are collectively called *halide ions* and include fluoride (F^-), chloride (Cl^-), bromide (Br^-), and iodide (I^-) ions.

Polyatomic ions (see Section C) include the *oxoanions,* which are ions that contain oxygen (see Table D.1). If only one oxoanion of an element exists, its name is formed by adding the suffix *-ate* to the stem of the name of the element, as in the carbonate ion, CO_3^{2-}. Some elements can form two types of oxoanions, with different numbers of oxygen atoms, so we need names that distinguish them. Nitrogen, for example, forms both NO_2^- and NO_3^-. In such cases, the ion with the larger number of oxygen atoms is given the suffix *-ate*, and that with the smaller number of oxygen atoms is given the suffix *-ite*. Thus, NO_3^- is nitrate, and NO_2^- is nitrite. The nitrate ion is an important source of nitrogen for plants and is included in some fertilizers (such as ammonium nitrate, NH_4NO_3).

Some elements—particularly the halogens—form more than two kinds of oxoanions. The name of the oxoanion with the smallest number of oxygen atoms is formed by adding the prefix *hypo-* to the *-ite* form of the name, as in the *hypo*chlor*ite* ion, ClO^-. The oxoanion with the most oxygen atoms is named with the prefix *per-* added to the *-ate* form of the name. An example is the *per*chlor*ate* ion, ClO_4^-. The rules for naming polyatomic ions are summarized in Appendix 3A and common examples are listed in Table D.1.

Hypo comes from the Greek word for "under."

Per is the Latin word for "all over," suggesting that the element's ability to combine with oxygen is finally satisfied.

Hydrogen is present in some anions. Two examples are HS^- and HCO_3^-. The names of these anions begin with "hydrogen." Thus, HS^- is the hydrogen sulfide ion, and HCO_3^- is the hydrogen carbonate ion. You might also see the name of the ion written as a single word, as in hydrogencarbonate ion, which is the more modern style. In an older system of nomenclature, which is still quite widely used, an anion containing hydrogen is named with the prefix *bi-*, as in bicarbonate ion for HCO_3^-. If two hydrogen atoms are present in an anion, as in $H_2PO_4^-$, then the ion is named as a dihydrogen anion, in this case as dihydrogen phosphate.

Self-Test D.1A Write (a) the name of the IO^- ion and (b) the formula of the hydrogen sulfite ion.

[***Answer:*** (a) Hypoiodite ion; (b) HSO_3^-]

Self-Test D.1B Write (a) the name of the $H_2AsO_4^-$ ion and (b) the formula of the chlorate ion.

Names of monatomic anions end in -ide. Oxoanions are anions that contain oxygen. The suffix -ate indicates a greater number of oxygen atoms than the

TABLE D.2 Prefixes Used for Naming Compounds

Prefix	Meaning	Prefix	Meaning
mono-	1	hepta-	7
di-	2	octa-	8
tri-	3	nona-	9
tetra-	4	deca-	10
penta-	5	undeca-	11
hexa-	6	dodeca-	12

suffix -ite within the same series of oxoanions. In series of three or more related oxoanions the prefix per- indicates the maximum number of oxygen atoms; the prefix hypo- indicates the least number of oxygen atoms.

FIGURE D.1 Blue crystals of copper(II) sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$) lose water above 150°C and form the white anhydrous powder ($CuSO_4$) seen in this petri dish. The color is restored when water is added; and, in fact, anhydrous copper sulfate has such a strong attraction for water that it is usually colored a very pale blue from reaction with the water in air.

Lab Video D.1

D.3 Names of Ionic Compounds

An ionic compound is named with the cation name first, followed by the name of the anion; the word *ion* is omitted in each case. The oxidation number of the cation is given if more than one charge is possible. However, if the cation comes from an element that exists in only one charge state (as listed in Fig. C.6), then the oxidation number is omitted. Typical names include potassium chloride (KCl), a compound containing K^+ and Cl^- ions; and ammonium nitrate (NH_4NO_3), which contains NH_4^+ and NO_3^- ions. The cobalt chloride that contains Co^{2+} ions ($CoCl_2$) is called cobalt(II) chloride; $CoCl_3$ contains Co^{3+} ions and is called cobalt(III) chloride. Notice that the number of chloride ions is determined by the need for charge balance.

Some ionic compounds form crystals that incorporate a definite proportion of molecules of water as well as the ions of the compound itself. These compounds are called **hydrates.** For example, copper(II) sulfate normally exists as blue crystals of composition $CuSO_4 \cdot 5H_2O$. The raised dot in this formula separates the waters of hydration from the rest of the formula and the number before the H_2O indicates how many water molecules are present in each formula unit. Hydrates are named by first giving the name of the compound, then adding the word *hydrate* with a Greek prefix indicating how many molecules of water are found in each formula unit (Table D.2). For example, the name of $CuSO_4 \cdot 5H_2O$, the common blue form of this compound, is copper(II) sulfate pentahydrate. When this compound is heated, the water of hydration is lost and the blue crystals crumble to a white powder (Fig. D.1). The white powder is $CuSO_4$ itself. When we wish to emphasize that the compound has lost its water of hydration, we call it **anhydrous.** Thus, $CuSO_4$ is anhydrous copper(II) sulfate.

The distinction can be important: if you buy sodium sulfate decahydrate, $Na_2SO_4 \cdot 10H_2O$, instead of its anhydrous form, Na_2SO_4, you are buying a lot of water!

TOOLBOX D.1 HOW TO NAME IONIC COMPOUNDS

CONCEPTUAL BASIS

The aim of chemical nomenclature is to be simple but unambiguous. Ionic and molecular compounds use different procedures; so it is important first to identify the type of compound. To name an ionic compound, we name the ions present and then combine the names of the ions.

PROCEDURE

Step 1 Identify the cation and the anion (see Table D.1 or Appendix 3A, if necessary). To determine the oxidation number of the cation, decide what cation charge is required to cancel the total negative charge of the anions.

Step 2 Name the cation. If the metal can have more than one oxidation number (most transition metals and some metals in Groups 12 through 15/V), give its charge as a Roman numeral.

Step 3 Name the anion. If the anion is monatomic, change the ending of the element's name to *-ide*.

For an oxoanion:

(a) For elements that form two oxoanions, give the ion with the larger number of oxygen atoms the suffix *-ate* and that with the smaller number of oxygen atoms the suffix *-ite*.

(b) For elements that form a series of four oxoanions, add the prefix *hypo-* to the name of the oxoanion with the smallest number of oxygen atoms. Add the prefix *per-* to the oxoanion with the highest number of oxygen atoms.

For other polyatomic anions, find the name of the ion in Table D.1 or Appendix 3A. If hydrogen is present, add "hydrogen" to the name of the anion. If two hydrogen atoms are present, add "dihydrogen" to the name of the anion.

Step 4 If water molecules appear in the formula, the compound is a hydrate. Add the word *hydrate* with a Greek prefix corresponding to the number in front of H_2O.

For examples of how these rules are applied, see Example D.1.

EXAMPLE D.1 Naming ionic inorganic compounds

Name (a) $CrCl_3 \cdot 6H_2O$ and (b) $Ba(ClO_4)_2$.

PLAN Use the rules in Toolbox D.1.

SOLVE

Step 1 Identify the cation and anion.

(a) $CrCl_3 \cdot 6H_2O$: Cr^{3+}, Cl^- **(b)** $Ba(ClO_4)_2$: Ba^{2+}, ClO_4^-

Step 2 Name the cation, giving the charge of the transition-metal cation as a Roman numeral. Note that in (a) there are three Cl^- ions; so the charge on Cr must be +3.

chromium(III) barium

Step 3 Name the anion and combine the names of the ions with the cation first.

chromium(III) chloride barium perchlorate

Step 4 If H_2O is present, add hydrate with a Greek prefix.

chromium(III) chloride hexahydrate

Self-Test D.2A Name the compounds (a) $NiCl_2 \cdot 2H_2O$; (b) AlF_3; (c) $Mn(IO_2)_2$.

[***Answer:*** (a) Nickel(II) chloride dihydrate; (b) aluminum fluoride; (c) manganese(II) iodite]

Self-Test D.2B Name the compounds (a) $AuCl_3$; (b) CaS; (c) Mn_2O_3.

Ionic compounds are named by starting with the name of the cation (with its oxidation number if more than one charge is possible), followed by the name of the anion; hydrates are named by adding the word hydrate, preceded by a Greek prefix indicating the number of water molecules in the formula unit.

D.4 Names of Inorganic Molecular Compounds

Many simple inorganic molecular compounds are named by using the Greek prefixes in Table D.2 to indicate the number of each type of atom present. Usually, we do not use a prefix if only one atom of an element is present; for example, NO_2 is nitrogen dioxide. An important exception to this rule is carbon monoxide, CO. When naming common binary molecular compounds—molecular compounds built from two elements—name the element that occurs further to the right in the periodic table second, with its ending changed to *-ide*:

phosphorus trichloride, PCl_3 dinitrogen oxide, N_2O
sulfur hexafluoride, SF_6 dinitrogen pentoxide, N_2O_5

Some exceptions to these rules are the phosphorus oxides and compounds that are generally known by their common names. The phosphorus oxides are distinguished by the oxidation number of phosphorus, which is written as though phosphorus were a metal and the oxygen present as O^{2-}. Thus, P_4O_6 is named phosphorus(III) oxide as though it were $(P^{3+})_4(O^{2-})_6$, and P_4O_{10} is named phosphorus(V) oxide as though it were $(P^{5+})_4(O^{2-})_{10}$. These compounds, though, are molecular. Some binary molecular compounds, such as NH_3 and H_2O, have widely used common names (Table D.3).

In both the names and the molecular formulas of compounds formed between hydrogen and nonmetals in Groups 16/VI or 17/VII hydrogen is written first: for example, the formula for hydrogen chloride is HCl and that for hydrogen sulfide is H_2S. Note that, when these compounds are dissolved in water, most act as acids and are named as acids. Binary acids are named by adding the prefix *hydro-* and changing the ending of the name of the second element to *-ic* acid, as in hydrochloric acid for HCl in water and hydrosulfuric acid for H_2S in water. An **aqueous solution,** a solution in water, is indicated by (aq) after the formula. Thus, HCl, the compound itself, is hydrogen chloride, and HCl(aq), its aqueous solution, is hydrochloric acid.

TABLE D.3 Common Names for Some Simple Molecular Compounds

Formula*	Common name
NH_3	ammonia
N_2H_4	hydrazine
NH_2OH	hydroxylamine
PH_3	phosphine
NO	nitric oxide
N_2O	nitrous oxide
C_2H_4	ethylene
C_2H_2	acetylene

*For historical reasons, the molecular formulas of binary hydrogen compounds of Group 15/V elements are written with the Group 15/V element first.

An **oxoacid** is an acidic molecular compound that contains oxygen. Oxoacids are the parents of the oxoanions in the sense that an oxoanion is formed by removing one or more hydrogen ions from an oxoacid molecule (see Table D.1). In general, *-ic* oxoacids are the parents of *-ate* oxoanions and *-ous* oxoacids are the parents of *-ite* oxoanions. For example, H_2SO_4, sulfuric acid, is the parent acid of the sulfate ion, SO_4^{2-}. Similarly, the parent acid of the sulfite ion, SO_3^{2-}, is the molecular compound H_2SO_3, sulfurous acid.

TOOLBOX D.2 HOW TO NAME SIMPLE INORGANIC MOLECULAR COMPOUNDS

CONCEPTUAL BASIS

The aim of chemical nomenclature is to be simple but unambiguous. A systematic name specifies the elements present in the molecule and the numbers of atoms of each element.

PROCEDURE

Determine the type of compound and then apply the corresponding rules.

Binary molecular compounds other than acids

The compound is generally not an acid if its formula does not begin with H.

Step 1 Write the name of the first element, followed by the name of the second, with its ending changed to *-ide*.

Step 2 Add Greek prefixes to indicate the number of atoms of each element. "Mono-" is usually omitted.

See Example D.2(a) and (b).

Acids

An inorganic acid has a formula that typically begins with H; oxoacids have formulas that begin with H and end in O. We distinguish between binary hydrides, such as HX, which are not named as acids, and their aqueous solutions, HX(aq), which are.

Step 1 If the compound is a binary acid in solution, add "hydro . . . ic acid" to the root of the element's name.

See Example D.2(c).

Step 2 If the compound is an oxoacid, derive the name of the acid from the name of the polyatomic ion that it produces, as in Toolbox D.1. In general,

-ate ions come from *-ic acids*
-ite ions come from *-ous acids*

Retain any prefix, such as *hypo-* or *per-*.

See Example D.2(d).

EXAMPLE D.2 Naming inorganic molecular compounds

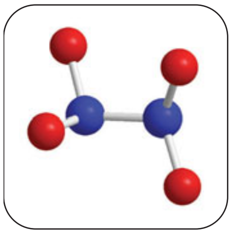
Give the systematic names of (a) N_2O_4, (b) ClO_2, (c) HI(aq), and (d) HNO_2.

PLAN Proceed as in Toolbox D.2.

SOLVE

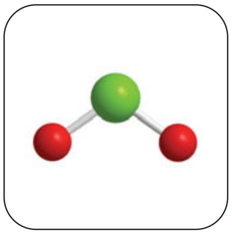
(a) The molecule N_2O_4 has two nitrogen atoms and four oxygen atoms.

Dinitrogen tetroxide



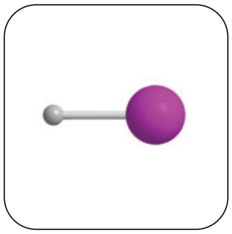
(b) A ClO_2 molecule has one chlorine atom and two oxygen atoms.

Chlorine dioxide



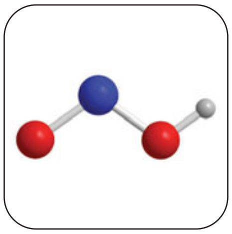
(c) HI(aq) is a binary acid formed when hydrogen iodide dissolves in water.

Hydroiodic acid (The molecular compound HI is hydrogen iodide.)



(d) HNO_2 is an oxoacid, the parent acid of the nitrite ion, NO_2^-.

Nitrous acid



Self-Test D.3A Name (a) HCN(aq); (b) BCl_3; (c) IF_5.

[*Answer:* (a) Hydrocyanic acid; (b) boron trichloride; (c) iodine pentafluoride]

Self-Test D.3B Name (a) PCl_3; (b) SO_3; (c) HBr(aq).

EXAMPLE D.3 Writing the formula of a binary compound from its name

Write the formulas of (a) cobalt(II) chloride hexahydrate; (b) diboron trisulfide.

PLAN First check to see whether the compounds are ionic or molecular. Many compounds that contain a metal are ionic. Write the symbol of the metal first, followed by the symbol of the nonmetal. The charges on the ions are determined as shown in Examples C.1 and C.2. Subscripts are chosen to balance charges. Compounds of two nonmetals are normally molecular. Write their formulas by listing the symbols of the elements in the same order as in the name, with subscripts corresponding to the Greek prefixes used.

SOLVE

(a) Determine if the compound is ionic or molecular.

Metal and nonmetal, so ionic.

Determine the charge on the cation.

The II in cobalt(II) indicates a +2 charge, so Co^{2+}.

Determine the charge on the anion.

Cl is in Group 17/VII, so has the charge $17 - 18 = -1$, so Cl^-.

Balance charges.

2 Cl^- ions are required for each Co^{2+} ion, so $CoCl_2$.

Add waters of hydration.

Hexahydrate, so 6 water molecules are attached: $CoCl_2 \cdot 6H_2O$.

(b) Determine if the compound is ionic or molecular.

Two nonmetals, so molecular.

Convert Greek prefixes into subscripts.

di = 2; tri = 3, so B_2S_3.

Self-Test D.4A Write the formulas for (a) vanadium(V) oxide; (b) calcium carbide; (c) germanium tetrafluoride; (d) dinitrogen trioxide.

[*Answer:* (a) V_2O_5; (b) Ca_2C; (c) GeF_4; (d) N_2O_3]

Self-Test D.4B Write the formulas for (a) cesium sulfide tetrahydrate; (b) manganese(VII) oxide; (c) hydrogen cyanide (a poisonous gas); (d) disulfur dichloride.

TABLE D.4 Alkane Nomenclature

Number of carbon atoms	Formula	Name of alkane	Name of alkyl group
1	CH_4	methane	methyl
2	CH_3CH_3	ethane	ethyl
3	$CH_3CH_2CH_3$	propane	propyl
4	$CH_3(CH_2)_2CH_3$	butane	butyl
5	$CH_3(CH_2)_3CH_3$	pentane	pentyl
6	$CH_3(CH_2)_4CH_3$	hexane	hexyl
7	$CH_3(CH_2)_5CH_3$	heptane	heptyl
8	$CH_3(CH_2)_6CH_3$	octane	octyl
9	$CH_3(CH_2)_7CH_3$	nonane	nonyl
10	$CH_3(CH_2)_8CH_3$	decane	decyl
11	$CH_3(CH_2)_9CH_3$	undecane	undecyl
12	$CH_3(CH_2)_{10}CH_3$	dodecane	dodecyl

Binary molecular compounds are named by using Greek prefixes to indicate the number of atoms of each element present; the element named second has its ending changed to -ide.

D.5 Names of Some Common Organic Compounds

There are millions of organic compounds; many consist of highly intricate molecules, so their names can be very complicated. You could, for example, find yourself asking for α-D-glucopyranosyl(1→2)-β-D-fructofuranose when all you wanted was sucrose (sugar). However, for most of this text, we will need to know only a few simple organic compounds, and this section will introduce some of them. Chapters 18 and 19 present a more complete introduction to the nomenclature of organic compounds.

At this stage it is helpful to know that compounds of hydrogen and carbon are called **hydrocarbons.** They include methane, CH_4 (**1**); ethane, C_2H_6 (**2**); and benzene, C_6H_6 (**3**). Hydrocarbons that have no carbon—carbon multiple bonds are called **alkanes.** Thus, methane and ethane are both alkanes. The unbranched alkanes with up to 12 carbon atoms are listed in Table D.4. Notice that Greek prefixes are used to name all the alkanes with five or more carbon atoms. Hydrocarbons with double bonds are called **alkenes.** Ethene, $CH_2{=}CH_2$, is the simplest example of an alkene. It used to be (and still widely is) called ethylene. Benzene is a hydrocarbon with double bonds, and it has such distinctive properties that it is regarded as the parent hydrocarbon of a separate class of compounds called **aromatic compounds.** The hexagonal benzene ring is exceptionally stable and can be found in many important compounds. Specific groups of atoms derived from hydrocarbons, such as —CH_3, methyl, and —CH_2CH_3, ethyl, are named by replacing the ending of the parent hydrocarbon's name by *-yl*.

The hydrocarbons are the basic framework for all organic compounds. Different classes of organic compounds have one or more of the hydrogen atoms replaced by other atoms or groups of atoms (see Chapter 19 for a more comprehensive list). All we need to be aware of at this stage are the three classes of compounds known as alcohols, carboxylic acids, and haloalkanes:

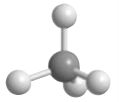
An **alcohol** is a type of organic compound that contains an —OH group.

Ethanol, CH_3CH_2OH (**4**), the "alcohol" of beer and wine, is an ethane molecule in which one H atom has been replaced by an —OH group, and CH_3OH (**5**) is the toxic alcohol called methanol, or wood alcohol.

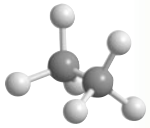
A **carboxylic acid** is a compound that contains the carboxyl group, —COOH (**6**).

The most common example is acetic acid, CH_3COOH (**7**), the acid that gives vinegar its sharp taste. Formic acid, HCOOH (**8**), is the acid of ant venom.

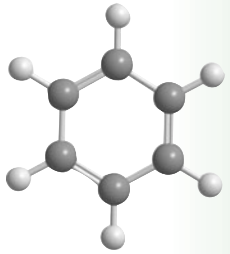
A **haloalkane** is an alkane in which one or more H atoms have been replaced by halogen atoms.



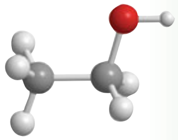
1 Methane, CH_4



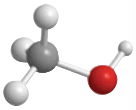
2 Ethane, C_2H_6



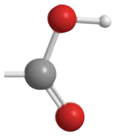
3 Benzene, C_6H_6



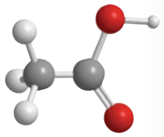
4 Ethanol, CH_3CH_2OH



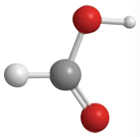
5 Methanol, CH_3OH



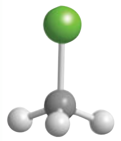
6 Carboxyl group, —COOH



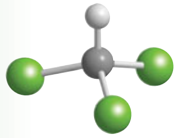
7 Acetic acid, CH_3COOH



8 Formic acid, HCOOH



9 Chloromethane, CH_3Cl



10 Trichloromethane, $CHCl_3$

Haloalkanes include chloromethane, CH_3Cl (**9**), and trichloromethane, $CHCl_3$ (**10**). The latter compound has the common name chloroform and was an early anesthetic. Notice that the names are formed by shortening the name of the halogen to fluoro-, chloro-, bromo-, or iodo- and adding a Greek prefix indicating the number of halogen atoms.

Self-Test D.5 A(a) Name CH_2BrCl. (b) What type of compound is $CH_3CH(OH)CH_3$?

[***Answer:*** (a) Bromochloromethane; (b) alcohol]

Self-Test D.5B (a) Name $CH_3CH_2CH_2CH_2CH_3$. (b) What type of compound is CH_3CH_2COOH?

The names of organic compounds are based on the names of the parent hydrocarbons; alcohols contain —OH groups, carboxylic acids contain —COOH groups, and haloalkanes contain halogen atoms.

SKILLS YOU SHOULD HAVE MASTERED

- ❑ 1 Name ions, binary inorganic compounds, oxoacids, compounds with common polyatomic ions, and hydrates, and write their formulas (Toolboxes D.1 and D.2, Self-Test D.1, and Examples D.1, D.2, and D.3).
- ❑ 2 Name simple hydrocarbons and substituted methane (Section D.5).
- ❑ 3 Identify alcohols and carboxylic acids from their formulas (Self-Test D.5).

EXERCISES

D.1 Write the formula of (a) manganese(II) chloride; (b) calcium phosphate; (c) aluminum sulfite; (d) magnesium nitride.

D.2 Write the formula of (a) barium hydroxide; (b) cobalt(II) phosphite; (c) manganese(II) bromide; (d) chromium(III) sulfide.

D.3 Name the following ionic compounds. Write both the old and the modern names wherever appropriate. (a) $Ca_3(PO_4)_2$, the major inorganic component of bones; (b) SnS_2; (c) V_2O_5; (d) Cu_2O.

D.4 The following ionic compounds are commonly found in laboratories. Write the modern name of (a) $NaHCO_3$ (baking soda); (b) Hg_2Cl_2 (calomel): (c) NaOH (lye); (d) ZnO (calamine).

D.5 Write the formula of (a) titanium dioxide; (b) silicon tetrachloride; (c) carbon disulfide; (d) sulfur tetrafluoride; (e) lithium sulfide; (f) antimony pentafluoride; (g) dinitrogen pentoxide; (h) iodine heptafluoride.

D.6 Write the formula of (a) dinitrogen pentoxide: (b) hydrogen iodide; (c) oxygen difluoride; (d) phosphorus trichloride; (e) sulfur trioxide; (f) carbon tetrabromide; (g) bromine trifluoride.

D.7 Name each of the following binary molecular compounds: (a) SF_6; (b) N_2O_5; (c) NI_3; (d) XeF_4; (e) $AsBr_3$; (f) ClO_2.

D.8 The following compounds are often found in chemical laboratories. Name each compound: (a) SiO_2 (silica); (b) SiC (carborundum); (c) N_2O (a general anesthetic); (d) P_4O_{10} (a drying agent for organic solvents); (e) CS_2 (a solvent); (f) SO_2 (a bleaching agent); (g) NH_3 (a common reagent).

D.9 The following aqueous solutions are common laboratory acids. What are their names? (a) HCl(aq); (b) H_2SO_4(aq); (c) HNO_3(aq); (d) CH_3COOH(aq); (e) H_2SO_3(aq); (f) H_3PO_4(aq).

D.10 The following acids are used in chemical laboratories, although they are less common than those in Exercise D.9. Write the formula of (a) perchloric acid; (b) hypochlorous acid; (c) hypoiodous acid; (d) hydrofluoric acid; (e) phosphorous acid; (f) periodic acid.

D.11 Write the formula for the ionic compound formed from (a) zinc and fluoride ions; (b) barium and nitrate ions; (c) silver and iodide ions; (d) lithium and nitride ions; (e) chromium(III) and sulfide ions.

D.12 Write the formula for the ionic compound formed from (a) calcium and bromide ions; (b) ammonium and phosphite ions; (c) cesium and oxide ions; (d) gallium and sulfide ions; (e) lithium and nitride ions.

D.13 (a) Write the formula for and name the compound formed when the element in Group 2, Period 6 of the periodic table combines with the element in Group 17/VII, Period 3. (b) Is the compound molecular or ionic?

D.14 (a) Write the formula for and name the compound formed when the element in Group 1, Period 5 of the periodic table combines with the element in Group 16/VI, Period 4. (b) Is the compound molecular or ionic?

D.15 Name each of the following compounds: (a) Na_2SO_3; (b) Fe_2O_3; (c) FeO; (d) $Mg(OH)_2$; (e) $NiSO_4\cdot 6H_2O$; (f) PCl_5; (g) $Cr(H_2PO_4)_3$; (h) As_2O_3; (i) $RuCl_2$.

D.16 Name each of the following compounds: (a) $CrBr_2\cdot 6H_2O$; (b) $Co(NO_3)_3\cdot 6H_2O$; (c) $InCl_3$; (d) BrF; (e) CrO_3; (f) $Cd(NO_2)_2$; (g) $Ca(ClO_3)_2$; (h) $Ni(ClO_2)_2$; (i) V_2O_5.

D.17 Each of the following compounds has an incorrect name. Correct each of the mistakes. (a) $CuCO_3$, copper(I) carbonate; (b) K_2SO_3, potassium sulfate; (c) LiCl, lithium chlorine.

D.18 Each of the following compounds has an incorrect formula. Correct each of the mistakes. (a) sodium sulfate, $NaSO_4$; (b) magnesium chlorite, $Mg(ClO)_2$; (c) phosphorus(V) oxide, P_2O_{10}.

D.19 Name each of the following organic compounds: (a) $CH_3CH_2CH_2CH_2CH_2CH_2CH_3$; (b) $CH_3CH_2CH_3$; (c) $CH_3CH_2CH_2CH_2CH_3$; (d) $CH_3CH_2CH_2CH_3$.

D.20 Name each of the following organic compounds: (a) CH_4; (b) CH_3F; (c) CH_3Br; (d) CH_3I.

D.21 You come across some old bottles in a storeroom that are labeled (a) cobaltic oxide monohydrate, (b) cobaltous hydroxide. Using Appendix 3C as a guide, write their modern names and chemical formulas.

D.22 The formal rules of chemical nomenclature result in a certain compound used for electronic components being called barium titanate(IV), in which the oxidation state of titanium is +4. See if you can work out its likely chemical formula. When you have identified the rules for naming oxoanions, suggest a formal name for H_2SO_4.

D.23 A main-group element E in Period 3 forms the molecular compound EH_4 and the ionic compound Na_4E. Identify element E and write the names of the compounds described.

D.24 A main-group element E in Period 5 forms the ionic compounds EBr_2 and EO. Identify element E and write the names of the compounds described.

D.25 The names of some compounds of hydrogen are exceptions to the usual rules of nomenclature. Look up the following compounds, write their names, and identify them as ionic or molecular: (a) $LiAlH_4$; (b) NaH.

D.26 The names of some compounds of oxygen are exceptions to the usual rules of nomenclature. Look up the following compounds, write their names, and identify them as ionic or molecular: (a) KO_2; (b) Na_2O_2; (c) CsO_3.

D.27 Name each of the following compounds, using analogous compounds with phosphorus and sulfur as a guide: (a) H_2SeO_4; (b) Na_3AsO_4; (c) $CaTeO_3$; (d) $Ba_3(AsO_4)_2$; (e) H_3SbO_4; (f) $Ni_2(SeO_4)_3$.

D.28 Name each of the following compounds, using analogous compounds with phosphorus and sulfur as a guide: (a) AsH_3; (b) H_2Se; (c) Cu_2TeO_4; (d) $Ca_3(AsO_3)_2$; (e) NaH_2SbO_4; (f) $BaSeO_3$.

D.29 What type of organic compound is (a) $CH_3CH_2CH_2OH$; (b) $CH_3CH_2CH_2CH_2COOH$; (c) CH_3F?

D.30 What type of organic compound is (a) $CH_3CH_2CH_3$; (b) CH_3CH_2Br; (c) CH_3CH_2COOH?

E MOLES AND MOLAR MASSES

E.1 The Mole
E.2 Molar Mass

Astronomically large numbers of molecules are present even in a tiny sample: even 1 mL of water contains 3×10^{23} H_2O molecules, more molecules than there are stars in the visible universe. How can we find out the numbers present and how do we report them? It is difficult to imagine and inconvenient to refer to large numbers such as 3×10^{23} molecules, just as wholesalers find it inconvenient to report individual items instead of dozens (12) or gross (144). To keep track of the enormous numbers of atoms, ions, or molecules in a sample, we need an efficient way of reporting them.

E.1 The Mole

Chemists report numbers of atoms, ions, and molecules in terms of a unit called a "mole." A mole is the analog of the wholesaler's "dozen." A "dozen" could be defined as the number of soda cans in a "twelve pack" carton supplied by a wholesaler. Even if you could not open the carton to count the number of cans inside, you could find out how many cans are in a dozen by weighing the carton and dividing the mass of the carton by the mass of one can. A similar approach is used to define the **mole** (abbreviated mol):

The name *mole* comes from the Latin word for "massive heap." Coincidentally, the animal of the same name makes massive heaps of soil on lawns.

> 1 mole of objects contains the same number of objects as there are atoms in exactly 12 g of carbon-12.

To see what we mean by 1 mol, we could weigh out 12 g of carbon-12 (Fig. E.1). But how can we tell how many atoms are present? Because counting atoms directly is impractical, we use an indirect route based on the mass of one atom. The mass of a carbon-12 atom has been found by mass spectrometry to be $1.992\,65 \times 10^{-23}$ g. It follows that the number of atoms in exactly 12 g of carbon-12 is

$$\text{Number of C atoms} = \frac{\overbrace{12\text{ g [exactly]}}^{\text{mass of sample}}}{\underbrace{1.992\,65 \times 10^{-23}\text{ g}}_{\text{mass of one C atom}}} = 6.0221 \times 10^{23}$$

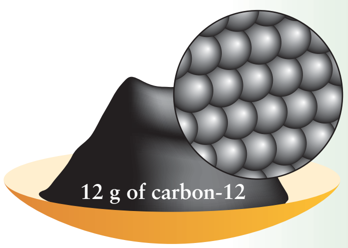


FIGURE E.1 The definition of the mole: if we measure out exactly 12 g of carbon-12, then we have exactly 1 mol of carbon-12 atoms. There will be exactly an Avogadro's number of atoms in the pile.

Because the mole is equal to this number, we can apply the definition to any object, not just carbon atoms (Fig. E.2):

> 1 mol of objects means 6.0221×10^{23} of those objects.

FIGURE E.2 Each sample consists of 1 mol of atoms of the element. Clockwise from the upper right are 32 g of sulfur, 201 g of mercury, 207 g of lead, 64 g of copper, and 12 g of carbon.

FIGURE E.3 Lorenzo Romano Amedeo Carlo Avogadro, Count of Quaregna and Cerreto (1776–1856).

Therefore, 1 mol of atoms of any element, 1 mol of ions, and 1 mol of molecules each contain 6.0221×10^{23} atoms, ions, and molecules, respectively.

Just as 1 g and 1 m are units for physical properties, so too is the unit 1 mol. The mole is the unit for the physical property formally called the **amount of substance,** n. However, that name has found little favor among chemists, who colloquially refer to n as "the number of moles." A compromise, which is gaining acceptance, is to refer to n as the "chemical amount" or simply "amount" of entities present in a sample. Thus, 1.0000 mol of hydrogen atoms (6.0221×10^{23} hydrogen atoms), which is written 1.0000 mol H, is the chemical amount of hydrogen atoms in the sample. Take the advice of your instructor on whether to use the formal term. Like any SI unit, the mole can be used with prefixes. For example, 1 mmol $= 10^{-3}$ mol and 1 μmol $= 10^{-6}$ mol. Chemists encounter such small quantities when dealing with rare or expensive natural products and pharmaceuticals.

The number of objects per mole, $6.0221 \times 10^{23}\ \text{mol}^{-1}$, is called **Avogadro's constant,** N_A, in honor of the nineteenth-century Italian scientist Amedeo Avogadro (Fig. E.3),who helped to establish the existence of atoms. Avogadro's constant is used to convert between the chemical amount (the number of moles) and the number of atoms, ions, or molecules in that amount:

$$\begin{aligned}\text{Number of objects} &= \text{amount in moles} \times \text{number of objects per mole}\\ &= \text{amount in moles} \times \text{Avogadro's constant}\end{aligned}$$

If we denote the number of objects by N and the amount of substance (in moles) by n, this relation is written

$$N = nN_A \qquad (\mathbf{1})^*$$

A note on good practice: Avogadro's constant is a constant with units, not a pure number. You will often hear people referring to *Avogadro's number*: this is the pure number 6.0221×10^{23}.

To be unambiguous when using moles, we must be specific about which entities (that is, which atoms, molecules, formula units, or ions) we mean. For example, hydrogen occurs naturally as a gas, with each molecule built from two atoms, which is why it is denoted H_2. We write 1 mol H if we mean hydrogen atoms or 1 mol H_2 if we mean hydrogen molecules. Note that 1 mol H_2 corresponds to 2 mol H.

EXAMPLE E.1 Converting number of atoms into an amount in moles

Nanotechnology researchers have developed a hydrogen storage device capable of storing 1.29×10^{24} hydrogen atoms. What is the chemical amount (in moles) of hydrogen atoms that can be stored in the device?

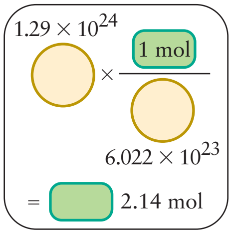
Anticipate Because the number of atoms in the sample is greater than 6×10^{23}, we anticipate that more than 1 mol of hydrogen atoms is present.

PLAN Rearrange Eq. 1 into $n = N/N_A$ and then substitute the data.

SOLVE

From $n = N/N_A$,

$$n = \frac{1.29 \times 10^{24}\ \text{H}}{6.0221 \times 10^{23}\ \text{mol}^{-1}} = 2.14\ \text{mol H}$$



Evaluate There is indeed more than 1 mol of hydrogen atoms present in the device, as we anticipated.

Self-Test E.1A A sample of a drug extracted from a fruit used by the Achuar Jivaro people of Peru to treat fungal infections is found to contain 2.58×10^{24} oxygen atoms. What is the chemical amount (in moles) of O atoms in the sample?

[***Answer:*** 4.28 mol O]

Self-Test E.1B A small cup of coffee contains 3.14 mol H_2O. What is the number of H atoms present in the coffee?

The amounts of atoms, ions, or molecules in a sample are expressed in moles, and Avogadro's constant, N_A, is used to convert between numbers of these particles and the numbers of moles.

E.2 Molar Mass

How can we determine the amount of substance present if we can't count the atoms directly? We can find the amount of substance if we know the mass of the sample and the **molar mass,** M, the mass per mole of particles:

The molar mass of an *element* is the mass per mole of its *atoms*.
The molar mass of a *molecular compound* is the mass per mole of its *molecules*.
The molar mass of an *ionic compound* is the mass per mole of its *formula units*.

The units of molar mass in each case are grams per mole ($\text{g}\cdot\text{mol}^{-1}$). The mass of a sample is the amount (in moles) multiplied by the mass per mole (the molar mass),

Mass of sample = amount in moles × mass per mole

Therefore, if we denote the total mass of the sample by m, we can write

$$m = nM \qquad (\mathbf{2})^*$$

It follows that $n = m/M$. That is, to find the amount in moles, n, we divide the total mass, m, of the sample by the molar mass of the species present.

EXAMPLE E.2 Calculating the amount of atoms in a sample

Calculate (a) the amount and (b) the number of F atoms in 22.5 g of fluorine. The molar mass of fluorine atoms is $19.00\ \text{g}\cdot\text{mol}^{-1}$, or, more specifically, $19.00\ \text{g}\cdot(\text{mol F})^{-1}$.

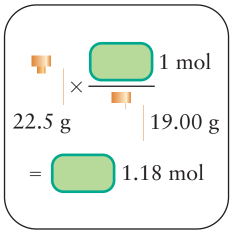
Anticipate Because the mass of fluorine present in the sample is greater than the mass of 1 mol F atoms, we should expect to find that more than 1 mol F is present.

PLAN To find the amount in moles, divide the total mass of the sample by the molar mass.

SOLVE

(a) From $n = m/M$,

$$n(\mathrm{F}) = \frac{22.5\ \mathrm{g}}{19.00\ \mathrm{g}\cdot(\mathrm{mol\ F})^{-1}} = \frac{22.5}{19.00}\ \mathrm{mol\ F}$$
$$= 1.18\ \mathrm{mol\ F}$$



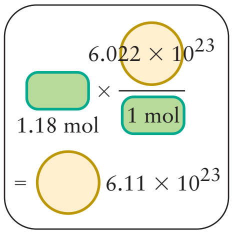
Evaluate As expected, more than 1 mol F is present.

A note on good practice: To avoid ambiguity, specify the entities (in this case, fluorine atoms, F, not F_2 molecules) in the units of the calculation.

(b) To calculate the actual number, N, of atoms in the sample, we multiply the amount (in moles) by Avogadro's constant:

From $N = nN_A$,

$$N = (1.18\ \mathrm{mol\ F}) \times (6.022 \times 10^{23}\ \mathrm{mol}^{-1})$$
$$= 7.11 \times 10^{23}\ \mathrm{F}$$



That is, the sample contains 7.11×10^{23} fluorine atoms.

Self-Test E.2A The mass of a copper coin is 3.20 g. Suppose it were pure copper. (a) How many moles of Cu atoms would the coin contain, given a molar mass of Cu of $63.55\ \mathrm{g \cdot mol^{-1}}$? (b) How many Cu atoms are present?

[***Answer:*** 0.0504 mol Cu; 3.03×10^{22} Cu atoms]

Self-Test E.2B In one day, 5.4 kg of aluminum was collected from a recycling bin. (a) How many moles of Al atoms did the bin contain, given that the molar mass of Al is $26.98\ \mathrm{g \cdot mol^{-1}}$? (b) How many Al atoms were collected?

The molar masses of elements are determined by using mass spectrometry to measure the masses of the individual isotopes and their abundances. The mass per mole of atoms is the mass of an individual atom multiplied by Avogadro's constant (the number of atoms per mole):

$$M = m_{\mathrm{atom}} N_A \qquad (3a)$$

The greater the mass of an individual atom, the greater the molar mass of the substance. However, most elements exist in nature as a mixture of isotopes. We saw in Section B, for instance, that neon exists as three isotopes, each with a different mass. In chemistry, we almost always deal with natural samples of elements, which have the natural abundance of isotopes. So, we need the *average* molar mass, the molar mass calculated by taking into account the masses of the isotopes and their relative abundances in typical samples:

$$M = m_{\mathrm{atom,\ average}} N_A \qquad (3b)$$

All molar masses quoted in this text refer to these average values. Their values are given in Appendix 2D. They are also included in the periodic table inside the front cover and in the alphabetical list of elements inside the back cover.

EXAMPLE E.3 Evaluating an average molar mass

Chlorine has two naturally occurring isotopes: chlorine-35 and chlorine-37. The mass of an atom of chlorine-35 is 5.807×10^{-23} g and that of an atom of chlorine-37 is 6.139×10^{-23} g. In a typical natural sample of chlorine, 75.77% of the sample is chlorine-35 and 24.23% is chlorine-37. What is the molar mass of a typical sample of chlorine?

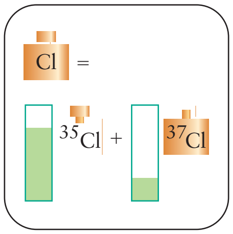
Anticipate Because the more abundant isotope is chlorine-35, we should expect to find that the molar mass of a typical sample will be close to 35 $\text{g}\cdot\text{mol}^{-1}$.

PLAN First calculate the average atomic mass of the isotopes by adding together the individual masses, each multiplied by the fraction that represents its abundance. Then obtain the molar mass, the mass per mole of atoms, by multiplying the average atomic mass by Avogadro's constant.

SOLVE The fraction (f) of chlorine-35 atoms in the sample is 75.77/100 = 0.7577, and the fraction of chlorine-37 is 24.23/100 = 0.2423. The average mass of an atom of chlorine in a natural sample is

From $m_{\text{atom, average}} = f_{\text{chlorine-35}} \times m_{\text{chlorine-35}} + f_{\text{chlorine-37}} \times m_{\text{chlorine-37}}$,

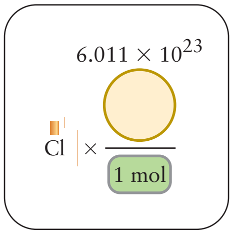
$$m_{\text{atom, average}} = 0.7577 \times (5.807 \times 10^{-23}\text{ g}) + 0.2423 \times (6.139 \times 10^{-23}\text{ g}) = 5.887 \times 10^{-23}\text{ g}$$



It follows from Eq. 3b that the molar mass of a typical sample of chlorine atoms is

From $M = m_{\text{atom, average}}N_A$,

$$\begin{aligned} M &= (5.887 \times 10^{-23}\text{ g}) \times (6.022 \times 10^{23}\text{ mol}^{-1}) \\ &= 35.45\ \text{g}\cdot\text{mol}^{-1} \end{aligned}$$



Evaluate As expected, the molar mass is close to 35 $\text{g}\cdot\text{mol}^{-1}$.

Self-Test E.3A In a typical sample of magnesium, 78.99% is magnesium-24 (with atomic mass 3.983×10^{-23} g), 10.00% is magnesium-25 (4.149×10^{-23} g), and 11.01% is magnesium-26 (4.315×10^{-23} g). Calculate the molar mass of a typical sample of magnesium, given the atomic masses (in parentheses).

[***Answer:*** 24.31 $\text{g}\cdot\text{mol}^{-1}$]

Self-Test E.3B Calculate the molar mass of copper, given that a natural sample typically consists of 69.17% copper-63, which has a molar mass of 62.94 $\text{g}\cdot\text{mol}^{-1}$, and 30.83% copper-65, which has a molar mass of 64.93 $\text{g}\cdot\text{mol}^{-1}$.

To calculate the molar masses of compounds, we use the molar masses of the elements present: *the molar mass of a compound is the sum of the molar masses of the elements that make up the molecule or the formula unit*. We need only note how many times each atom or ion appears in the molecular formula or the formula unit of the ionic compound. For example, 1 mol of the ionic compound $Al_2(SO_4)_3$ contains 2 mol Al, 3 mol S, and 12 mol O. Therefore, the molar mass of $Al_2(SO_4)_3$ is

$$\begin{aligned} M(Al_2(SO_4)_3) &= 2M(\text{Al}) + 3M(\text{S}) + 12M(\text{O}) \\ &= 2(26.98\ \text{g}\cdot\text{mol}^{-1}) + 3(32.06\ \text{g}\cdot\text{mol}^{-1}) + 12(16.00\ \text{g}\cdot\text{mol}^{-1}) \\ &= 342.14\ \text{g}\cdot\text{mol}^{-1} \end{aligned}$$

Self-Test E.4A Calculate the molar mass of (a) ethanol, C_2H_5OH; (b) copper(II) sulfate pentahydrate.

[***Answer:*** (a) 46.07 $g\cdot mol^{-1}$; (b) 249.69 $g\cdot mol^{-1}$]

Self-Test E.4B Calculate the molar mass of (a) phenol, C_6H_5OH; (b) sodium carbonate decahydrate.

Two terms used throughout the chemical literature are *atomic weight* and *molecular weight:*

For the most authoritative and up-to-date listing of atomic weights, see the IUPAC link on the Web site for this text.

> The **atomic weight** of an element is the numerical value of its molar mass.
> The **molecular weight** of a molecular compound or the **formula weight** of an ionic compound is the numerical value of its molar mass.

For instance, the atomic weight of hydrogen (molar mass 1.0079 $g\cdot mol^{-1}$) is 1.0079, the molecular weight of water (molar mass 18.02 $g\cdot mol^{-1}$) is 18.02, and the formula weight of sodium chloride (molar mass 58.44 $g\cdot mol^{-1}$) is 58.44. These three terms are traditional and deeply ingrained in chemical conversations, even though the numbers are not "weights." The mass of an object is a measure of the *quantity of matter* that it contains, whereas the weight of an object is a measure of the *gravitational pull* that it experiences. Mass and weight are proportional to each other, but they are not identical. An astronaut would have the same mass (contain the same quantity of matter) but different weights on Earth and on Mars.

A final point to keep in mind is that the "atomic weight" of an element allows us to make a good estimate of the numbers of protons and neutrons in its nuclei, because each proton and each neutron contribute close to one unit of mass to the atomic weight. Thus, we know that carbon, atomic weight 12.01, contains a total of 12 protons and neutrons. The atomic weight, however, is not exactly the mass number, because the mass of a nucleus is not exactly the sum of the masses of its protons and neutrons, and atomic weights (that is, molar masses) are averages that take into account the isotopic composition of typical samples of the element.

Once the molar mass of a compound has been calculated, we can use the same technique used for elements to determine how many moles of molecules or formula units are in a sample of a given mass.

Self-Test E.5A Calculate the amount of urea molecules, $OC(NH_2)_2$, in 2.3×10^5 g of urea, which is used in facial creams and, on a bigger scale, as an agricultural fertilizer.

[***Answer:*** 3.8×10^3 mol]

Self-Test E.5B Calculate the amount of $Ca(OH)_2$ formula units in 1.00 kg of slaked lime (calcium hydroxide), which is used to adjust the acidity of soils.

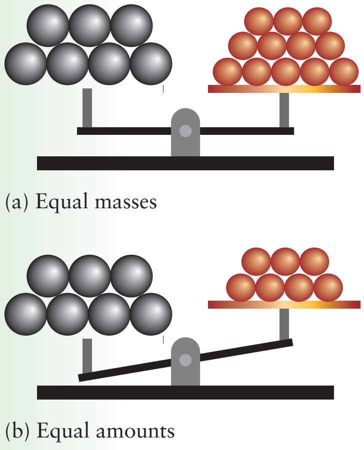


FIGURE E.4 (a) The two samples have the same mass but, because the atoms on the right are lighter than those on the left, more of them are required to balance the sample on the left. (b) The two samples contain the same number of atoms but, because the atoms on the right are lighter than those on the left, the mass of the sample on the right is the smaller of the two. Equal amounts (equal numbers of moles) of atoms do not necessarily have the same mass.

Molar mass is important when we need to know the number of atoms in a sample. It would be impossible to count out 6×10^{23} atoms of an element, but it is easy to measure out a mass equal to the molar mass of the element in grams. Each of the samples shown in Fig. E.2 was obtained in this way: each sample contains the same number of atoms of the element (6.022×10^{23}), but the masses vary because the masses of the atoms are different (Fig. E.4).The same rule applies to compounds. Because the molar mass of sodium chloride is 58.44 $g\cdot mol^{-1}$, if we measure out 58.44 g of sodium chloride, we obtain a sample that contains 1.000 mol NaCl formula units (Fig. E.5).

In practice, chemists rarely try to measure out an exact mass. Instead, they estimate the mass required and spoon out that mass approximately. Then they measure the mass of the sample precisely and convert it into an amount in moles (by using Eq. 2, $n = m/M$) to find the precise amount that they have obtained.

EXAMPLE E.4 Calculating the mass of a sample corresponding to a given amount in moles

Suppose we are preparing a solution of potassium permanganate, $KMnO_4$, and need about 0.10 mol of the compound (that is, 0.10 mol $KMnO_4$). How many grams of the compound do we need?

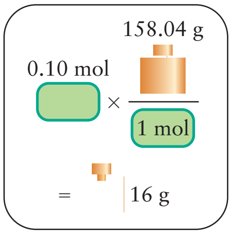
FIGURE E.5 Each sample contains 1 mol of formula units of an ionic compound. From left to right are 58 g of sodium chloride (NaCl), 100 g of calcium carbonate ($CaCO_3$), 278 g of iron(II) sulfate heptahydrate ($FeSO_4 \cdot 7H_2O$), and 78 g of sodium peroxide (Na_2O_2).

PLAN To find the mass of a stated amount of compound, we multiply the amount by the molar mass of the compound.

SOLVE To find the mass of $KMnO_4$ that corresponds to 0.10 mol $KMnO_4$, we note that, because the molar mass of the compound is 158.04 $g \cdot mol^{-1}$,

From $m = nM$,

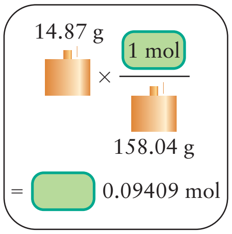
$$m = (0.10\ \text{mol}) \times (158.04\ \text{g}\cdot\text{mol}^{-1}) = 16\ \text{g}$$



So, we need to measure out about 16 g of $KMnO_4$. If, when we weigh the sample, we find that its actual mass is 14.87 g, the amount of $KMnO_4$ that we actually weighed out is

From $n = m/M$,

$$n(\text{KMnO}_4) = \frac{14.87\ \text{g}}{158.04\ \text{g}\cdot(\text{mol KMnO}_4)^{-1}} = 0.094\ 09\ \text{mol KMnO}_4$$



Self-Test E.6A What mass of anhydrous sodium hydrogen sulfate should you weigh out to obtain about 0.20 mol $NaHSO_4$?

[***Answer:*** About 24 g]

Self-Test E.6B What mass of acetic acid should you weigh out to obtain 1.5 mol CH_3COOH?

The molar mass of a compound, the mass per mole of its molecules or formula units, is used to convert between the mass of a sample and the amount of molecules or formula units that it contains.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Use Avogadro's constant to convert between amount in moles and the number of atoms, molecules, or ions in a sample (Examples E.1 and E.2).

❑ 2 Calculate the molar mass of an element, given its isotopic composition (Example E.3).

❑ 3 Calculate the molar mass of a compound, given its chemical formula.

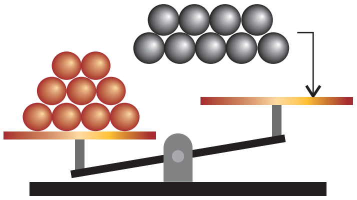
❑ 4 Convert between mass and amount in moles by using the molar mass (Example E.4).

EXERCISES

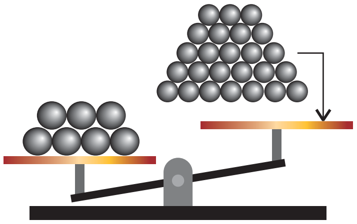
E.1 The field of nanotechnology offers some intriguing possibilities, such as the creation of fibers one atom wide. Suppose you were able to string together 1.00 mol Ag atoms, each of radius 144 pm, into one of these fibers by encapsulating them in carbon nanotubes (see Chapter 6). How long would the fiber extend?

E.2 If you won 1 mol of dollars in a lottery the day you were born, and spent 1 billion dollars a second for the rest of your life, what percentage of the prize money would remain, if any, when you decide to retire from spending at 90 years of age?

E.3 In a nanotechnology lab you might have the capability to manipulate individual atoms. The atoms on the left are bromine atoms (molar mass 80 $g\cdot mol^{-1}$), those on the right are atoms of calcium (molar mass 40 $g\cdot mol^{-1}$). How many calcium atoms would have to be added to the pan on the right for the masses on the two pans to be equal?



E.4 In a nanotechnology lab you might have the capability to manipulate individual atoms. The atoms on the left are aluminum atoms (molar mass 27 $g\cdot mol^{-1}$), those on the right are atoms of beryllium (molar mass 9 $g\cdot mol^{-1}$). How many beryllium atoms would have to be added to the pan on the right for the masses on the two pans to be equal?



E.5 (a) The approximate population of Earth is 6.0 billion people. How many moles of people inhabit Earth? (b) If all people were pea pickers, then how long would it take for the entire population of Earth to pick 1 mol of peas at the rate of one pea per second, working 24 hours per day, 365 days per year?

E.6 (a) One thousand tonnes (1000 t, 1 t = 10^3 kg) of sand contains about a trillion (10^{12}) grains of sand. How many tonnes of sand are needed to provide 1 mol of grains of sand? (b) Assuming the volume of a grain of sand is 1 mm^3 and the land area of the continental United States is 3.6×10^6 mi^2, how deep would the sand pile over the United States be if this area were evenly covered with 1 mol of grains of sand?

E.7 Epsom salts consist of magnesium sulfate heptahydrate. Write its formula. (a) How many atoms of oxygen are in 5.15 g of Epsom salts? (b) How many formula units of the compound are present in 5.15 g? (c) How many moles of water molecules are in 5.15 g of Epsom salts?

E.8 Copper metal can be extracted from a copper(II) sulfate solution by electrolysis (as described in Chapter 13). If 45.20 g of copper(II) sulfate pentahydrate, $CuSO_4\cdot 5H_2O$, is dissolved in 100mL of water and all the copper is electroplated out, what mass of copper would be obtained?

E.9 The nuclear power industry extracts ^{6}Li but not ^{7}Li from natural samples of lithium. As a result, the molar mass of commercial samples of lithium is increasing. The current abundances of the two isotopes are 7.42% and 92.58%, respectively, and the masses of their atoms are 9.988×10^{24} g and 1.165×10^{23} g, respectively. (a) What is the current molar mass of a natural sample of lithium? (b) What will the molar mass be when the abundance of ^{6}Li is reduced to 5.67%?

E.10 Calculate the molar mass of sulfur in a sample that consists of 95.0% ^{32}S (molar mass 31.97 $g\cdot mol^{-1}$), 0.8% ^{33}S (molar mass 32.97 $g\cdot mol^{-1}$), and 4.2% ^{34}S (molar mass 33.97 $g\cdot mol^{-1}$).

E.11 The molar mass of boron atoms in a natural sample is 10.81 $g\cdot mol^{-1}$. The sample is known to consist of ^{10}B (molar mass 10.013 $g\cdot mol^{-1}$) and ^{11}B (molar mass 11.093 $g\cdot mol^{-1}$). What are the percentage abundances of the two isotopes?

E.12 Calculate the molar mass of the noble gas krypton in a natural sample, which is 0.3% ^{78}Kr (molar mass 77.92 $g\cdot mol^{-1}$), 2.3% ^{80}Kr (molar mass 79.91 $g\cdot mol^{-1}$), 11.6% ^{82}Kr (molar mass 81.91 $g\cdot mol^{-1}$), 11.5% ^{83}Kr (molar mass 82.92 $g\cdot mol^{-1}$), 56.9% ^{84}Kr (molar mass 83.91 $g\cdot mol^{-1}$), and 17.4% ^{86}Kr (molar mass 85.91 $g\cdot mol^{-1}$).

E.13 Which sample in each of the following pairs contains the greater number of moles of atoms? (a) 75 g of indium or 80 g of tellurium; (b) 15.0 g of P or 15.0 g of S; (c) 7.36×10^{27} atoms of Ru or 7.36×10^{27} atoms of Fe.

E.14 Calculate the mass, in micrograms, of (a) 3.27×10^{16} Hg atoms; (b) 963 nmol Hf atoms; (c) 5.50 μmol Gd atoms; (d) 6.02×10^{25} Sb atoms.

E.15 A report stated that the Sudbury Neutrino Observatory in Sudbury, Canada, uses 1.00×10^3 tonne (1 t = 10^3 kg) of heavy water, D_2O, in a spherical tank of diameter 12 m to detect subatomic particles called neutrinos. The density of normal water (H_2O) at the temperature of the tank is 1.00 $g\cdot cm^{-3}$. (a) Using a molar mass for deuterium of 2.014 $g\cdot mol^{-1}$, calculate the molar mass of D_2O. (b) Assuming that the volume occupied by a D_2O molecule is the same as that occupied by an H_2O molecule, calculate the density of heavy water. (c) Calculate the volume of the tank in cubic meters from your density data and the given mass of the heavy water then compare this volume with the volume of the tank calculated from its reported diameter. (d) Is the reported mass of heavy water accurate? (e) Is the assumption you made in part (b) reasonable? Explain your reasoning. (The volume of a sphere of radius r is $V = \frac{4}{3}\pi r^3$.)

E.16 A chemist orders 1.000 kg of D_2O from an isotope supplier, who claims that the compound is 98% pure (that is, it contains no more than 2% H_2O by mass). To check this claim, the chemist measures the density of the D_2O and finds it to be 1.10 $g\cdot cm^{-3}$. The density of normal water (H_2O) at the temperature of the test is 1.00 $g\cdot cm^{-3}$. Is the D_2O as pure as advertised? (Molar mass of deuterium is 2.014 $g\cdot mol^{-1}$.)

E.17 Calculate the amount (in moles) and the number of molecules and formula units (or atoms, if indicated) in (a) 10.0 g of alumina, Al_2O_3; (b) 25.92 mg of hydrogen fluoride, HF; (c) 1.55 mg of hydrogen peroxide, H_2O_2; (d) 1.25 kg of glucose, $C_6H_{12}O_6$; (e) 4.37 g of nitrogen as N atoms and as N_2 molecules.

E.18 Convert each of the following masses into amount (in moles) and into number of molecules (and atoms, if indicated). (a) 2.40 kg of H_2O; (b) 49 kg of benzene (C_6H_6); (c) 260.0 g of phosphorus, as P atoms and as P_4 molecules; (d) 5.0 g of CO_2; (e) 5.0 g of NO_2.

E.19 Calculate the amount (in moles) of (a) Cu^{2+} ions in 3.00 g of $CuBr_2$; (b) SO_3 molecules in 7.00×10^2 mg of SO_3; (c) F^- ions in 25.2 kg of UF_6; (d) H_2O in 2.00 g of $Na_2CO_3 \cdot 10H_2O$.

E.20 Calculate the amount (in moles) of (a) CN^- in 4.00 g of NaCN; (b) O atoms in 4.00×10^2 ng of H_2O; (c) $CaSO_4$ in 4.00 kg of $CaSO_4$; (d) H_2O in 4.00 mg of $Al_2(SO_4)_3 \cdot 8H_2O$.

E.21 (a) Determine the number of KNO_3 formula units in 0.750 mol KNO_3. (b) What is the mass (in milligrams) of 2.39×10^{20} formula units of Ag_2SO_4? (c) Estimate the number of $NaHCO_2$ formula units in 3.429 g of $NaHCO_2$, sodium formate, which is used in dyeing and printing fabrics.

E.22 (a) How many CaH_2 formula units are present in 5.294 g of CaH_2? (b) Determine the mass of 6.25×10^{24} formula units of $NaBF_4$, sodium tetrafluoroborate. (c) Calculate the amount (in moles) of 9.54×10^{21} formula units of CeI_3, cerium(III) iodide, a bright yellow, water-soluble solid.

E.23 (a) Calculate the mass, in grams, of one water molecule. (b) Determine the number of H_2O molecules in 1.00 kg of water.

E.24 Octane, C_8H_{18}, is typical of the molecules found in gasoline. (a) Calculate the mass of one octane molecule. (b) Determine the number of C_8H_{18} molecules in 1.00 mL of octane, the mass of which is 0.82 g.

E.25 A chemist measured out 8.61 g of copper(II) chloride tetrahydrate, $CuCl_2 \cdot 4H_2O$. (a) How many moles of $CuCl_2 \cdot 4H_2O$ were measured out? (b) How many moles of Cl^- ions are present in the sample? (c) How many H_2O molecules are present in the sample? (d) What fraction of the total mass of the sample was due to oxygen?

E.26 Anhydrous copper(II) sulfate is difficult to dry completely. What mass of copper(II) sulfate would remain after removing 90% of the water from 250. g of $CuSO_4 \cdot 5H_2O$?

E.27 Suppose you had bought 2.5 kg of $Na_2CO_3 \cdot 10H_2O$ for \$175, instead of 2.5 kg of Na_2CO_3 for \$195. (a) How much water did you buy and how much did you pay per liter of water? (The mass of 1 L of water is 1 kg.) (b) What would have been a fair price for the hydrated compound, valuing water at zero cost?

E.28 A chemist wants to extract the gold from 57.75 g of gold(III) chloride dihydrate, $AuCl_3 \cdot 2H_2O$, by electrolysis of an aqueous solution (this technique is described in Chapter 13). What mass of gold could be obtained from the sample?

E.29 The king of Zirconia is naturally fond of the element zirconium and has established an independent definition of the mole based on zirconium. The mass of one zirconium-90 atom is 1.4929×10^{-22} g. If zirconium were the standard used for molar mass (instead of carbon-12), 1 mol would be defined as the amount of substance that contains the same number of entities as there are atoms in exactly 90 g of zirconium-90. In that case, what would be (a) the molar mass of carbon-12; (b) the (average) molar mass of gold?

E.30 The isotope silicon-28 has been proposed as a new standard for the molar masses of elements because it can be prepared to a very high degree of purity. The mass of one silicon-28 atom is 4.64567×10^{-23} g. If silicon were the standard used for molar mass (instead of carbon-12), 1 mol would be defined as the amount of substance that contains the same number of entities as there are atoms in exactly 28 g of silicon-28. In that case, what would be (a) the molar mass of carbon-12; (b) the (average) molar mass of chlorine?

E.31 The density of sodium borohydride is $1.074\ g \cdot cm^{-3}$. If 3.93 g of sodium borohydride contains 2.50×10^{23} H atoms, how many moles of H atoms are present in 28.0 cm^3 of sodium borohydride?

E.32 Chloroform is produced industrially from dichloroethane ($C_2H_4Cl_2$). Chloroform consists of molecules containing five atoms each and, at 20°C, has a density of $1.492\ g \cdot cm^{-3}$. Given that 0.250 mol of chloroform molecules occupies 20.0 mL, what mass (in grams) of dichloroethane contains the same number of atoms as 36.8 g of chloroform?

E.33 The decay of teeth can be slowed by the use of fluoridated toothpaste. The fluoride ions convert the hydroxyapatite, $Ca_5(PO_4)_3OH$, in tooth enamel into fluorapatite, $Ca_5(PO_4)_3F$. If all the hydroxyapatite is converted into fluorapatite, by what percentage does this conversion increase the mass of the enamel?

E.34 The antibiotic tetracycline has the formula $C_{22}H_{24}N_2O_8$. Safe dosage of the drug is 0.24 μmol/kg/day. If a child weighing 45 lb is administered tetracycline in four equally divided doses per day, what mass of tetracycline should be present in each dose?

F DETERMINATION OF CHEMICAL FORMULAS

F.1 Mass Percentage Composition
F.2 Determining Empirical Formulas
F.3 Determining Molecular Formulas

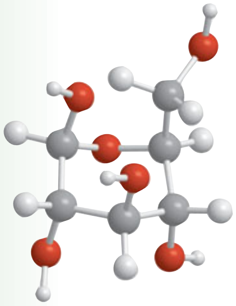
One way that scientists discover new drugs is by studying the properties of compounds found in plants or other materials that have been used as medicines for centuries (Fig. F.1). Once chemists have extracted a biologically active compound from a natural product, they try to identify its molecular structure so that it can be improved or manufactured in greater quantities. This section focuses on the first step in identifying the molecular structure, the determination of the "empirical formula" and the "molecular formula" of the compound.

First, consider the empirical formula:

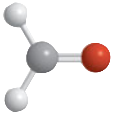
The **empirical formula** shows the relative numbers of atoms of each element present in the compound.

For example, the empirical formula of glucose, which is CH_2O, tells us that carbon, hydrogen, and oxygen atoms are present in the ratio 1:2:1. The elements are present in these proportions regardless of the size of the sample. After the empirical formula has been determined, the next step is to determine the molecular formula (Section C):

The **molecular formula** shows the actual numbers of atoms of each element in a molecule.



1 α-D-Glucose, $C_6H_{12}O_6$



2 Formaldehyde, CH_2O

The molecular formula for glucose, which is $C_6H_{12}O_6$, tells us that each glucose molecule consists of 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms (**1**, which shows one common configuration of the glucose molecule). In contrast, the empirical formula gives only the *ratios* of the numbers of atoms of each element. Therefore, different compounds with different molecular formulas can have the same empirical formula. For example, formaldehyde, CH_2O (**2**, the preservative in formalin solution), acetic acid, $C_2H_4O_2$ (the acid in vinegar), and lactic acid, $C_3H_6O_3$ (the acid in sour milk), all have the same empirical formula (CH_2O) as that of glucose, but are different compounds with different properties.

F.1 Mass Percentage Composition

To determine the empirical formula of a compound, we begin by measuring the mass of each element present in a sample. The result is usually reported as the **mass percentage composition**—that is, the mass of each element expressed as a percentage of the total mass:

$$\text{Mass percentage of element} = \frac{\text{mass of element in the sample}}{\text{total mass of sample}} \times 100\% \qquad (1)^*$$

Because the mass percentage composition is independent of the size of the sample—in the language of Section A, it is an intensive property—every sample of the substance has that same composition. A principal technique for determining the mass percentage composition of an unknown organic compound is "combustion analysis," which is described in Section M.

Self-Test F.1A For centuries, the Australian Aborigines have used the leaves of the eucalyptus tree to alleviate sore throats and other pains. The primary active ingredient has been identified and named eucalyptol. An analysis of a sample of eucalyptol of total mass 3.16 g gave its composition as 2.46 g of carbon, 0.373 g of hydrogen, and 0.329 g of oxygen. Determine the mass percentages of carbon, hydrogen, and oxygen in eucalyptol.

[***Answer:*** 77.8% C, 11.8% H, 10.4% O]

Self-Test F.1B The compound α-pinene, a natural antiseptic found in the resin of the piñon tree, has been used since ancient times by Zuni healers. A 7.50-g sample of α-pinene contains 6.61 g of carbon and 0.89 g of hydrogen. What are the mass percentages of carbon and hydrogen in α-pinene?

If the chemical formula of a compound is already known, its mass percentage composition can be obtained from the formula.

FIGURE F.1 The research vessel *Alpha Helix* is used by chemists at the University of Illinois at Urbana-Champaign to search for marine organisms that contain compounds of medicinal value. Compounds found to have antifungal or antiviral properties are then subjected to the kinds of analyses described in this section.

EXAMPLE F.1 Calculating the mass percentage of an element in a compound

Suppose we are generating hydrogen from water to use as a fuel and need to know the mass of hydrogen that a given mass of water can provide. What is the mass percentage of hydrogen in water?

Anticipate Even though there are two hydrogen atoms in each H_2O molecule, because hydrogen atoms are much lighter than oxygen atoms, they contribute only a small mass to each molecule and we should therefore expect only a small mass percentage contribution.

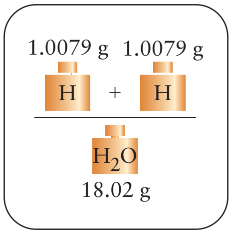
PLAN To calculate the mass percentage of hydrogen in water, find the mass of H atoms in 1 mol H_2O molecules by noting that there are 2 mol H in 1 mol H_2O, dividing that mass by the mass of 1 mol H_2O, and multiplying by 100%.

SOLVE

From mass percentage of

$$\text{H} = \frac{\text{mass of H atoms}}{\text{mass of } H_2O \text{ molecules}} \times 100\%,$$

$$\text{Mass percentage of H} = \frac{(2 \text{ mol}) \times (1.0079 \text{ g·mol}^{-1})}{(1 \text{ mol}) \times (18.02 \text{ g·mol}^{-1})} \times 100\%$$
$$= 11.19\%$$



Evaluate As expected, the mass percentage of hydrogen in water, 11.19%, is quite small.

Self-Test F.2A Calculate the mass percentage of Cl in NaCl.

[***Answer:*** 60.66%]

Self-Test F.2B Calculate the mass percentage of Ag in $AgNO_3$.

Mass percentage composition is found by calculating the fraction of the total mass contributed by each element present in a compound and expressing the fraction as a percentage.

F.2 Determining Empirical Formulas

Recall that an empirical formula gives the relative numbers of atoms of each element in the compound. To convert the mass percentages into an empirical formula, we must convert the mass percentage of each type of atom into the relative number of atoms of that element. The simplest procedure is to imagine that we have a sample with a mass of exactly 100 g. In this case the mass percentage composition gives the mass in grams of each element. Then we use the molar mass of each element to convert these masses into amounts in moles and go on to find the relative numbers of moles of each type of atom.

EXAMPLE F.2 Determining the elemental composition from mass percentage composition

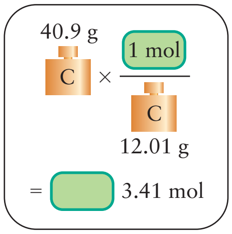
Suppose that an analytical laboratory reported a composition of 40.9% carbon, 4.58% hydrogen, and 54.5% oxygen for a sample of vitamin C. In what atom ratios are the elements present in vitamin C?

PLAN We consider a sample of exactly 100 g, then convert the masses into amounts in moles by dividing the mass percentage for each element by the element's molar mass. We denote the amount of a substance J by $n(\text{J})$.

SOLVE The mass of carbon in a sample of vitamin C of mass 100 g is 40.9 g. Because the molar mass of carbon is 12.01 g·mol^{-1},

From $n = m/M$,

$$n(\text{C}) = \frac{40.9 \text{ g}}{12.01 \text{ g·(mol C)}^{-1}} = 3.41 \text{ mol C}$$



Likewise, from the mass percentages of hydrogen and oxygen, we find

$$n(\text{H}) = 4.54 \text{ mol H} \quad \text{and} \quad n(\text{O}) = 3.41 \text{ mol O}$$

It follows that, in any sample of vitamin C, the atoms are present in the ratio

$$3.41 \text{ C} : 4.54 \text{ H} : 3.41 \text{ O}$$

Self-Test F.3A Pyrophosphoric acid has the composition 2.27% H, 34.81% P, and 62.93% O. Find the relative amounts of H, P, and O atoms present in pyrophosphoric acid.

[***Answer:*** 100 g contains 2.25 mol H, 1.12 mol P, and 3.93 mol O; 2.25 H : 1.12 P : 3.93 O]

Self-Test F.3B Use the information in Self-Test F.1A to find the relative amounts of C, H, and O atoms present in eucalyptol.

To find the empirical formula of vitamin C from the data in Example F.1 we must express the ratios of numbers of atoms as the simplest whole numbers. First, we divide each number by the smallest value (3.41), which gives a ratio of 1.00:1.33:1.00. Molecules contain only whole numbers of atoms, and one of these numbers is still not a whole number. Hence, we must multiply each number by the correct factor so that all numbers can be rounded off to whole numbers. Because 1.33 is $\frac{4}{3}$ (within experimental error), we multiply all three numbers by 3 to obtain 3.00:3.99:3.00, or approximately 3:4:3. Now we know that the empirical formula of vitamin C is $C_3H_4O_3$.

The calculated values are not exact, because they are derived from experimental data, which are subject to experimental error.

EXAMPLE F.3 Determining the empirical formula from mass percentage composition

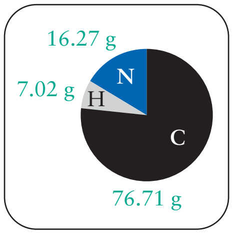
The mass percentage composition of a compound that assists in the coagulation of blood is 76.71% C, 7.02% H, and 16.27% N. Determine the empirical formula of the compound.

PLAN Divide each mass percentage by the molar mass of the corresponding element to obtain the number of moles of that element found in exactly 100 g of the compound. Divide the number of moles of each element by the smallest number of moles. If fractional numbers result, then multiply by the factor that gives the smallest whole numbers of moles.

SOLVE

The mass of each element X, $m(X)$, in exactly 100 g of the compound is equal to its mass percentage in grams.

$$m(C) = 76.71 \text{ g}$$
$$m(H) = 7.02 \text{ g}$$
$$m(N) = 16.27 \text{ g}$$

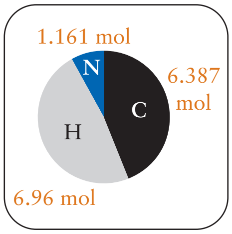


Convert each mass to an amount, $n(J)$, in moles by using the molar mass, $M(J)$, of the element, $n(J) = m(J)/M(J)$.

$$n(C) = \frac{76.71 \text{ g}}{12.01 \text{ g}\cdot(\text{mol C})^{-1}} = 6.387 \text{ mol C}$$

$$n(H) = \frac{7.02 \text{ g}}{1.0079 \text{ g}\cdot(\text{mol H})^{-1}} = 6.96 \text{ mol H}$$

$$n(N) = \frac{16.27 \text{ g}}{14.01 \text{ g}\cdot(\text{mol N})^{-1}} = 1.161 \text{ mol N}$$

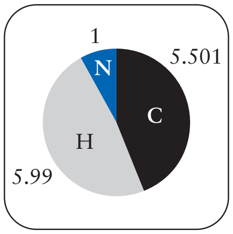


Divide each amount by the smallest amount (1.161 mol).

$$\text{Carbon: } \frac{6.387 \text{ mol}}{1.161 \text{ mol}} = 5.501$$

$$\text{Hydrogen: } \frac{6.96 \text{ mol}}{1.161 \text{ mol}} = 5.99$$

$$\text{Nitrogen: } \frac{1.161 \text{ mol}}{1.161 \text{ mol}} = 1.000$$



A note on good practice: Note that the number of significant figures in the data controls the number of significant figures in the calculated amounts.

Because 5.501 is approximately $^{11}/_{2}$, we multiply all the numbers by 2 to get the ratios 11.00:12.0:2.000. The empirical formula is therefore $C_{11}H_{12}N_2$.

Self-Test F4.A Use the molar composition of eucalyptol calculated in Self-Test F.3B to determine its empirical formula.

[***Answer:*** $C_{10}H_{18}O$]

Self-Test F.4B The mass percentage composition of the compound thionyl difluoride is 18.59% O, 37.25% S, and 44.16% F. Calculate its empirical formula.

The empirical formula of a compound is determined from the mass percentage composition and the molar masses of the elements present.

F.3 Determining Molecular Formulas

We have determined that the empirical formula of vitamin C is $C_3H_4O_3$. However, the empirical formula tells us only that the C, H, and O atoms are present in the sample in the ratio 3:4:3, not the number of each type of atom in a molecule. The molecular formula could be $C_3H_4O_3$, $C_6H_8O_6$, $C_9H_{12}O_9$, or any other whole-number multiple of the empirical formula.

To find the molecular formula of a compound, we need one more piece of information—its molar mass. Then all we have to do is to calculate how many empirical formula units are needed to account for the molar mass. One of the best ways of determining the molar mass of an organic compound is by mass spectrometry. We saw this technique applied to atoms in Section B. It can be applied to molecules, too; and, although there are important changes of detail (see Major Technique 6, following Chapter 18), the technique is essentially the same.

EXAMPLE F.4 Determining the molecular formula from the empirical formula

Mass spectrometry has been used to show that the molar mass of vitamin C is 176.12 g·mol^{-1}. Given its empirical formula of $C_3H_4O_3$, what is the molecular formula of vitamin C?

PLAN To find the number of formula units needed to account for the observed molar mass of a compound, divide the molar mass of the compound by the molar mass of the empirical formula unit.

SOLVE

The molar mass of a $C_3H_4O_3$ formula unit is

$$\text{Molar mass of } C_3H_4O_3 = 3 \times (12.01\ \text{g·mol}^{-1}) + 4 \times (1.008\ \text{g·mol}^{-1}) + 3 \times (16.00\ \text{g·mol}^{-1})$$
$$= 88.06\ \text{g·mol}^{-1}$$

Dividing the molar mass of the compound by the molar mass of the empirical formula unit yields the factor by which we must multiply the coefficients in the empirical formula to obtain the molecular formula:

$$\frac{\text{Molar mass of compound}}{\text{Molar mass of empirical formula unit}} = \frac{176.14\ \text{g·mol}^{-1}}{88.06\ \text{g·mol}^{-1}} = 2.000$$

We conclude that the molecular formula of vitamin C is $2 \times (C_3H_4O_3)$, or $C_6H_8O_6$.

Self-Test F.5A The molar mass of styrene, which is used in the manufacture of the plastic polystyrene, is 104 $g \cdot mol^{-1}$, and its empirical formula is CH. Deduce its molecular formula.

[***Answer:*** C_8H_8]

Self-Test F.5B The molar mass of oxalic acid, an acid present in rhubarb, is 90.0 $g \cdot mol^{-1}$, and its empirical formula is CHO_2. What is its molecular formula?

The molecular formula of a compound is found by determining how many empirical formula units are needed to account for the measured molar mass of the compound.

SKILLS YOU SHOULD HAVE MASTERED

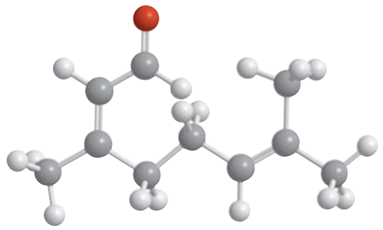
❑ 1 Calculate the mass percentage of an element in a compound from a formula (Example F.1).

❑ 2 Calculate the empirical formula of a compound from its mass percentage composition (Example F.3).

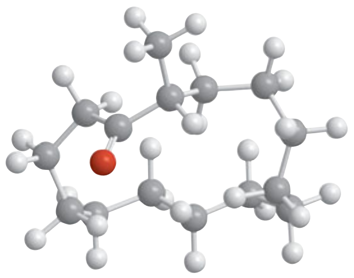
❑ 3 Determine the molecular formula of a compound from its empirical formula and its molar mass (Example F.4).

EXERCISES

F.1 Citral is a fragrant component of lemon oil that is used in colognes. It has the molecular structure shown. Calculate the mass percentage composition of citral (gray = C, white = H, red = O).



F.2 The compound mainly responsible for the odor of musk produced by musk deer is muscone, which has the molecular structure shown. Calculate the mass percentage composition of muscone (gray = C, white = H, red = O).



F.3 What is the mass percentage composition of L-carnitine, $C_7H_{15}NO_3$, a compound that is taken as a dietary supplement to reduce muscle fatigue?

F.4 What is the mass percentage composition of sucralose, $C_{12}H_{19}Cl_3O_8$, a chlorinated derivative of sucrose (table sugar) that has an enhanced sweetness and is used as an artificial sweetener?

F.5 A metal M forms an oxide with the formula M_2O, for which the mass percentage of the metal is 88.8%. (a) What is the molar mass of the metal? (b) Write the name of the compound.

F.6 A metal M forms an oxide with the formula M_2O_3, for which the mass percentage of the metal is 69.9%. (a) What is the identity of the metal? (b) Write the name of the compound.

F.7 Determine the empirical formulas from the following analyses. (a) The mass percentage composition of cryolite, a compound used in the production of aluminum, is 32.79% Na, 13.02% Al, and 54.19% F. (b) A compound used to generate O_2 gas in the laboratory has mass percentage composition 31.91% K and 28.93% Cl, the remainder being oxygen. (c) A fertilizer is found to have the following mass percentage composition: 12.2% N, 5.26% H, 26.9% P, and 55.6% O.

F.8 Determine the empirical formula of each of the following compounds from the data given. (a) Talc (used in talcum powder) has mass composition 19.2% Mg, 29.6% Si, 42.2% O, and 9.0% H. (b) Saccharin, a sweetening agent, has mass composition 45.89% C, 2.75% H, 7.65% N, 26.20% O, and 17.50% S. (c) Salicylic acid, used in the synthesis of aspirin, has mass composition 60.87% C, 4.38% H, and 34.75% O.

F.9 In an experiment, 4.14 g of phosphorus combined with chlorine to produce 27.8 g of a white solid compound. (a) What is the empirical formula of the compound? (b) Assuming that the empirical and molecular formulas of the compound are the same, what is its name?

F.10 A chemist found that 4.69 g of sulfur combined with fluorine to produce 15.81 g of a gas. (a) What is the empirical formula of the gas? (b) Assuming that the empirical and molecular formulas of the compound are the same, what is its name?

F.11 Diazepam, a drug used to treat anxiety, is 67.49% C, 4.60% H, 12.45% Cl, 9.84% N, and 5.62% O. What is the empirical formula of the compound?

F.12 The compound fluoxetine is sold as Prozac when combined with HCl. Fluoxetine has the composition 66.01% C, 5.87% H, 18.43% F, 4.53% N, and 5.17% O. What is the empirical formula of fluoxetine?

F.13 Osmium forms a molecular compound with mass percentage composition 15.89% C, 21.18% O, and 62.93% Os. (a) What is the empirical formula of this compound? (b) From the mass spectrum of the compound, the molecule was determined to have a molar mass of 907 $g \cdot mol^{-1}$. What is its molecular formula?

F.14 Paclitaxel, which is extracted from the Pacific yew tree *Taxus brevifolia*, has antitumor activity for ovarian and breast cancer. It is sold under the trade name Taxol. On analysis, its mass percentage composition is 66.11% C, 6.02% H, and 1.64% N, with the balance being oxygen. What is the empirical formula of paclitaxel?

F.15 Caffeine, a stimulant in coffee and tea, has a molar mass of 194.19 $g \cdot mol^{-1}$ and a mass percentage composition of 49.48% C, 5.19% H, 28.85% N, and 16.48% O. What is the molecular formula of caffeine?

F.16 A sample of a pungent compound was extracted from skunk spray. Upon analysis the 2.00-mg sample was found to have the following composition: 1.09 mg C, 0.183 mg H, and 0.727 mg S. The molar mass of the compound was found to be 88.17 $g \cdot mol^{-1}$. What is the molecular formula of this compound?

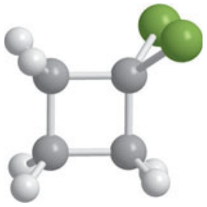
F.17 In 1978, scientists extracted a compound with antitumor and antiviral properties from marine animals in the Caribbean Sea. A sample of the compound didemnin-A of mass 1.78 mg was analyzed and found to have the following composition: 1.11 mg C, 0.148 mg H, 0.159 mg N, and 0.363 mg O. The molar mass of didemnin-A was found to be 942 $g \cdot mol^{-1}$. What is the molecular formula of didemnin-A?

F.18 A sample of the fungicide chloranil of mass 1.50 mg was found to have the following composition: 0.440 mg C, 0.865 mg Cl, and 0.195 mg O. The molar mass of chloranil is 245.88 $g \cdot mol^{-1}$. What is the molecular formula of chloranil?

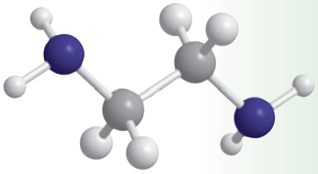
F.19 The CO_2 produced by the combustion of hydrocarbons contributes to global warming. Rank the following fuels according to increasing mass percentage of carbon: (a) ethene, C_2H_4; (b) propanol, C_3H_7OH; (c) heptane, C_7H_{16}.

F.20 Dolomite is a mixed carbonate of calcium and magnesium. Calcium and magnesium carbonates both decompose on heating to produce the metal oxides (MgO and CaO) and carbon dioxide (CO_2). If 4.84 g of residue consisting of MgO and CaO remains when 9.66 g of dolomite is heated until decomposition is complete, what percentage by mass of the original sample was $MgCO_3$?

F.21 In the following ball-and-stick molecular structures, gray indicates carbon, white hydrogen, blue nitrogen, and green chlorine. Write the empirical and molecular formulas of each structure. *Hint*: It may be easier to write the molecular formula first.

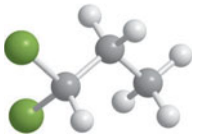


(a)

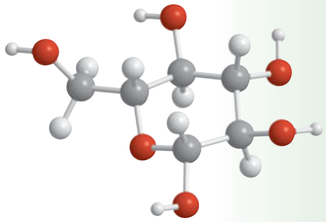


(b)

F.22 Write the empirical and molecular formulas of each ball-and-stick structure. Gray indicates carbon, white hydrogen, red oxygen, and green chlorine. *Hint*: It may be easier to write the molecular formula first.



(a)



(b)

F.23 A mixture of $NaNO_3$ and Na_2SO_4 of mass 5.37 g contains 1.61 g of sodium. What is the percentage by mass of $NaNO_3$ in the mixture?

F.24 A mixture of KBr and K_2S of mass 8.02 g contains 4.50 g of potassium. What is the percentage by mass of KBr in the mixture?

G MIXTURES AND SOLUTIONS

G.1 Classifying Mixtures
G.2 Separation Techniques
G.3 Concentration
G.4 Dilution

So far, we have discussed only pure substances. However, most materials are neither pure elements nor pure compounds, and so they are not "substances" in the technical sense of the term (Section A); they are **mixtures** of these simpler substances, with one substance mingled with another. For example, air, blood, and seawater are mixtures. A medicine, such as a cough syrup, is often a mixture of various ingredients that has been formulated to achieve an overall biological effect. Much the same can be said of a perfume.

Chemists need to be able to specify the composition of mixtures *quantitatively*. For example, a chemist may need to monitor a pollutant, administer a dosage, or transfer a known amount of a solute. In this section we examine the properties and types of mixtures as well as how to use the "molar concentration" of a dissolved substance to analyze solutions quantitatively.

G.1 Classifying Mixtures

A compound has a fixed composition, whereas the composition of a mixture may be varied. There are always two H atoms for each O atom in a sample of the compound water, but sugar and sand, for instance, can be mixed in any proportions. Because the

FIGURE G.1 This piece of granite is a heterogeneous mixture of several substances.

TABLE G.1 Differences Between Mixtures and Compounds

Mixture	Compound
components can be separated by using physical techniques	components cannot be separated by using physical techniques
composition is variable	composition is fixed
properties are related to those of its components	properties are unlike those of its components

components of a mixture are merely mingled with one another, they retain their own chemical properties in the mixture. In contrast, a compound has chemical properties that differ from those of its component elements. The formation of a mixture is a *physical* change, whereas the formation of a compound requires a *chemical* change. The differences between mixtures and compounds are summarized in Table G.1.

Some mixtures have component particles that are so large we can see them with an optical microscope or even the unaided eye (Fig. G.1). Such a patchwork of different substances is called a **heterogeneous mixture**. Many of the rocks that form the landscape are heterogeneous mixtures of crystals of different minerals. Milk, which looks like a pure substance, is in fact a heterogeneous mixture: through a microscope, we can see the individual globules of butterfat floating in a liquid that is largely water. Human bodies are heterogeneous mixtures of thousands of compounds.

In some mixtures, the molecules or ions of the components are so well mixed that the composition is the same throughout, no matter how small the sample. Such a mixture is called a **homogeneous mixture** (Fig. G.2). For example, syrup is a homogeneous mixture of sugar and water. The molecules of sugar are dispersed and mixed so thoroughly with the water that we cannot see separate regions or particles. Even when using a microscope, we cannot distinguish between a pure substance and a homogeneous mixture.

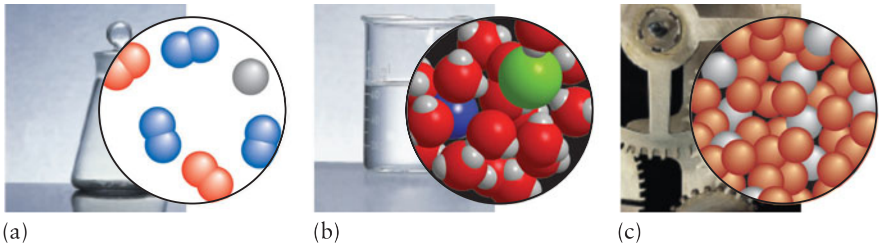


FIGURE G.2 Three examples of homogeneous mixtures. (a) Air is a homogeneous mixture of many gases, including the nitrogen, oxygen, and argon depicted here. (b) Table salt dissolved in water consists of sodium ions and chloride ions among water molecules. (c) Many alloys are solid homogeneous mixtures of two or more metals. The insets show that the mixing is uniform at the molecular level.

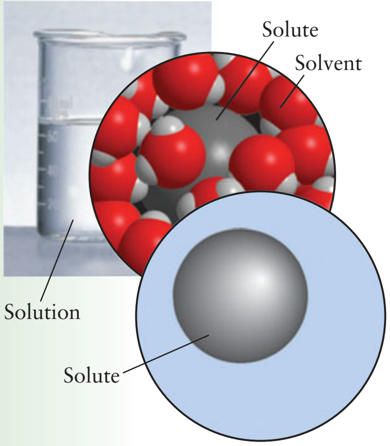

FIGURE G.3 Solutions are homogeneous mixtures in which one substance, the solvent (here water), is usually in large excess. A dissolved substance is called a solute. The inset shows only the solute particles.

A homogeneous mixture is also called a **solution.** Many of the materials around us are solutions. Root beer is a solution consisting mostly of water, along with sugar, plant extracts, and various additives. Filtered seawater is a solution of common table salt (sodium chloride) and many other substances in water. Although a solution looks uniform in composition, the components that form it retain their identities. Forming a solution is a physical change, not a chemical change.

When we use the everyday term *dissolving*, we mean the process of producing a solution. Usually the component of the solution present in the larger amount (water in these examples) is called the **solvent,** and any dissolved substance is a **solute** (Fig. G.3). However, if we want to emphasize the role of one of the substances as the one that the others are "dissolved in," we may identify that substance as the solvent. For example, in a thick syrup, the sugar may be present in a much greater amount than the water, but water is considered the solvent. Normally, the solvent determines the physical state of the solution (whether it is a solid, a liquid, or a gas).

Crystallization takes place when the solute slowly comes out of solution as crystals, perhaps as the solvent evaporates. For example, salt crystals that form when water evaporates line the shores of the Great Salt Lake in Utah. In **precipitation,** a solute

comes out of solution so rapidly that a single crystal does not have time to form. Instead, the solute forms a finely divided powder called a precipitate. Precipitation is often almost instantaneous (Fig. G.4).

Beverages and seawater are examples of **aqueous solutions,** solutions in which the solvent is water. Aqueous solutions are very common in everyday life and in chemical laboratories; for that reason, most of the solutions mentioned in this text are aqueous. **Nonaqueous solutions** are solutions in which the solvent is not water. Although they are less common than aqueous solutions, nonaqueous solutions have important uses. In "dry cleaning," the grease and dirt on fabrics are dissolved in a nonaqueous liquid solvent such as tetrachloroethene, C_2Cl_4. There are also **solid solutions,** in which the solvent is a solid. An example is a common form of brass that can be regarded as a solution of zinc in copper. Although gaseous solutions exist, they are normally referred to as gaseous mixtures. The atmosphere could be regarded as a vast gaseous solution of various substances in nitrogen, its major component, but it is normally termed a gaseous mixture.

In mixtures, the properties of the constituents are retained; they differ from compounds, as summarized in Table G.1. Mixtures are classified as homogeneous or heterogeneous; solutions are homogeneous mixtures of two or more substances and can be solid, liquid, or gaseous.

FIGURE G.4 Precipitation occurs when an insoluble substance is formed. Here lead(II) iodide, PbI_2, which is an insoluble yellow solid, precipitates when we mix solutions of lead(II) nitrate, $Pb(NO_3)_2$, and potassium iodide, KI.

Lab Video G.4

G.2 Separation Techniques

Natural products, such as enzymes and vitamins, are almost invariably extracted from mixtures. To analyze the composition of any sample that we suspect is a mixture, we first separate its components by physical means and then identify each individual substance present (Fig. G.5). Common physical separation techniques include decanting, filtration, chromatography, and distillation.

Decanting makes use of differences in density. One liquid floats on another liquid or lies above a solid and is poured off. **Filtration** is used to separate substances when there is a difference in solubility (the ability to dissolve in a particular solvent). The sample is stirred with a liquid and then poured through a fine mesh, the filter. Components of the mixture that have dissolved in the liquid pass through the filter, whereas solid components that do not dissolve are captured by the filter. The technique can be used to separate sugar from sand because sugar is soluble in water but sand is not. Filtration is a common first stage in the treatment of domestic water supplies. A related technique, one of the most sensitive techniques available for separating a mixture, is **chromatography,** which relies on the different abilities of substances to **adsorb,** or stick, to surfaces (Fig. G.6). Chromatography is discussed in detail in Major Technique 5, following Chapter 8.

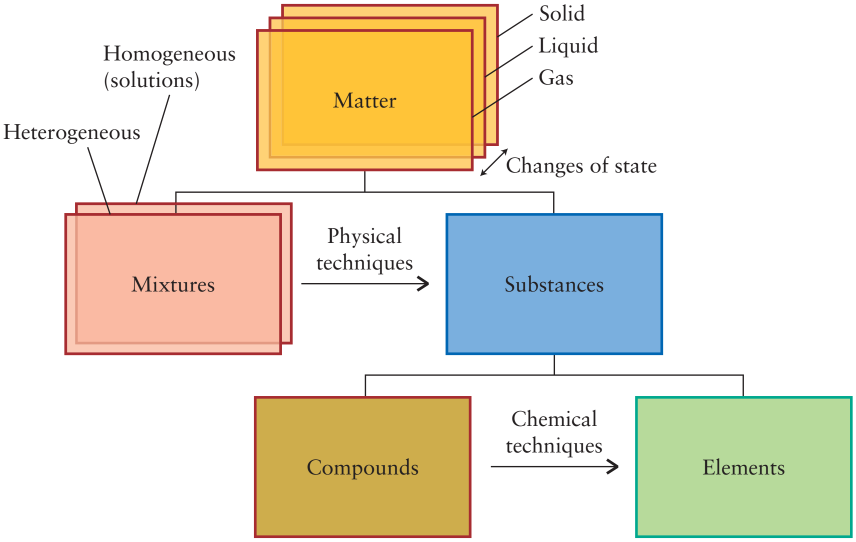

FIGURE G.5 The hierarchy of materials: matter, whether solid, liquid, or gas, consists of either mixtures or substances; substances consist of either compounds or elements. Physical techniques are used to separate mixtures into pure substances. Chemical techniques are used to separate compounds into elements.

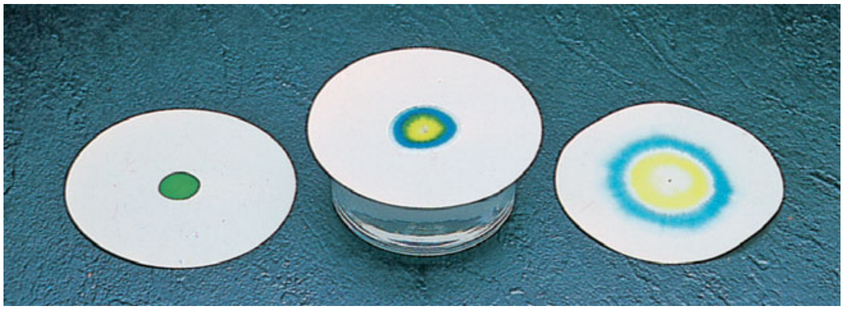

FIGURE G.6 In paper chromatography, the components of a mixture are separated by washing them along a paper—the support—with a solvent. A primitive form of the technique is shown here. On the left is a dry filter paper to which a drop of green food coloring was applied. Solvent was then poured on to the center of the filter paper. The blue and yellow dyes that were combined to make the green color begin to separate. The filter paper on the right was allowed to dry after the solvent had spread out to the edges of the paper, carrying the two dyes to different distances as it spread. The dried support showing the separated components of a mixture is called a chromatogram.

The first known distillation apparatus, assembled in the first century CE, is attributed to Mary the Jewess, an alchemist who lived in the Middle East.

Distillation makes use of differences in boiling points to separate mixtures. When a solution is distilled, the components of the mixture boil away at different temperatures and condense in a cooled tube called a *condenser* (Fig. G.7). Distillation can be used to remove water (which boils at 100°C) from table salt (sodium chloride), which does not even melt until 801°C; the solid salt is left behind when the water evaporates.

Mixtures are separated by making use of the differences in physical properties of the components; common techniques based on physical differences include decanting, filtration, chromatography, and distillation.

G.3 Concentration

In Section F we saw that the composition of a compound could be expressed in terms of the mass percentage of each element. Similarly, we can express the composition of a mixture as the mass percentage of each component, the mass of each component in a total of 100 grams of the mixture. For example, if we were to dissolve 15 g NaCl in 60. g water, the total mass of the mixture is 75 g and the percentage of NaCl in the solution is (15 g/75 g) × 100% = 20.% NaCl. If we made up a sample containing 30. g of that solution, that sample would have the same composition, 20.% NaCl by mass, and would therefore contain 6.0 g NaCl.

The formal name for molarity is the "amount of substance concentration."

In chemistry it is often important to know the amount of solute in a given volume of solution. The **molar concentration**, c, of a solute in a solution, which is widely but unofficially called the "molarity" of the solute, is the amount of solute molecules or formula units (in moles) present in a given volume of the solution (in liters):

$$\text{Molarity} = \frac{\text{amount of solute (in moles)}}{\text{volume of solution (in liters)}} \quad \text{or} \quad c = \frac{\overbrace{n}^{\text{mol}}}{\underbrace{V}_{\text{L}}} \qquad (1)$$

The units of molarity are moles per liter ($\text{mol}\cdot\text{L}^{-1}$), often denoted M:

$$1\ \text{M} = 1\ \text{mol}\cdot\text{L}^{-1}$$

The symbol M is often read "molar"; it is not an SI unit. Note that $1\ \text{mol}\cdot\text{L}^{-1}$ is the same as $1\ \text{mmol}\cdot\text{mL}^{-1}$. Chemists working with very low concentrations of solutes also report molar concentrations as millimoles per liter ($\text{mmol}\cdot\text{L}^{-1}$) and micromoles per liter ($\mu\text{mol}\cdot\text{L}^{-1}$).

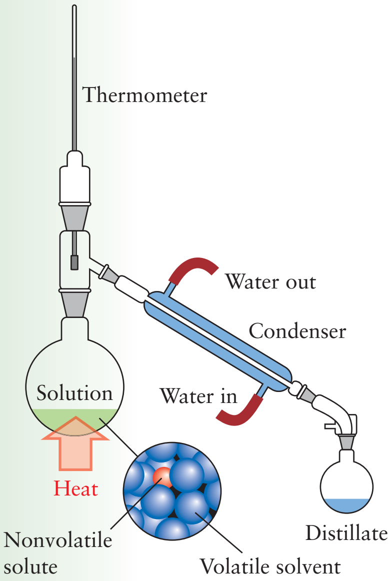

FIGURE G.7 The technique of distillation, which is used to separate a low-boiling liquid from a dissolved solid or a liquid with a much higher boiling point. When the solution is heated, the low-boiling liquid boils off, condenses in the water-jacketed tube (the condenser), and is collected as the distillate.

EXAMPLE G.1 Calculating the molarity of a solute

Suppose we dissolved 10.0 g of cane sugar in enough water to make 200. mL of solution, which we might do (with less precision) if we were making a glass of lemonade. Cane sugar is sucrose ($C_{12}H_{22}O_{11}$, molar mass = $342\ \text{g}\cdot\text{mol}^{-1}$). What is the molarity of sucrose in the solution?

Anticipate The mass of sugar is only about 3% of the mass of 1 mole of sugar; therefore, although only 0.200 L is being prepared, we should expect a small concentration.

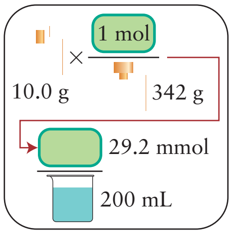
PLAN The definition of molar concentration (molarity) is $c = n/V$; we first need to convert the mass of solute to an amount in moles (by using $n = m/M$) and then substitute that amount into this expression for c.

SOLVE

From $c = n/V$ and $n = m/m$,

$$c = \frac{\overbrace{(10.0\ \text{g})/(342\ \text{g}\cdot\text{mol}^{-1})}^{n=m/M}}{\underbrace{0.200\ \text{L}}_{V}}$$

$$= \frac{10.0\ \text{g}}{(342\ \text{g}\cdot\text{mol}^{-1}) \times (0.200\ \text{L})} = 0.146\ \text{mol}\cdot\text{L}^{-1}$$



Evaluate The molar concentration, which we report as 0.146 M $C_{12}H_{22}O_{11}$(aq), is small, as expected.

A note on good practice: Note that we refer to the molarity of the solute, not the molarity of the solution.

Self-Test G.1A If instead of 10.0 g, we were to dissolve 20.0 g of cane sugar in the same volume of solution, what would be the molarity of the sugar?

[***Answer:*** 0.292 M $C_{12}H_{22}O_{11}$(aq)]

Self-Test G.1B What is the molarity of sodium sulfate in a solution prepared by dissolving 15.5 g of sodium sulfate in enough water to make 350. mL of solution?

Because molarity is defined in terms of the *volume of the solution*, not the volume of solvent used to prepare the solution, the volume must be measured after the solutes have been added. The usual way to prepare an aqueous solution of a solid substance of given molarity is to transfer a known mass of the solid into a **volumetric flask,** a flask calibrated to contain a specified volume, dissolve it in a little water, fill the flask up to the mark with water, and then mix the solution thoroughly by tipping the flask end over end (Fig. G.8).

To use the molarity of a solution to calculate the amount of solute in a given volume of solution, we use Eq. 1 rearranged into

$$\overbrace{n}^{\text{mol}} = \overbrace{c}^{\text{mol}\cdot\text{L}^{-1}} \times \overbrace{V}^{\text{L}} \qquad (2)$$

where c is the molarity, V is the volume, and n is the amount. Because we can convert moles into mass by using the molar mass of the solute, we can also use this formula to estimate the mass of solute needed to make up a given volume of solution of known concentration.

FIGURE G.8 The steps in making up a solution of known molarity. A known mass of the solute is dispensed into a volumetric flask (top). Some water is added to dissolve it (center). Finally, water is added up to the mark on the stem of the flask (bottom). The bottom of the solution's meniscus (the curved top surface of the liquid) should be level with the mark.

EXAMPLE G.2 Determining the mass of solute required for a given concentration

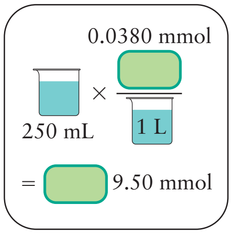
Suppose we were asked to prepare 250. mL of a solution that was approximately 0.0380 M $CuSO_4$(aq) from solid copper(II) sulfate pentahydrate, $CuSO_4\cdot 5H_2O$. What mass of the solid do we need?

PLAN Find the amount of solute from the relation $n = cV$, then convert moles of solute to grams by using $m = nM$.

SOLVE First we need to know the amount of $CuSO_4$ in 250. mL (0.250 L) of solution:

From $n = cV$,

$$n(\text{CuSO}_4) = (0.0380\ \text{mol}\cdot\text{L}^{-1}) \times (0.250\ \text{L})$$
$$= 0.0380 \times 0.250\ \text{mol} = 0.009\ 50\ \text{mol}$$



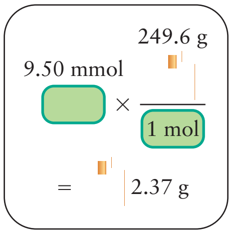
Because 1 mol $CuSO_4{\cdot}5H_2O$ contains 1 mol $CuSO_4$, the amount of $CuSO_4{\cdot}5H_2O$ we need to supply is the same as the amount of $CuSO_4$ needed to prepare the solution. That is,

$$n(CuSO_4{\cdot}5H_2O) = n(CuSO_4) = 0.009\ 50\ \text{mol}$$

Then, because the molar mass of copper(II) sulfate pentahydrate is 249.6 $g{\cdot}mol^{-1}$, we calculate the mass of the pentahydrate that we need to supply as follows.

From $m = nM$,

$$m(CuSO_4{\cdot}5H_2O) = (0.009\ 50\ \text{mol}) \times (249.6\ g{\cdot}mol^{-1}) = 2.37\ g$$



We conclude that we need about 2.37 g of copper(II) sulfate pentahydrate. In practice, we might find that we had measured out 2.403 g, in which case the molarity would be 0.0385 M $CuSO_4(aq)$.

Self-Test G.2A Calculate the mass of glucose needed to prepare 150. mL of 0.442 M $C_6H_{12}O_6(aq)$.

[***Answer:*** 11.9 g]

Self-Test G.2B Calculate the mass of oxalic acid needed to prepare 50.00 mL of 0.125 M $C_2H_2O_4(aq)$.

The molarity is also used to calculate the volume of solution, V, that contains a given amount of solute. For this type of calculation, we rearrange Eq. 1 into

$$\overbrace{V}^{\text{L}} = \frac{\overbrace{n}^{\text{mol}}}{\underbrace{c}_{\text{mol}\cdot\text{L}^{-1}}} \qquad (3)$$

and then substitute the data.

EXAMPLE G.3 Calculating the volume of solution that contains a given amount of solute

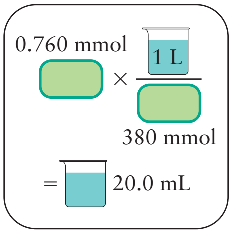
Suppose we want to measure out 0.760 mmol CH_3COOH, acetic acid, an acid found in vinegar and often used in the laboratory, and we have available 0.0380 M $CH_3COOH(aq)$. What volume of solution should we use?

PLAN Noting that $c = n/V$ can be rearranged into $V = n/c$, to find the volume we divide the amount of solute by its molarity, as in Eq. 3. It is best first to convert the units of amount from millimole (mmol) to mole (mol).

SOLVE

From $V = n/c$,

$$V = \frac{0.760 \times 10^{-3}\ \text{mol}}{0.0380\ \text{mol}{\cdot}\text{L}^{-1}} = 0.0200\ \text{L}$$



We should therefore transfer 20.0 mL of the acetic acid solution into a flask by using a buret or a pipet (Fig. G.9). The flask will then contain 0.760 mmol CH_3COOH.

Self-Test G.3A What volume of 1.25×10^{-3} M $C_6H_{12}O_6(aq)$ contains 1.44 μmol of glucose molecules?

[***Answer:*** 1.15 mL]

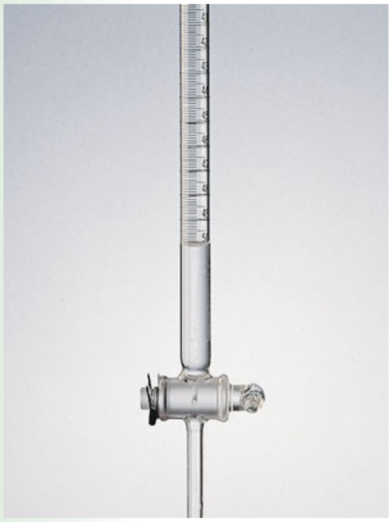


FIGURE G.9 A buret is calibrated so that the volume of liquid delivered can be measured.

Self-Test G.3B What volume of 0.358 M HCl(aq) contains 2.55 mmol HCl?

The molarity (molar concentration) of a solute in a solution is the amount of solute in moles divided by the volume of the solution in liters.

G.4 Dilution

A common space-saving practice in chemistry is to store a solution in a concentrated form called a **stock solution** and then to **dilute** it, or reduce its concentration, to whatever concentration is needed. Chemists use solutions and techniques such as dilution when they need very precise control over the amounts of the substances that they are handling, especially very small quantities of substances. For example, pipetting 25.0 mL of 1.50×10^{-3} M NaOH(aq) corresponds to transferring only 37.5 μmol NaOH or 1.50 mg of the compound. A mass this small would be difficult to weigh out accurately.

To dilute a stock solution to a desired concentration, we use a pipet to transfer the appropriate volume of stock solution to a volumetric flask. Then we add enough solvent to increase the volume of the solution to its final value. Toolbox G.1 shows how to calculate the initial volume of stock solution required for a given volume of diluted solution.

TOOLBOX G.1 HOW TO CALCULATE THE VOLUME OF STOCK SOLUTION REQUIRED FOR A GIVEN DILUTION

CONCEPTUAL BASIS

This procedure is based on a simple idea: although we may add more solvent to a given volume of solution, we change only the concentration, not the amount of solute (Fig. G.10). After dilution, the same amount of solute simply occupies a larger volume of solution.

PROCEDURE

The procedure has two steps:

Step 1 Calculate the amount of solute, n, in the final, dilute solution of volume V_{final}. (This is the amount of solute to be transferred into the volumetric flask.)

$$n = c_{\text{final}} V_{\text{final}}$$

Step 2 Calculate the volume, V_{initial}, of the initial stock solution of molarity, c_{initial}, that contains this amount of solute. (This is the volume of stock solution that contains the amount of solute calculated in step 1.)

$$V_{\text{initial}} = \frac{n}{c_{\text{initial}}} \qquad \text{(4a)*}$$

This procedure is illustrated in Example G.4.

Because the amount of solute, n, is the same in these two expressions, they can be combined into

$$V_{\text{initial}} = \frac{c_{\text{final}} V_{\text{final}}}{c_{\text{initial}}}$$

and rearranged into an easily remembered form.

$$c_{\text{initial}} V_{\text{initial}} = c_{\text{final}} V_{\text{final}} \qquad \text{(4b)*}$$

In Eq. 4b, the amount of solute in the final solution (the product on the right) is the same as the amount of solute in the initial volume of solution (the product on the left), $n_{\text{final}} = n_{\text{initial}}$.

EXAMPLE G.4 Calculating the volume of stock solution to dilute

We need to prepare 250. mL of 1.25×10^{-3} M NaOH(aq) and will use a 0.0380 M NaOH(aq) stock solution. How much stock solution do we need?

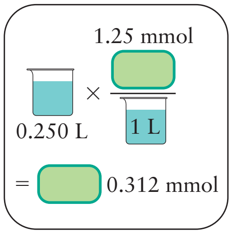
Anticipate Because the stock solution is about 30 times more concentrated than the diluted solution, we should expect to use about 1/30 of 250. mL, or just over 8 mL.

PLAN We proceed as in Toolbox G.1.

SOLVE

Step 1 From $n = c_{\text{final}} V_{\text{final}}$,

$$n = (1.25 \times 10^{-3}\ \text{mol·L}^{-1}) \times (0.250\ \text{L})$$
$$= (1.25 \times 10^{-3} \times 0.250)\ \text{mol}$$



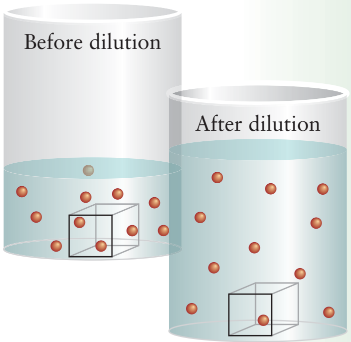


FIGURE G.10 When a solution is diluted, the same number of solute molecules occupy a larger volume. Therefore, the same volume (as depicted by the cube) will contain fewer molecules than in the concentrated solution.

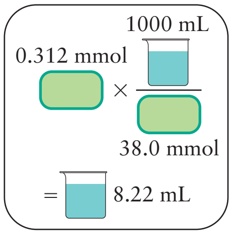
Step 2 From $V_{\text{initial}} = n/c_{\text{initial}}$,

$$V_{\text{initial}} = \frac{(1.25 \times 10^{-3} \times 0.250)\ \text{mol}}{0.0380\ \text{mol}\cdot\text{L}^{-1}} = 8.22 \times 10^{-3}\ \text{L}$$



Evaluate The volume of stock solution required is 8.22 mL, close to the expected value. This volume should be measured into a 250.-mL volumetric flask (by using a buret) and water should then be added up to the mark (Fig. G.11).

A note on good practice: Note how, to minimize rounding errors, we carry out the calculation in a single step. However, to help guide you through the calculation, we shall often give intermediate numerical results in the examples.

Self-Test G.4A Calculate the volume of 0.0155 M HCl(aq) that we should use to prepare 100. mL of 5.23×10^{-4} M HCl(aq).

[***Answer:*** 3.37 mL]

Self-Test G.4B Calculate the volume of 0.152 M $C_6H_{12}O_6$(aq) that should be used to prepare 25.00 mL of 1.59×10^{-5} M $C_6H_{12}O_6$(aq).

When a solution is diluted to a larger volume, the total amount of solute in the solution does not change, but the concentration of solute is reduced.

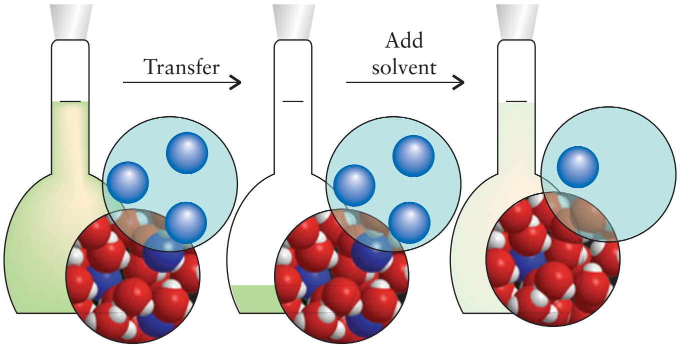


FIGURE G.11 The steps in dilution. A small sample of the original solution is transferred to a volumetric flask, and then solvent is added up to the mark.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Distinguish between heterogeneous and homogeneous mixtures and describe methods of separation (Sections G.1 and G.2).

❑ 2 Calculate the molarity of a solute in a solution, volume of solution, and mass of solute, given the other two quantities (Examples G.1–G.3).

❑ 3 Determine the volume of stock solution needed to prepare a dilute solution of a given molarity (Toolbox G.1 and Example G.4).

EXERCISES

G.1 Indicate whether each statement is true or false. If false, explain what is wrong with the statement: (a) The components of a compound can be separated from each other by physical means. (b) The composition of a solution can be varied. (c) The properties of a compound are the same as those of the elements that compose it.

G.2 Indicate whether each statement is true or false. If false, explain what is wrong with the statement: (a) A nonaqueous solution is one in which the solvent is water. (b) Decanting makes use of differences in boiling points to separate the components of a mixture. (c) In chromatography the components of a mixture are separated according to their ability to adsorb onto a surface.

G.3 Identify the following mixtures as homogeneous or heterogeneous, and suggest a technique for separating their components: (a) oil and vinegar; (b) chalk and table salt; (c) salt water.

G.4 Identify the following mixtures as homogeneous or heterogeneous, and suggest a technique for separating their components: (a) lemonade; (b) salad oil and vinegar; (c) salt and ground pepper.

G.5 You need to prepare 510. g of an aqueous solution containing 5.45% K_2NO_3 by mass. Describe how you would prepare the solution and what mass of each component you would use.

G.6 You need to prepare a sample containing 0.872 g of $CuSO_4$ from a solution that is 6.75% $CuSO_4$ by mass. What mass of solution do you need?

G.7 A chemist studying the properties of photographic emulsions needed to prepare 500.0 mL of 0.179 M $AgNO_3$(aq). What mass of silver nitrate must be placed into a 500.0-mL volumetric flask, dissolved, and diluted to the mark with water?

G.8 (a) A chemist prepares a solution by dissolving 3.750 g of $NaNO_3$ in enough water to make 500.0 mL of solution. What molar concentration of sodium nitrate should appear on the label? (b) If the chemist mistakenly uses a 250.0-mL volumetric flask instead of the 500.0-mL flask in part (a), what molar concentration of sodium nitrate will the chemist actually prepare?

G.9 A student prepared a solution of sodium carbonate by adding 2.111 g of the solid to a 250.0-mL volumetric flask and adding water to the mark. Some of this solution was transferred to a buret. What volume of solution should the student transfer into a flask to obtain (a) 2.15 mmol Na^+; (b) 4.98 mmol CO_3^{2-}; (c) 50.0 mg Na_2CO_3?

G.10 A student investigating the properties of solutions containing carbonate ions prepared a solution containing 8.124 g of Na_2CO_3 in a flask of volume 250.0 mL. Some of the solution was transferred to a buret. What volume of solution should be dispensed from the buret to provide (a) 5.124 mmol Na_2CO_3; (b) 8.726 mmol Na^+?

G.11 Explain how you would prepare 0.010 M $KMnO_4$(aq) by starting with (a) solid $KMnO_4$; (b) 0.050 M $KMnO_4$(aq).

G.12 (a) A sample of 1.345 M K_2SO_4(aq) of volume 12.56 mL is diluted to 250.0 mL. What is the molar concentration of K_2SO_4 in the diluted solution? (b) A sample of 0.366 M HCl(aq) of volume 25.00 mL is drawn from a reagent bottle with a pipet. The sample is transferred to a flask of volume 125.00 mL and diluted to the mark with water. What is the molar concentration of the dilute hydrochloric acid solution?

G.13 (a) What volume of 0.778 M Na_2CO_3(aq) should be diluted to 150.0 mL with water to reduce its concentration to 0.0234 M Na_2CO_3(aq)? (b) An experiment requires the use of 60.0 mL of 0.50 M NaOH(aq). The stockroom assistant can only find a reagent bottle of 2.5 M NaOH(aq). How can the 0.50 M NaOH(aq) be prepared?

G.14 A chemist dissolves 0.033 g of $CuSO_4 \cdot 5H_2O$ in water and dilutes the solution to the mark in a 250.0-mL volumetric flask. A 2.00-mL sample of this solution is then transferred to a second 250.0-mL volumetric flask and diluted. (a) What is the molarity of $CuSO_4$ in the final solution? (b) To prepare the final 250.0-mL solution directly, what mass of $CuSO_4 \cdot 5H_2O$ would need to be weighed out?

G.15 (a) Determine the mass of anhydrous copper(II) sulfate that must be used to prepare 250 mL of 0.20 M $CuSO_4$(aq). (b) Determine the mass of $CuSO_4 \cdot 5H_2O$ that must be used to prepare 250 mL of 0.20 M $CuSO_4$(aq).

G.16 The ammonia solution that is purchased for a stockroom has a molarity of 15.0 $mol \cdot L^{-1}$. (a) Determine the volume of 15.0 M NH_3(aq) that must be diluted to 500. mL to prepare 1.25 M NH_3(aq). (b) An experiment requires 0.32 M NH_3(aq). The stockroom manager estimates that 12.0 L of the base is needed. What volume of 15.0 M NH_3(aq) must be used for the preparation?

G.17 A solution is prepared by dissolving 0.500 g of KCl, 0.500 g of K_2S, and 0.500 g of K_3PO_4 in 500. mL of water. What is the concentration in the final solution of (a) potassium ions; (b) sulfide ions?

G.18 To prepare a very dilute solution, it is advisable to perform successive dilutions of a single prepared reagent solution, rather than to weigh out a very small mass or to measure a very small volume of stock chemical. A solution was prepared by transferring 0.661 g of $K_2Cr_2O_7$ to a 250.0-mL volumetric flask and adding water to the mark. A sample of this solution of volume 1.000 mL was transferred to a 500.0-mL volumetric flask and diluted to the mark with water. Then 10.0 mL of the diluted solution was transferred to a 250.0-mL flask and diluted to the mark with water. (a) What is the final concentration of $K_2Cr_2O_7$ in solution? (b) What mass of $K_2Cr_2O_7$ is in this final solution? (The answer to the last question gives the amount that would have had to have been weighed out if the solution had been prepared directly.)

G.19 What mass (in grams) of anhydrous solute is needed to prepare each of the following solutions? (a) 1.00 L of 0.125 M K_2SO_4(aq); (b) 375 mL of 0.015 M NaF(aq); (c) 500. mL of 0.35 M $C_{12}H_{22}O_{11}$(aq).

G.20 Describe the preparation of each of the following solutions, starting with the anhydrous solute and water and using the indicated size of volumetric flask: (a) 75.0 mL of 5.0 M NaOH(aq); (b) 5.0 L of 0.21 M $BaCl_2$(aq); (c) 300. mL of 0.0340 M $AgNO_3$(aq).

G.21 In medicine it is sometimes necessary to prepare solutions with a specific concentration of a given ion. A lab technician has made up a 100.0-mL solution containing 0.50 g of NaCl and 0.30 g of KCl, as well as glucose and other sugars. What is the concentration of chloride ions in the solution?

G.22 When a 1.850-g sample of iron ore is treated with 50.0 mL of hydrochloric acid the iron dissolves in the acid to form a solution of $FeCl_3$. The $FeCl_3$ solution is diluted to 100.0 mL and the concentration of Fe^{3+} ions is determined by spectrometry to be 0.103 $mol \cdot L^{-1}$. What is the mass percentage of iron in the ore?

G.23 Practitioners of the branch of alternative medicine known as homeopathy claim that very dilute solutions of substances can have an effect. Is the claim plausible? To explore this question, suppose that you prepare a solution of a supposedly active substance, X, with a molarity of 0.10 $mol \cdot L^{-1}$. Then you dilute 10. mL of that solution by doubling the volume, doubling it again, and so on, for 90 doublings in all. How many molecules of X will be present in 10. mL of the final solution? Comment on the possible health benefits of the solution.

G.24 Refer to Exercise G.23. How many successive tenfold dilutions of the original solution will result in one molecule of X being left in 10 mL of solution?

G.25 Concentrated hydrochloric acid is 37.50% HCl by mass and has a density of 1.205 $g \cdot cm^{-3}$. What volume (in milliliters) of concentrated hydrochloric acid must be used to prepare 10.0 L of 0.7436 M HCl(aq)?

G.26 You need 500. mL of 0.10 M $AgNO_3$(aq). You have on hand 100. mL of 0.30 M $AgNO_3$(aq), 1.00 L of 0.050 M $AgNO_3$(aq), and

lots of distilled water. Describe how you would prepare the desired solution and what volume of each solution you would use.

G.27 The concentration of toxic chemicals in the environment is often measured in parts per million (ppm) or even parts per billion (ppb). A solution in which the concentration of the solute is 3 ppb by mass has 3 g of the solute for every billion grams (1000 t) of the solution. The World Health Organization has set the acceptable standard for lead in drinking water at 10 ppb. You need to analyze some tap water for lead concentration, but your equipment is able to detect lead in concentrations only as low as 1×10^{-8} mol·L^{-1}. Is your equipment satisfactory? You can assume that in such dilute solutions the density of the solution is 1.00 g·cm^{-3}. Explain your reasoning.

G.28 Refer to Exercise G.27. In 1992 the tap water in one-third of the homes in Chicago was found to have a lead concentration of about 10 ppb. If you lived in one of these homes and drank 2 L of tap water at home each day, what is the total mass of lead you would have ingested per year?

H.1 Symbolizing Chemical Reactions
H.2 Balancing Chemical Equations

H CHEMICAL EQUATIONS

The growth of a child, the production of polymers from petroleum, and the digestion of food are all the outcome of **chemical reactions,** processes by which one or more substances are converted into other substances. This type of process is a **chemical change.** The starting materials are called the **reactants** and the substances formed are called the **products.** The chemicals available in a laboratory are called **reagents.** Only when a reagent is being used in a particular reaction is it called a reactant.

This section reviews a number of very important aspects of chemical reactions. For instance, we see how to express the outcome of a chemical reaction in terms of symbols: this procedure is an absolutely fundamental part of the language of chemistry and you will encounter it at every stage of your studies. Chemists have also identified a number of patterns that can be used to classify chemical reactions into different types. Once patterns have been identified a subject becomes not only more systematic but also much easier to learn.

H.1 Symbolizing Chemical Reactions

A chemical reaction is symbolized by an arrow:

$$\text{Reactants} \longrightarrow \text{products}$$

For example, sodium is a soft, shiny metal that reacts vigorously with water. When we drop a small lump of sodium metal into a container of water, hydrogen gas forms rapidly and sodium hydroxide is produced in solution (Fig. H.1). We could describe this reaction in words:

$$\text{Sodium} + \text{water} \longrightarrow \text{sodium hydroxide} + \text{hydrogen}$$

We can summarize this statement by using chemical formulas:

$$Na + H_2O \longrightarrow NaOH + H_2$$

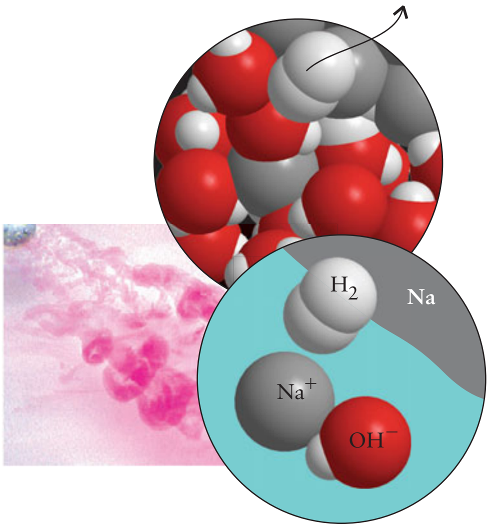

FIGURE H.1 When a small piece of sodium is dropped into water, a vigorous reaction takes place. Hydrogen gas and sodium hydroxide are formed, and the heat released is enough to melt the sodium into a sphere. The pink color is due to the presence of a dye that changes color in the presence of sodium hydroxide. The (balanced) chemical equation on the next page shows that when two sodium atoms give rise to two sodium ions, two water molecules give rise to one hydrogen molecule (which escapes as a gas) and two hydroxide ions. There is a rearrangement of partners, not a creation or annihilation of atoms. The unreacted water molecules are not shown in the inset on the right.

This expression is called a **skeletal equation** because it shows the bare bones of the reaction (the identities of the reactants and products) in terms of chemical formulas. A skeletal equation is a *qualitative* summary of a chemical reaction.

To summarize reactions *quantitatively*, we note that atoms are neither created nor destroyed in a chemical reaction: they simply change their partners. The principal evidence for this conclusion is that there is no overall change in mass when a reaction takes place in a sealed container. The observation that the total mass is constant during a chemical reaction is called the **law of conservation of mass.** Because atoms are neither created nor destroyed, chemists regard each elemental symbol as representing one atom of the element. Subscripts in a formula tell us how many atoms of that element are present in one molecule or formula unit (Section C). The formulas are then multiplied by factors that result in the same numbers of atoms of each element on both sides of the arrow. The resulting expression is said to be **balanced** and is called a **chemical equation.** For example, there are two H atoms on the left of the preceding skeletal equation but three H atoms on the right. So, we rewrite the expression as

$$2\,Na + 2\,H_2O \longrightarrow 2\,NaOH + H_2$$

Now there are four H atoms, two Na atoms, and two O atoms on each side, and the equation conforms to the law of conservation of mass. The number multiplying an *entire* chemical formula in a chemical equation (for example, the 2 multiplying H_2O) is called the **stoichiometric coefficient** of the substance. A coefficient of 1 (as for H_2) is not written explicitly.

The somewhat awkward word *stoichiometric* is derived from the Greek words for "element" and "measure."

A chemical equation typically also shows the physical state of each reactant and product by using a **state symbol:**

(s): solid (l): liquid (g): gas (aq): aqueous solution

For the reaction between solid sodium and liquid water, the complete, balanced chemical equation is therefore

$$2\,Na(s) + 2\,H_2O(l) \longrightarrow 2\,NaOH(aq) + H_2(g)$$

When we want to show that a reaction requires a high temperature, we write the Greek letter Δ (delta) over the arrow. For example, the conversion of limestone into quicklime takes place at about 800°C, and we write

$$CaCO_3(s) \xrightarrow{\Delta} CaO(s) + CO_2(g)$$

Sometimes a **catalyst**, a substance that increases the rate of a reaction but is not itself consumed in the reaction, is added. For example, vanadium pentoxide, V_2O_5, is a catalyst in one step of the industrial process for the production of sulfuric acid. The presence of a catalyst is indicated by writing the formula of the catalyst above the reaction arrow:

$$2\,SO_2(g) + O_2(g) \xrightarrow{V_2O_5} 2\,SO_3(g)$$

Now we come to an important interpretation of a chemical equation. First, we note that the equation for the reaction of sodium with water tells us that

- when any 2 *atoms* of sodium react with 2 *molecules* of water, they produce 2 *formula units* of NaOH and one *molecule* of hydrogen.

We can multiply through by Avogadro's number (Section E) and conclude that

- when 2 *moles* of Na atoms react with 2 *moles* of H_2O molecules, they produce 2 *moles* of NaOH formula units and 1 *mole* of H_2 molecules.

In other words, the stoichiometric coefficients multiplying the chemical formulas in any balanced chemical equation tell us the relative number of moles of each substance that reacts or is produced in the reaction.

A balanced chemical equation symbolizes both the qualitative and the quantitative changes that take place in a chemical reaction. The stoichiometric coefficients tell us the relative numbers of moles of reactants and products taking part in the reaction.

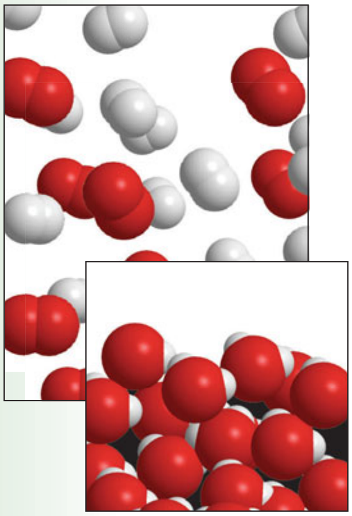

FIGURE H.2 A representation of the reaction between hydrogen and oxygen, with the production of water. No atoms are created or destroyed; they simply change partners. For every two hydrogen molecules that react (background, shown in white), one oxygen molecule (shown in red) is consumed and two water molecules are formed (foreground).

H.2 Balancing Chemical Equations

In some cases, the stoichiometric coefficients needed to balance an equation are easy to determine. For example, let's consider the reaction in which hydrogen and oxygen gases combine to form water. We start by summarizing the qualitative information as a skeletal equation:

$$H_2 + O_2 \longrightarrow H_2O \quad ⚠$$

We use the international *Hazard!* road sign ⚠ to warn that a skeletal equation is not balanced. Then we balance hydrogen and oxygen atoms:

$$2\,H_2 + O_2 \longrightarrow 2\,H_2O$$

There are four H atoms and two O atoms on each side of the arrow. At this stage, we insert the state symbols:

$$2\,H_2(g) + O_2(g) \longrightarrow 2\,H_2O(l)$$

Figure H.2 is a molecular-level representation of this reaction.

An equation must never be balanced by changing the subscripts in the chemical formulas. That change would imply that different substances were taking part in the reaction. For example, changing H_2O to H_2O_2 in the skeletal equation and writing

$$H_2 + O_2 \longrightarrow H_2O_2$$

certainly results in a balanced equation. However, it is a summary of a different reaction—the formation of hydrogen peroxide (H_2O_2) from its elements. Nor should we write

$$H_2 + O \longrightarrow H_2O$$

Although this equation is balanced, it summarizes the reaction between hydrogen molecules and oxygen atoms, not the oxygen molecules that are the actual starting materials.

Although normally the coefficients in a balanced chemical equation are the smallest possible whole numbers, a chemical equation can be multiplied through by a factor and still be a valid equation. At times it is convenient to use fractional coefficients; for example, we could write

$$H_2(g) + \tfrac{1}{2}\,O_2(g) \longrightarrow H_2O(l)$$

if we want the equation to correspond to the consumption of 1 mol H_2.

Sometimes we need to construct a balanced chemical equation from a verbal description of a reaction. For example, methane, CH_4, is the principal ingredient of natural gas (Fig. H.3). It burns in oxygen to form carbon dioxide and water, both formed initially as gases. To write the balanced equation for the reaction reported as "methane burns in oxygen to form carbon dioxide and water," we first write the skeletal equation:

$$CH_4 + O_2 \longrightarrow CO_2 + H_2O \quad ⚠$$

Then we balance the equation. A good strategy is to balance one element at a time, starting with one that appears in the fewest formulas, such as carbon and hydrogen. Then specify the states. If under the conditions of the experiment water is produced as a vapor, we write

$$CH_4(g) + 2\,O_2(g) \longrightarrow CO_2(g) + 2\,H_2O(g)$$

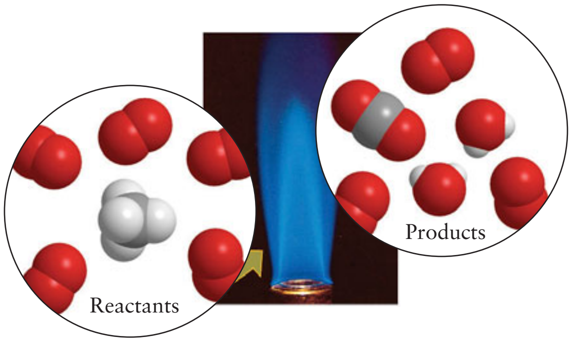

FIGURE H.3 When methane burns, it forms carbon dioxide and water. The blue color is due to the presence of C_2 molecules in the flame. If the oxygen supply is inadequate, these carbon molecules can stick together and form soot, thereby producing a smoky flame. Note that one carbon dioxide molecule and two water molecules are produced for each methane molecule that is consumed. The two hydrogen atoms in each water molecule do not necessarily come from the same methane molecule: the illustration depicts the overall outcome, not the specific outcome of the reaction of one molecule. The excess oxygen remains unreacted.

EXAMPLE H.1 Writing and balancing a chemical equation

Write and balance the chemical equation for the combustion of liquid hexane, C_6H_{14}, to gaseous carbon dioxide gas and gaseous water.

Anticipate Combustion refers to burning in air, specifically to reaction with molecular oxygen. Because hexane contains six C atoms and 14 H atoms, we can expect each molecule to give rise to six CO_2 molecules and seven H_2O molecules, so the balanced equation will be of the form $C_6H_{14} + ?\ O_2 \longrightarrow 6\ CO_2 + 7\ H_2O$ or a multiple of it.

PLAN First write the skeletal equation, using the rules in Section D if necessary. Balance first the element that occurs in the fewest formulas. Verify that the coefficients are the smallest whole numbers. Specify the states of each reactant and product.

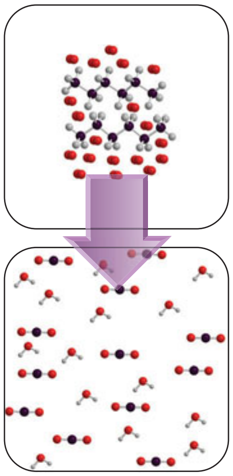
SOLVE

Write the skeletal equation.

$$C_6H_{14} + O_2 \longrightarrow CO_2 + H_2O$$

Balance carbon and hydrogen.

$$C_6H_{14} + O_2 \longrightarrow 6\ CO_2 + 7\ H_2O$$



Next balance oxygen. In this case, a fractional stoichiometric coefficient is needed.

$$C_6H_{14} + \tfrac{19}{2}\ O_2 \longrightarrow 6\ CO_2 + 7\ H_2O$$

Multiply by 2 to clear the fraction.

$$2\ C_6H_{14} + 19\ O_2 \longrightarrow 12\ CO_2 + 14\ H_2O$$

Add the physical states.

$$2\ C_6H_{14}(g) + 19\ O_2(g) \longrightarrow 12\ CO_2(g) + 14\ H_2O(g)$$

Evaluate As we anticipated, the balanced equation, $2\ C_6H_{14}(g) + 19\ O_2(g) \longrightarrow 12\ CO_2(g) + 14\ H_2O(g)$, is a multiple (in fact, by a factor of 2) of an equation of the form $C_6H_{14} + ?\ O_2 \longrightarrow 6\ CO_2 + 7\ H_2O$.

Self-Test H.1A When aluminum is melted and heated with solid barium oxide, a vigorous reaction takes place, and elemental molten barium and solid aluminum oxide are formed. Write the balanced chemical equation for the reaction.

[***Answer:*** $2\ Al(l) + 3\ BaO(s) \xrightarrow{\Delta} Al_2O_3(s) + 3\ Ba(l)$]

Self-Test H.1B Write the balanced chemical equation for the reaction of solid magnesium nitride with aqueous sulfuric acid to form aqueous magnesium sulfate and aqueous ammonium sulfate.

A chemical equation expresses a chemical reaction in terms of chemical formulas; the stoichiometric coefficients are chosen to show that atoms are neither created nor destroyed in the reaction.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Explain the role of stoichiometric coefficients (Section H.1).

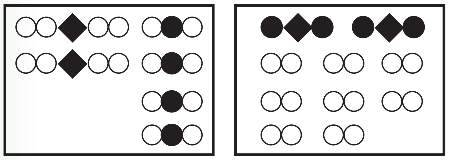
❑ 2 Write, balance, and label a chemical equation on the basis of information given in sentence form (Example H.1).

EXERCISES

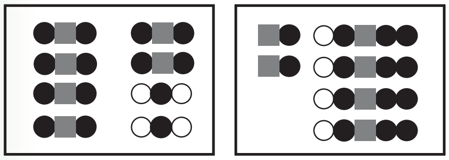
H.1 It appears that balancing the chemical equation $Cu + SO_2 \longrightarrow CuO + S$ would be simple if we could just add another O to the product side: $Cu + SO_2 \longrightarrow CuO + S + O$. (a) Why is that balancing procedure not allowed? (b) Balance the equation correctly.

H.2 Indicate which of the following are conserved in a chemical reaction: (a) mass; (b) number of atoms; (c) number of molecules; (d) number of electrons.

H.3 The first box below represents the reactants for a chemical reaction and the second box the products that form if all the reactant molecules shown react. Using the key below, write a balanced equation for the reaction. Assume that if two atoms are touching, they are bonded together. Key: ● oxygen; ○ hydrogen; ◆ silicon.



H.4 The first box below represents the reactants for a chemical reaction and the second box the products that form if all the reactant molecules shown react. Using the key below, write a balanced equation for the reaction using the smallest whole-number coefficients. Assume that if two atoms are touching, they are bonded together. Key: ● oxygen; ○ hydrogen; ■ nitrogen.



H.5 Balance the following skeletal chemical equations:

(a) $NaBH_4(s) + H_2O(l) \longrightarrow NaBO_2(aq) + H_2(g)$
(b) $Mg(N_3)_2(s) + H_2O(l) \longrightarrow Mg(OH)_2(aq) + HN_3(aq)$
(c) $NaCl(aq) + SO_3(g) + H_2O(l) \longrightarrow Na_2SO_4(aq) + HCl(aq)$
(d) $Fe_2P(s) + S(s) \longrightarrow P_4S_{10}(s) + FeS(s)$

H.6 Balance the following skeletal chemical equations:

(a) $KClO_3(s) + C_6H_{12}O_6(s) \xrightarrow{\Delta} KCl(s) + CO_2(g) + H_2O(g)$
(b) $P_2S_5(s) + PCl_5(s) \longrightarrow PSCl_3(g)$
(c) (in ether) $LiBH_4 + BF_3 \longrightarrow B_2H_6 + LiBF_4$
(d) $Ca_3(PO_4)_2(s) + SiO_2(s) + C(s) \xrightarrow{\Delta} CaSiO_3(l) + CO(g) + P_4(g)$

H.7 Write a balanced chemical equation for each of the following reactions. (a) Calcium metal reacts with water to produce hydrogen gas and aqueous calcium hydroxide. (b) The reaction of solid sodium oxide, Na_2O, and water produces aqueous sodium hydroxide. (c) Hot solid magnesium metal reacts in a nitrogen atmosphere to produce solid magnesium nitride, Mg_3N_2. (d) The reaction of ammonia gas with oxygen gas at high temperatures in the presence of a copper metal catalyst produces the gases water and nitrogen dioxide.

H.8 Write a balanced chemical equation for each of the following reactions. (a) In the first step of recovering copper metal from ores containing $CuFeS_2$ the ore is heated in air. During this "roasting" process, molecular oxygen reacts with the $CuFeS_2$ to produce solid copper(II) sulfide, iron(II) oxide, and sulfur dioxide gas. (b) The diamond-like abrasive silicon carbide, SiC, is made by reacting solid silicon dioxide with elemental carbon at 2000°C to produce solid silicon carbide and carbon monoxide gas. (c) The reaction of elemental hydrogen and nitrogen gases is used for the commercial production of gaseous ammonia in the Haber process. (d) Under acidic conditions oxygen gas can react with aqueous hydrobromic acid to form liquid water and liquid bromine.

H.9 In one stage in the commercial production of iron metal in a blast furnace, the iron(III) oxide, Fe_2O_3, reacts with carbon monoxide to form solid Fe_3O_4 and carbon dioxide gas. In a second stage, the Fe_3O_4 reacts further with carbon monoxide to produce solid elemental iron and carbon dioxide. Write the balanced equation for each stage in the process.

H.10 The bacteria-catalyzed oxidation of ammonia in waste water takes place in two steps. In the first step aqueous ammonia reacts with oxygen gas to form aqueous nitrous acid and water. In the second step the nitrous acid reacts with additional oxygen to form aqueous nitric acid. Write the balanced equation for each stage in the process.

H.11 When nitrogen and oxygen gases react in the cylinder of an automobile engine, nitric oxide gas, NO, is formed. After it escapes into the atmosphere with the other exhaust gases, the nitric oxide reacts with oxygen to produce nitrogen dioxide gas, one of the precursors of acid rain. Write the two balanced equations for the reactions leading to the formation of nitrogen dioxide.

H.12 The reaction of boron trifluoride, $BF_3(g)$, with sodium borohydride, $NaBH_4(s)$, leads to the formation of sodium tetrafluoroborate, $NaBF_4(s)$, and diborane gas, $B_2H_6(g)$. The diborane reacts with the oxygen in air, forming boron oxide, $B_2O_3(s)$, and water. Write the two balanced equations leading to the formation of boron oxide.

H.13 Hydrofluoric acid is used to etch grooves in glass because it reacts with the silica, $SiO_2(s)$, in glass. The products of the reaction are aqueous silicon tetrafluoride and water. Write a balanced equation for the reaction.

H.14 The compound $Sb_4O_5Cl_2(s)$, which has been investigated because of its interesting electrical properties, can be prepared by warming a mixture of antimony(III) oxide and antimony(III) chloride, both of which are solids. Write a balanced equation for the reaction.

H.15 Write a balanced equation for the complete combustion (reaction with oxygen gas) of liquid heptane, C_7H_{16}, a component typical of the hydrocarbons in gasoline, to carbon dioxide gas and water vapor.

H.16 Write a balanced equation for the incomplete combustion (reaction with oxygen gas) of liquid heptane, C_7H_{16}, to carbon monoxide gas and water vapor.

H.17 Aspartame, $C_{14}H_{18}N_2O_5$, is a solid used as an artificial sweetener. Write the balanced equation for its combustion to carbon dioxide gas, liquid water, and nitrogen gas.

H.18 Dimethazan, $C_{11}H_{17}N_5O_2$, is a solid antidepressant drug. Write the balanced equation for its combustion to carbon dioxide gas, liquid water, and nitrogen gas.

H.19 The psychoactive drug sold as methamphetamine ("speed"), $C_{10}H_{15}N$, undergoes a series of reactions in the body; the net result of these reactions is the oxidation of solid methamphetamine by oxygen gas to produce carbon dioxide gas, liquid water, and an aqueous solution of urea, CH_4N_2O. Write the balanced equation for this net reaction.

H.20 The psychoactive street drug sold as MDMA ("Ecstacy"), $C_{11}H_{15}NO_2$, undergoes a series of reactions in the body; the net result of these reactions is the oxidation of aqueous MDMA by oxygen gas to produce carbon dioxide gas, liquid water, and an aqueous solution of urea, CH_4N_2O. Write the balanced equation for this net reaction.

H.21 Sodium thiosulfate, which as the pentahydrate $Na_2S_2O_3{\cdot}5H_2O$ forms the large white crystals used as "photographer's hypo," can be prepared by bubbling oxygen through a solution of sodium polysulfide, Na_2S_5, in alcohol and adding water. Sulfur dioxide gas is formed as a by-product. Sodium polysulfide is made by the action of hydrogen sulfide gas on a solution of sodium sulfide, Na_2S, in alcohol, which, in turn, is made by the reaction of hydrogen sulfide gas, H_2S, with solid sodium hydroxide. Write the three chemical equations that show how hypo is prepared from hydrogen sulfide and sodium hydroxide. Use (alc) to indicate the state of species dissolved in alcohol.

H.22 The first stage in the production of nitric acid by the Ostwald process is the reaction of ammonia gas with oxygen gas, producing nitric oxide gas, NO, and liquid water. The nitric oxide further reacts with oxygen to produce nitrogen dioxide gas, which, when dissolved in water, produces nitric acid and nitric oxide. Write the three balanced equations that lead to the production of nitric acid.

H.23 Phosphorus and oxygen react to form two different phosphorus oxides. The mass percentage of phosphorus in one of these oxides is 43.64%; in the other, it is 56.34%. (a) Write the empirical formula of each phosphorus oxide. (b) The molar mass of the former oxide is 283.33 $g{\cdot}mol^{-1}$ and that of the latter is 219.88 $g{\cdot}mol^{-1}$. Determine the molecular formula and name of each oxide. (c) Write a balanced chemical equation for the formation of each oxide.

H.24 One step in the refining of titanium metal is the reaction of $FeTiO_3$ with chlorine gas and carbon. Balance the equation for the reaction: $FeTiO_3(s) + Cl_2(g) + C(s) \longrightarrow TiCl_4(l) + FeCl_3(s) + CO(g)$.

I AQUEOUS SOLUTIONS AND PRECIPITATION

I.1 Electrolytes
I.2 Precipitation Reactions
I.3 Ionic and Net Ionic Equations
I.4 Putting Precipitation to Work

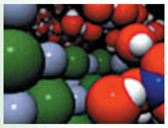
When we mix two solutions the result is often simply a new solution that contains both solutes. However, in some cases the solutes can react with each other. For instance, when we mix a colorless aqueous solution of silver nitrate with a clear yellow aqueous solution of potassium chromate, a powdery red solid forms, indicating that a chemical reaction has occurred (Fig. I.1). This section and the next two introduce three of the main types of chemical reactions: precipitation reactions, acid–base reactions, and redox reactions, all of which are discussed in more depth in later chapters. (The fourth type of reaction discussed in this text, Lewis acid–base reactions, is introduced in Section 11.2.) Many chemical reactions take place in solution, particularly in water; therefore, in this section we begin by considering the nature of aqueous solutions.

FIGURE I.1 When a solution of yellow K_2CrO_4 is mixed with a colorless solution of $AgNO_3$ a red precipitate of silver chromate, Ag_2CrO_4, forms.

I.1 Electrolytes

A **soluble substance** is one that dissolves to a significant extent in a specified solvent. When we refer simply to solubility without mentioning the solvent, we mean "soluble in water." An **insoluble substance** is one that does not dissolve significantly in a specified solvent; substances are often regarded as "insoluble" if they do not dissolve to more than about 0.1 $mol{\cdot}L^{-1}$. Unless otherwise specified in this text, we use the term *insoluble* to mean "insoluble in water." For instance, calcium carbonate, $CaCO_3$, which makes up limestone and chalk, dissolves to form a solution that contains only 0.01 $g{\cdot}L^{-1}$ (corresponding in this case to 1×10^{-4} $mol{\cdot}L^{-1}$), and we regard $CaCO_3$ as insoluble. This insolubility is important for landscapes: chalk hills and limestone buildings do not wash away in natural rainwater.

A solute may be present as ions or as molecules. We can find out if the solute is present as ions by noting whether the solution conducts an electric current. Because a current is a flow of electric charge, only solutions that contain ions conduct electricity.



Animation I.2

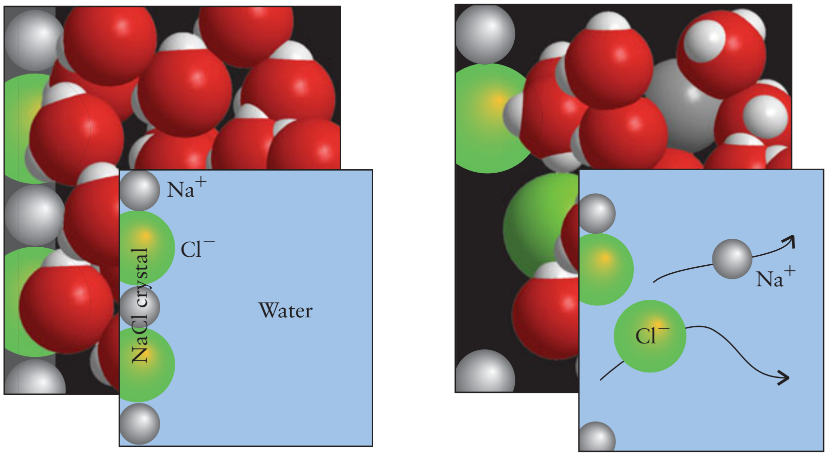


FIGURE I.2 Sodium chloride consists of sodium ions and chloride ions. When sodium chloride comes in contact with water (left), the ions are separated by the water molecules, and they spread throughout the solvent (right). The solution consists of water, sodium ions, and chloride ions. There are no NaCl molecules present. In the insets water molecules are represented by the blue background.

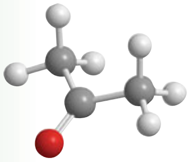
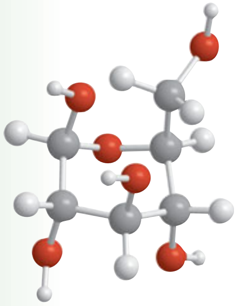


1 Acetone, C_3H_6O



2 α-D-Glucose, $C_6H_{12}O_6$

The term *electrolyte* is also used in some contexts to denote a medium, such as a liquid solution or a porous solid, that can conduct electricity by the migration of ions.

There is such a tiny concentration of ions in pure water (about 10^{-7} mol·L^{-1}) that pure water itself does not conduct electricity significantly.

An **electrolyte** is a substance that, in solution, is present as ions. Ionic solids that are soluble in water are electrolytes because the ions become free to move when water molecules separate the ions (Fig. I.2). Some electrolytes, such as acids, exist as molecules that form ions only when they dissolve. The term **electrolyte solution** is commonly used to emphasize that the medium is in fact a solution. A **nonelectrolyte** is a substance that does not form ions in solution; it dissolves to give a **nonelectrolyte solution**. Aqueous solutions of acetone (**1**) and glucose (**2**) are nonelectrolyte solutions. Except for acids, most organic compounds that dissolve in water form nonelectrolyte solutions. If we could see the individual molecules in a nonelectrolyte solution, we would see the intact solute molecules dispersed among the solvent molecules (Fig. I.3).

A **strong electrolyte** is a substance that is present almost entirely as ions in solution. Three types of solutes are strong electrolytes: strong acids and strong bases, which will be described in more detail in Section J, and soluble ionic compounds. Hydrogen chloride is a strong electrolyte; so are sodium hydroxide and the salt sodium chloride. A **weak electrolyte** is a substance that is incompletely ionized in solution; in other words, most of the molecules remain intact. Acetic acid is a weak electrolyte: in aqueous solution at normal concentrations, only a small fraction of CH_3COOH molecules separate into hydrogen ions, H^+, and acetate ions, $CH_3CO_2^-$. One way to distinguish strong and weak electrolytes is to measure the abilities of their solutions to conduct electricity: for the same molar concentration of solute, a solution of strong electrolyte is a better conductor than a solution of a weak electrolyte (Fig. I.4).

Self-Test I.1A Identify each of the following substances as an electrolyte or a nonelectrolyte and predict which will conduct electricity when dissolved in water: (a) NaOH; (b) Br_2.

[***Answer:*** (a) Ionic compound, so a strong electrolyte, conducts electricity; (b) molecular compound and not an acid, so a nonelectrolyte, does not conduct electricity]

Self-Test I.1B Identify each of the following substances as an electrolyte or a nonelectrolyte and predict which will conduct electricity when dissolved in water: (a) ethanol, $CH_3CH_2OH(aq)$; (b) $Pb(NO_3)_2(aq)$.

The solute in an aqueous strong electrolyte solution is present as ions that can conduct electricity through the solution. The solutes in nonelectrolyte solutions are present as molecules. Only a small fraction of the solute molecules in weak electrolyte solutions are present as ions.

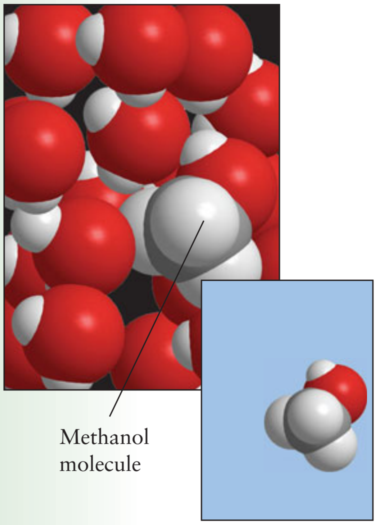


FIGURE I.3 In a nonelectrolyte solution, the solute remains as a molecule and does not break up into ions. Methanol, CH_3OH, is a nonelectrolyte and is present as intact molecules when it is dissolved in water. The inset shows the methanol molecule alone.

(a) (b) (c)

FIGURE I.4 (a) Pure water is a poor conductor of electricity, as shown by the very dim glow of the bulb in the circuit on the left. (b) When ions are present, as in this weak electrolyte solution, the solution has a low ability to conduct electricity. That ability is significant when the solute is a strong electrolyte (c), even when the solute concentration is the same in each instance.

Lab Video I.4

I.2 Precipitation Reactions

Some ionic compounds are soluble, others are not. Consider what happens when we pour a solution of sodium chloride (a strong electrolyte) into a solution of silver nitrate (another strong electrolyte). A solution of sodium chloride contains Na^+ cations and Cl^- anions. Similarly, a solution of silver nitrate, $AgNO_3$, contains Ag^+ cations and NO_3^- anions. When we mix these two aqueous solutions, a white **precipitate**, a cloudy, finely divided solid deposit, forms immediately. Analysis shows that the precipitate is silver chloride, AgCl, an insoluble white solid. The colorless solution remaining above the precipitate contains dissolved Na^+ cations and NO_3^- anions. These ions remain in solution because sodium nitrate, $NaNO_3$, is soluble in water.

In a **precipitation reaction**, an insoluble solid product forms when we mix two electrolyte solutions. When an insoluble substance is formed in water, it immediately precipitates. In the chemical equation for a precipitation reaction, we use (aq) to indicate substances that are dissolved in water and (s) to indicate the solid that has precipitated:

$$AgNO_3(aq) + NaCl(aq) \longrightarrow AgCl(s) + NaNO_3(aq)$$

A precipitation reaction takes place when solutions of two electrolytes are mixed and react to form an insoluble solid.

I.3 Ionic and Net Ionic Equations

A **complete ionic equation** for a precipitation reaction shows all the species as they actually exist in solution; because dissolved ionic compounds exist as separate aqueous ions, the ions are shown separately. For example, the complete ionic equation for the silver chloride precipitation reaction shown in Fig. I.5 is

$$Ag^+(aq) + NO_3^-(aq) + Na^+(aq) + Cl^-(aq) \longrightarrow AgCl(s) + Na^+(aq) + NO_3^-(aq)$$

Because the Na^+ and NO_3^- ions appear as both reactants and products, they play no direct role in the reaction. They are **spectator ions**, ions that are present while the reaction takes place but do not participate in it, like spectators at a sports event. Because spectator ions remain unchanged, we can simplify the chemical equation by canceling them on each side of the arrow in the ionic equation:

$$Ag^+(aq) + \cancel{NO_3^-(aq)} + \cancel{Na^+(aq)} + Cl^-(aq) \longrightarrow AgCl(s) + \cancel{Na^+(aq)} + \cancel{NO_3^-(aq)}$$

Canceling the spectator ions leaves the **net ionic equation** for the reaction, the chemical equation that displays only the net change taking place in the reaction:

$$Ag^+(aq) + Cl^-(aq) \longrightarrow AgCl(s)$$

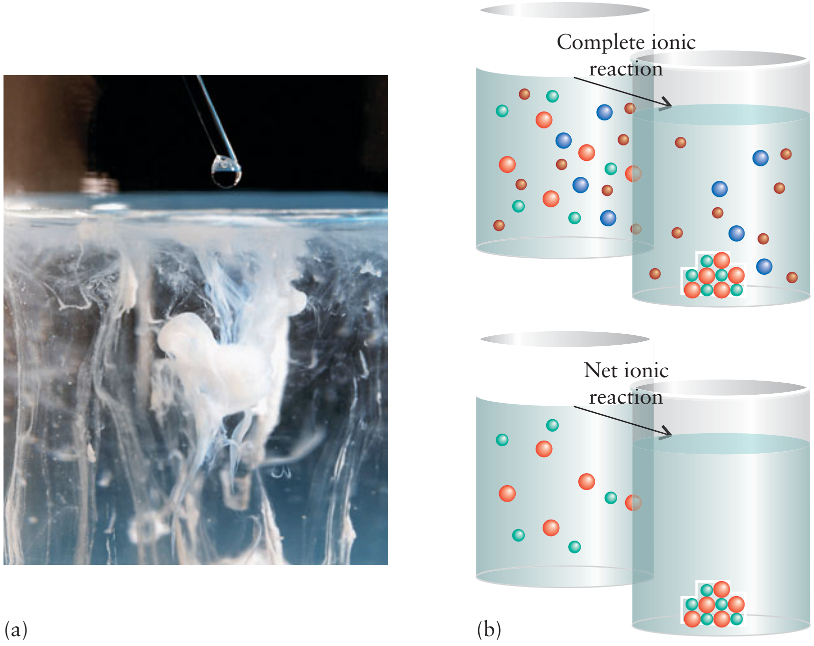

FIGURE I.5 (a) Silver chloride precipitates immediately when sodium chloride solution is added to a solution of silver nitrate. (b) If we imagine the removal of the spectator ions from the complete ionic reaction (top), we can focus on the essential process, the net ionic reaction (bottom).

The net ionic equation shows that Ag^+ ions combine with Cl^- ions to precipitate as solid silver chloride, AgCl (see Fig. I.5). A net ionic equation focuses our attention on the change that results from the chemical reaction.

EXAMPLE I.1 Writing a net ionic equation

When concentrated aqueous solutions of barium nitrate, $Ba(NO_3)_2$, and ammonium iodate, NH_4IO_3, are mixed, insoluble barium iodate, $Ba(IO_3)_2$, forms. The chemical equation for the precipitation reaction is

$$Ba(NO_3)_2(aq) + 2\,NH_4IO_3(aq) \longrightarrow Ba(IO_3)_2(s) + 2\,NH_4NO_3(aq)$$

Write the net ionic equation for the reaction.

Anticipate Nitrate ions and ammonium ions occur in solution on both sides of the equation, so we can expect them to cancel and the ionic equation to involve only iodate ions and barium ions.

PLAN First, write and balance the complete ionic equation, showing all the dissolved ions as they actually exist in solution, as separate, charged ions. Insoluble solids are shown as complete compounds. Next, cancel the spectator ions, the ions that appear as aqueous ions on both sides of the arrow.

SOLVE

The complete ionic equation, which shows all the dissolved ions, both those that react and the spectator ions, is

$$Ba^{2+}(aq) + 2\,NO_3^-(aq) + 2\,NH_4^+(aq) + 2\,IO_3^-(aq) \longrightarrow Ba(IO_3)_2(s) + 2\,NH_4^+(aq) + 2\,NO_3^-(aq)$$

We cancel the spectator ions, NH_4^+ and NO_3^-:

$$Ba^{2+}(aq) + \cancel{2\,NO_3^-(aq)} + \cancel{2\,NH_4^+(aq)} + 2\,IO_3^-(aq) \longrightarrow Ba(IO_3)_2(s) + \cancel{2\,NH_4^+(aq)} + \cancel{2\,NO_3^-(aq)}$$

and obtain the net ionic equation:

$$Ba^{2+}(aq) + 2\,IO_3^-(aq) \longrightarrow Ba(IO_3)_2(s)$$

Evaluate As we anticipated, the NH_4^+ and NO_3^- ions do not appear in the net ionic equation.

Self-Test I.2A Write the net ionic equation for the reaction in Fig. I.1, in which aqueous solutions of colorless silver nitrate and yellow potassium chromate react to give a precipitate of red silver chromate.

[***Answer:*** $2\,Ag^+(aq) + CrO_4^{2-}(aq) \longrightarrow Ag_2CrO_4(s)$]

Self-Test I.2B The mercury(I) ion, Hg_2^{2+}, consists of two Hg^+ ions joined together. Write the net ionic equation for the reaction in which colorless aqueous solutions of mercury(I) nitrate, $Hg_2(NO_3)_2$, and potassium phosphate, K_3PO_4, react to give a white precipitate of mercury(I) phosphate.

A complete ionic equation expresses a reaction in terms of the ions that are present in solution; a net ionic equation is the chemical equation that remains after the cancellation of the spectator ions.

I.4 Putting Precipitation to Work

Precipitation reactions have many applications in chemistry. One is to make compounds by mixing two solutions that form a precipitate of the desired insoluble compound when they are mixed. Then we can separate the insoluble compound from the reaction mixture by filtration. Precipitation reactions are also used in chemical analysis. In **qualitative analysis**—the identification of the substances present in a sample—the formation of a precipitate is used to confirm the identity of certain ions. In **quantitative analysis**, the aim is to determine the amount of each substance or element present. In particular, in **gravimetric analysis,** the amount of substance present is determined by measurements of mass. In this application, an insoluble compound is precipitated, the precipitate is filtered off and weighed, and from its mass the amount of a substance in one of the original solutions is calculated (Fig. I.6). Gravimetric analysis can be used in environmental monitoring to find out how much of a heavy metal ion, such as lead or mercury, is in a sample of water.

Section 12.14 describes the use of precipitates in qualitative analysis in more detail.

You will find an example of how to use this technique in Section L.

Table I.1 summarizes the solubility patterns of common ionic compounds in water. Notice that all nitrates and all common compounds of the Group 1 metals are soluble; so they make useful starting solutions for precipitation reactions. Any spectator ions can be used, provided that they remain in solution and do not otherwise react. For example, Table I.1 shows that mercury(I) iodide, Hg_2I_2, is insoluble. It is formed as a precipitate when solutions containing Hg_2^{2+} ions and I^- ions are mixed:

$$Hg_2^{2+}(aq) + 2\,I^-(aq) \longrightarrow Hg_2I_2(s)$$

Because the spectator ions are not shown, the net ionic equation will be the same when any soluble mercury(I) compound is mixed with any soluble iodide.

FIGURE I.6 A step in a gravimetric analysis. To determine how much of a particular type of ion was present in a solution, the ion was precipitated and the precipitate is being filtered. The filter paper, which has a known mass, will then be dried and weighed, thereby allowing the mass of the precipitate to be determined.

TABLE I.1 Solubility Rules for Inorganic Compounds

Soluble compounds	Insoluble compounds
compounds of Group 1 elements	carbonates (CO_3^{2-}), chromates (CrO_4^{2-}), oxalates ($C_2O_4^{2-}$), and phosphates (PO_4^{3-}), **except** those of the Group 1 elements and NH_4^+
ammonium (NH_4^+) compounds	sulfides (S^{2-}), **except** those of the Group 1 and 2 elements and NH_4^+
chlorides (Cl^-), bromides (Br^-), and iodides (I^-), **except** those of Ag^+, Hg_2^{2+}, and Pb^{2+}*	hydroxides (OH^-) and oxides (O^{2-}), **except** those of the Group 1 elements and Group 2 elements below Period 2‡
nitrates (NO_3^-), acetates ($CH_3CO_2^-$), chlorates (ClO_3^-), and perchlorates (ClO_4^-)	
sulfates (SO_4^{2-}), **except** those of Ca^{2+}, Sr^{2+}, Ba^{2+}, Pb^{2+}, Hg_2^{2+}, and Ag^+†	

*$PbCl_2$ is slightly soluble.
† Ag_2SO_4 is slightly soluble.
‡ $Ca(OH)_2$ and $Sr(OH)_2$ are sparingly (slightly) soluble; $Mg(OH)_2$ is only very slightly soluble.

EXAMPLE I.2 Predicting the outcome of a precipitation reaction

Predict the precipitate likely to be formed, if any, when aqueous solutions of sodium phosphate and lead(II) nitrate are mixed. Write the net ionic equation for the reaction.

PLAN Decide which ions are present in the mixed solutions and consider all possible combinations. Use the solubility rules in Table I.1 to decide which combination corresponds to an insoluble compound and write the net ionic equation to match.

SOLVE

The mixed solution will contain Na^+, PO_4^{3-}, Pb^{2+}, and NO_3^- ions. All nitrates and all compounds of Group 1 metals are soluble, but phosphates of other elements are generally insoluble.

Hence, we can predict that Pb^{2+} and PO_4^{3-} ions will form an insoluble compound and that lead(II) phosphate, $Pb_3(PO_4)_2$, will precipitate.

Now write the net ionic equation. The Na^+ and NO_3^- ions are spectators, and so they are omitted.

$$3\,Pb^{2+}(aq) + 2\,PO_4^{3-}(aq) \longrightarrow Pb_3(PO_4)_2(s)$$

Self-Test I.3A Predict the identity of the precipitate that forms, if any, when aqueous solutions of ammonium sulfide and copper(II) sulfate are mixed, and write the net ionic equation for the reaction.

[***Answer:*** Copper(II) sulfide; $Cu^{2+}(aq) + S^{2-}(aq) \longrightarrow CuS(s)$]

Self-Test I.3B Suggest two solutions that can be mixed to prepare strontium sulfate, and write the net ionic equation for the reaction.

The solubility rules in Table I.1 are used to predict the outcomes of precipitation reactions.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Identify electrolytes or nonelectrolytes on the basis of the formulas of the solutes (Self-Test I.1).

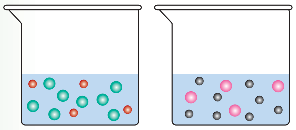
❑ 2 Construct balanced complete ionic and net ionic equations for reactions involving ions (Example I.1).

❑ 3 Use the solubility rules to select appropriate solutions that, when mixed, will produce a desired precipitate (Section I.4).

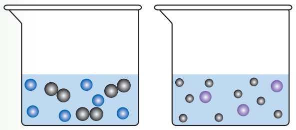
❑ 4 Identify any precipitate that may form on mixing two given solutions (Example I.2).

EXERCISES

I.1 The beaker on the left pictured below contains 0.50 M $CaCl_2(aq)$and the beaker on the right contains 0.50 M $Na_2SO_4(aq)$. Suppose the contents of the two beakers are mixed. Draw a picture of the resulting products.



I.2 The beaker on the left pictured below contains 0.50 M $Hg_2(NO_3)_2(aq)$ and the beaker on the right contains 0.50 M $K_3PO_4(aq)$. Suppose the contents of the two beakers are mixed. Draw a picture of the resulting products.



I.3 How would you use the solubility rules in Table I.1 to separate the following pairs of ions? In each case indicate what reagent you would add and write the net ionic equation for the precipitation reaction: (a) lead(II) and copper(II) ions; (b) ammonium and magnesium ions.

I.4 How would you use the solubility rules in Table I.1 to separate the following pairs of ions? In each case indicate what reagent you would add and write the net ionic equation for the precipitation reaction: (a) barium and mercury(I) ions; (b) silver and zinc ions.

I.5 Classify each of the following substances as a strong electrolyte or a nonelectrolyte: (a) CH_3OH; (b) $BaCl_2$; (c) KF.

I.6 Classify each of the following substances as a strong electrolyte, a weak electrolyte, or a nonelectrolyte: (a) H_2SO_4; (b) KOH; (c) $CH_3CH_2CH_2COOH$.

I.7 Use the information in Table I.1 to classify each of the following ionic compounds as soluble or insoluble in water: (a) potassium phosphate, K_3PO_4; (b) lead(II) chloride, $PbCl_2$; (c) cadmium sulfide, CdS; (d) barium sulfate, $BaSO_4$.

I.8 Use the information in Table I.1 to classify each of the following ionic compounds as soluble or insoluble in water: (a) cadmium nitrate, $Cd(NO_3)_2$; (b) copper(II) acetate, $Cu(CH_3CO_2)_2$; (c) cobalt(III) hydroxide, $Co(OH)_3$; (d) silver bromide, AgBr.

I.9 What are the principal solute species present in an aqueous solution of (a) NaI; (b) Ag_2CO_3; (c) $(NH_4)_3PO_4$; (d) $FeSO_4$?

I.10 What are the principal solute species present in an aqueous solution of (a) $CoCO_3$; (b) $LiNO_3$; (c) K_2CrO_4; (d) Hg_2Cl_2?

I.11 (a) When aqueous solutions of iron(III) sulfate and sodium hydroxide were mixed, a precipitate formed. Write the formula of the precipitate. (b) Does a precipitate form when aqueous solutions of silver nitrate, $AgNO_3$, and potassium carbonate are mixed? If so, write the formula of the precipitate. (c) If aqueous solutions of lead(II) nitrate and sodium acetate are mixed, does a precipitate form? If so, write the formula of the precipitate.

I.12 (a) Solid calcium nitrate and solid sodium carbonate were mixed, placed in water, and stirred. What is observed? If a precipitate is present, write its formula. (b) Solid nickel(II) sulfate and solid copper(II) chloride were placed in water, and the mixture was stirred. Is the formation of a precipitate expected? If so, write the formula of the precipitate. (c) Aqueous solutions of sodium phosphate and barium chloride are mixed. What is observed? If a precipitate is present, write its formula.

I.13 When the solution in Beaker 1 is mixed with the solution in Beaker 2, a precipitate forms. Using the following table, write the net ionic equation describing the formation of the precipitate, and then identify the spectator ions.

	Beaker 1	Beaker 2
(a)	$FeCl_2(aq)$	$Na_2S(aq)$
(b)	$Pb(NO_3)_2(aq)$	$KI(aq)$
(c)	$Ca(NO_3)_2(aq)$	$K_2SO_4(aq)$
(d)	$Na_2CrO_4(aq)$	$Pb(NO_3)_2(aq)$
(e)	$Hg_2(NO_3)_2(aq)$	$K_2SO_4(aq)$

I.14 The contents of Beaker 1 are mixed with those of Beaker 2. If a reaction takes place, write the net ionic equation and indicate the spectator ions.

	Beaker 1	Beaker 2
(a)	$K_2SO_4(aq)$	$AgNO_3(aq)$
(b)	$H_3PO_4(aq)$	$SrBr_2(aq)$
(c)	$Na_2S(aq)$	$NH_4NO_3(aq)$
(d)	$CdSO_4(aq)$	$(NH_4)_2CO_3(aq)$
(e)	$H_2SO_4(aq)$	$Hg_2Cl_2(aq)$

I.15 Each of the following procedures results in the formation of a precipitate. For each reaction, write the chemical equations describing the formation of the precipitate: the overall equation, the complete ionic equation, and the net ionic equation. Identify the spectator ions.
(a) $(NH_4)_2CrO_4(aq)$ is mixed with $BaCl_2(aq)$.
(b) $CuSO_4(aq)$ is mixed with $Na_2S(aq)$.
(c) $FeCl_2(aq)$ is mixed with $(NH_4)_3PO_4(aq)$.
(d) Potassium oxalate, $K_2C_2O_4(aq)$, is mixed with $Ca(NO_3)_2(aq)$.
(e) $NiSO_4(aq)$ is mixed with $Ba(NO_3)_2(aq)$.

I.16 Each of the following procedures results in the formation of a precipitate. For each reaction, write the chemical equations describing the formation of the precipitate: the overall equation, the complete ionic equation, and the net ionic equation. Identify the spectator ions.
(a) $AgNO_3(aq)$ is mixed with $Na_2CO_3(aq)$.
(b) $Pb(NO_3)_2(aq)$ is mixed with KI(aq).
(c) $Ba(OH)_2(aq)$ is mixed with $H_2SO_4(aq)$.
(d) $(NH_4)_2S(aq)$ is mixed with $Cd(NO_3)_2(aq)$.
(e) KOH(aq) is mixed with $CuCl_2(aq)$.

I.17 Write the balanced overall, complete ionic, and net ionic equations corresponding to each of the following reactions:
(a) $Ba(CH_3CO_2)_2(aq) + Li_2CO_3(aq) \longrightarrow BaCO_3(s) + LiCH_3CO_2(aq)$
(b) $NH_4Cl(aq) + Hg_2(NO_3)_2(aq) \longrightarrow NH_4NO_3(aq) + Hg_2Cl_2(s)$
(c) $Cu(NO_3)_2(aq) + Ba(OH)_2(aq) \longrightarrow Cu(OH)_2(s) + Ba(NO_3)_2(aq)$

I.18 Write the balanced overall, complete ionic, and net ionic equations corresponding to each of the following reactions:
(a) $BaCl_2(aq) + K_3PO_4(aq) \longrightarrow Ba_3(PO_4)_2(s) + KCl(aq)$
(b) $KCl(aq) + Hg_2(NO_3)_2(aq) \longrightarrow Hg_2Cl_2(s) + KNO_3(aq)$
(c) $K_2C_2O_4(aq) + Fe(CH_3CO_2)_3(aq) \longrightarrow Fe_2(C_2O_4)_3(s) + KCH_3CO_2(aq)$

I.19 For each of the following reactions, suggest two soluble ionic compounds that, when mixed together in water, result in the net ionic equation given:
(a) $2\ Ag^+(aq) + CrO_4^{2-}(aq) \longrightarrow Ag_2CrO_4(s)$
(b) $Ca^{2+}(aq) + CO_3^{2-}(aq) \longrightarrow CaCO_3(s)$, the reaction responsible for the deposition of chalk hills and sea urchin spines
(c) $Cd^{2+}(aq) + S^{2-}(aq) \longrightarrow CdS(s)$, a yellow substance used to color glass

I.20 For each of the following reactions, suggest two soluble ionic compounds that, when mixed together in water, result in the net ionic equation given:
(a) $2\ Ag^+(aq) + CO_3^{2-}(aq) \longrightarrow Ag_2CO_3(s)$
(b) $Mg^{2+}(aq) + 2\ OH^-(aq) \longrightarrow Mg(OH)_2(s)$, the suspension present in milk of magnesia
(c) $3\ Ca^{2+}(aq) + 2\ PO_4^{3-}(aq) \longrightarrow Ca_3(PO_4)_2(s)$, gypsum, a component of concrete

I.21 Write the net ionic equation for the formation of each of the following insoluble compounds in aqueous solution: (a) silver sulfate, Ag_2SO_4; (b) mercury(II) sulfide, HgS, used as an electrolyte in some primary batteries; (c) calcium phosphate, $Ca_3(PO_4)_2$, a component of bones and teeth. (d) Select two soluble ionic compounds that, when mixed in solution, form each of the insoluble compounds in parts (a), (b), and (c). Identify the spectator ions.

I.22 Write the net ionic equation for the formation of each of the following insoluble compounds in aqueous solution: (a) lead(II) chromate, $PbCrO_4$, the yellow pigment that has been used for centuries in oil paints; (b) aluminum phosphate, $AlPO_4$, used in cements and as an antacid; (c) iron(II) hydroxide, $Fe(OH)_2$; (d) Select two soluble ionic compounds that, when mixed in

solution, form each of the insoluble compounds in parts (a), (b), and (c). Identify the spectator ions.

I.23 You are given a solution and asked to analyze it for the cations Ag^+, Ca^{2+}, and Zn^{2+}. You add hydrochloric acid, and a white precipitate forms. You filter out the solid and add sulfuric acid to the solution. Nothing appears to happen. Then you add hydrogen sulfide. A black precipitate forms. Which ions should you report as present in your solution?

I.24 You are given a solution and asked to analyze it for the cations Ag^+, Ca^{2+}, and Hg^{2+}. You add hydrochloric acid. Nothing appears to happen. You then add dilute sulfuric acid, and a white precipitate forms. You filter out the solid and add hydrogen sulfide to the solution that remains. A black precipitate forms. Which ions should you report as present in your solution?

I.25 Suppose that 40.0 mL of 0.100 M NaOH(aq) is added to 10.0 mL of 0.200 M $Cu(NO_3)_2$(aq). (a) Write the chemical equation for the precipitation reaction, the complete ionic equation, and the net ionic equation. (b) What is the molarity of Na^+ ions in the final solution?

I.26 Suppose that 2.50 g of solid $(NH_4)_3(PO_4)$ is added to 50.0 mL of 0.125 M $CaCl_2$(aq). (a) Write the chemical equation for the precipitation reaction and the net ionic equation. (b) What is the molarity of each spectator ion after reaction is complete? Assume a final volume of 70.0 mL.

I.27 Suppose that 5.20 g of solid potassium chromate is added to 75.0 mL of 0.250 M $Mg(NO_3)_2$(aq). (a) What is the initial molarity of potassium chromate in the solution? (b) What mass of potassium is present in solution? (c) Write the formula for the precipitate that forms. Assume a final volume of 75.0 mL.

J.1 Acids and Bases in Aqueous Solution
J.2 Strong and Weak Acids and Bases
J.3 Neutralization

J ACIDS AND BASES

Early chemists applied the term *acid* to substances that had a sharp or sour taste. Vinegar, for instance, contains acetic acid, CH_3COOH. Aqueous solutions of substances that they called *bases* or *alkalis* were recognized by their soapy feel. Fortunately, there are less hazardous ways of recognizing acids and bases. For instance, acids and bases change the color of certain dyes known as *indicators* (Fig. J.1). One of the best-known indicators is litmus, a vegetable dye obtained from a lichen. Aqueous solutions of acids turn litmus red; aqueous solutions of bases turn it blue. Later (in Chapter 12), we shall see that the electronic instrument known as a "pH meter" provides a rapid way of identifying a solution as acidic or basic:

a pH *lower* than 7 ($pH < 7$) denotes an acidic solution
a pH *higher* than 7 ($pH > 7$) denotes a basic solution

J.1 Acids and Bases in Aqueous Solution

Chemists debated the concepts of acid and base for many years before precise definitions emerged. Among the first useful definitions was the one proposed by the Swedish chemist Svante Arrhenius in about 1884:

An **acid** is a compound that contains hydrogen and reacts with water to form hydrogen ions.
A **base** is a compound that produces hydroxide ions in water.

FIGURE J.1 The acidities of various household products can be demonstrated by adding an indicator (an extract of red cabbage, in this case) and noting the resulting color. Red indicates an acidic solution, blue basic. From left to right, the household products are stomach acid, lemon-lime soda, tap water, detergent, and a solution of lye. The yellow seen in the lye solution is a sign that the lye is so basic that it has destroyed some of the dye.

These compounds are called **Arrhenius acids and bases.** For instance, HCl is an Arrhenius acid, because it releases a hydrogen ion, H^+ (a proton), when it dissolves in water; CH_4 is not an Arrhenius acid, because it does not release hydrogen ions in water. Sodium hydroxide is an Arrhenius base, because OH^- ions go into solution when it dissolves; ammonia is an Arrhenius base, because it produces OH^- ions by reacting with water:

$$NH_3(aq) + H_2O(l) \longrightarrow NH_4^+(aq) + OH^-(aq) \qquad (1)$$

Sodium metal, although it produces OH^- ions when it reacts with water, is not an Arrhenius base, because it is an element, not a compound, as the definition requires.

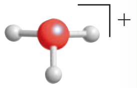
The problem with the Arrhenius definitions is that they are specific to one particular solvent, water. When chemists studied nonaqueous solvents, such as liquid ammonia, they found that a number of substances showed the same pattern of acid–base behavior. A major advance in our understanding of what it means to be an acid or a base came in 1923, when two chemists working independently, Thomas Lowry in England and Johannes Brønsted in Denmark, came up with the same idea. Their insight was to realize that the key process responsible for the properties of acids and bases was the transfer of a proton (a hydrogen ion) from one substance to another. The **Brønsted–Lowry definition** of acids and bases is as follows:

Acids and bases are described in more detail in Chapter 11.

An **acid** is a proton donor.
A **base** is a proton acceptor.

We call such substances "Brønsted acids and bases" or just plain "acids and bases" because the Brønsted–Lowry definition is the one commonly accepted today and the one used throughout this text.

First consider acids. When a molecule of an acid dissolves in water, it donates a hydrogen ion, H^+, to one of the water molecules and forms a *hydronium ion*, H_3O^+ (**1**). For example, when hydrogen chloride, HCl, dissolves in water, it releases a hydrogen ion to water, and the resulting solution consists of hydronium ions and chloride ions:

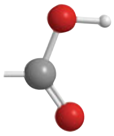


1 Hydronium ion, H_3O^+

$$HCl(aq) + H_2O(l) \longrightarrow H_3O^+(aq) + Cl^-(aq)$$

Notice that because H_2O accepts the hydrogen ion to form H_3O^+, water is acting as a Brønsted base.

Hydrogen chloride, HCl, and nitric acid, HNO_3, are Brønsted acids. The molecules of both compounds contain hydrogen atoms that they can donate as protons to other substances. Both compounds form hydronium ions in water. Methane, CH_4, is not a Brønsted acid under ordinary conditions. Although it contains hydrogen, it does not normally release hydrogen ions to other substances. Acetic acid, CH_3COOH, releases *one* hydrogen ion (from the hydrogen atom of the carboxyl group, —COOH (**2**)) to water and any other Brønsted bases present in the solution. Like HCl and HNO_3, acetic acid is a **monoprotic acid,** an acid that can donate only one proton from each molecule. Sulfuric acid, H_2SO_4, can release both its hydrogen atoms as ions—the first one much more readily than the second—and so it is an example of a **polyprotic acid,** an acid that can donate more than one proton from each molecule.



2 Carboxyl group, —COOH

The **acidic hydrogen atom** in a compound is the hydrogen atom that can be released as a proton. It is often written as the first element in a molecular formula, as in HCl and HNO_3. However, for organic acids, such as acetic acid, it is more informative to write the formulas to show the carboxyl group, —COOH, explicitly, thereby making it easier to remember that the H atom in this group of atoms is the acidic one. Thus, we can immediately recognize from their formulas that HCl, H_2CO_3 (carbonic acid), H_2SO_4 (sulfuric acid), and C_6H_5COOH (benzoic acid) are acids in water but that CH_4, NH_3 (ammonia) and $CH_3CO_2^-$ (the acetate ion) are not. The common oxoacids, acids containing oxygen, were introduced in Section D and are listed in Table D.1.

Now consider bases, species that accept protons. First, we can see that hydroxide ions are bases, because they accept protons from acids to form molecules of water:

$$OH^-(aq) + CH_3COOH(aq) \longrightarrow H_2O(l) + CH_3CO_2^-(aq)$$

Ammonia is a base because, as we see from Eq. 1, it accepts protons from water and forms NH_4^+ ions. Notice that because water donates a hydrogen ion it is acting as a Brønsted acid in that reaction.

A note on good practice: In the Arrhenius system, sodium hydroxide is a base; however, from the Brønsted point of view it simply *provides* the base OH^-. Chemists commonly slip into using the Arrhenius definition.

Self-Test J.1A Which of the following compounds are Brønsted acids or bases in water? (a) HNO_3; (b) C_6H_6; (c) KOH; (d) C_3H_5COOH.

[***Answer:*** (a) and (d) are acids; (b) is neither an acid nor a base; (c) *supplies* the base OH^-]

Self-Test J.1B Which of the following compounds are Brønsted acids or bases in water? (a) KCl; (b) HClO; (c) HF; (d) $Ca(OH)_2$.

Acids are molecules or ions that are proton donors. Bases are molecules or ions that are proton acceptors.

J.2 Strong and Weak Acids and Bases

We saw in Section I.1 that electrolytes are classified as strong or weak according to the extent to which they are present as ions in solution. We classify acids and bases in a similar fashion. In these definitions the term **deprotonation** means loss of a proton and **protonation** means the gain of a proton:

The terms *ionized* and *dissociated* are commonly used instead of "deprotonated."

A **strong acid** is completely deprotonated in solution.
A **weak acid** is incompletely deprotonated in solution.
A **strong base** is completely protonated in solution.
A **weak base** is incompletely protonated in solution.

By "completely deprotonated" we mean that *each* acid molecule or ion has lost the proton of its acidic hydrogen atom by transferring it as a hydrogen ion to a solvent molecule. "Completely protonated" means that *each* base molecule or ion has acquired a proton. By "incompletely deprotonated" or "incompletely protonated," we mean that only a fraction (usually a very tiny fraction) of the acid molecules or ions have lost acidic hydrogen atoms as protons or only a tiny fraction of the base molecules or ions have acquired protons.

To understand the distinction between strong and weak acids, we compare two acids. Hydrogen chloride is a strong acid in water. A solution of hydrogen chloride and water, which we call hydrochloric acid, contains hydronium ions, chloride ions, and virtually no HCl molecules. This reaction goes to completion:

$$HCl(g) + H_2O(l) \longrightarrow H_3O^+(aq) + Cl^-(aq)$$

Acetic acid, on the other hand, is a weak acid in water. Only a small fraction of its molecules undergo deprotonation in this reaction:

$$CH_3COOH(aq) + H_2O(l) \longrightarrow H_3O^+(aq) + CH_3CO_2^-(aq)$$

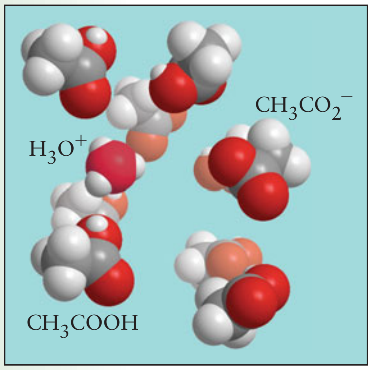


FIGURE J.2 Acetic acid, like all carboxylic acids, is a weak acid in water. This classification means that most of it remains as acetic acid molecules, CH_3COOH; however, a small proportion of these molecules donate a hydrogen ion to a water molecule to form hydronium ions, H_3O^+, and acetate ions, $CH_3CO_2^-$.

Therefore, the solute consists principally of CH_3COOH molecules (Fig. J.2). In fact, 0.1 M $CH_3COOH(aq)$ contains only about one $CH_3CO_2^-$ ion for every hundred acetic acid molecules used to make a solution.

Table J.1 lists all the common strong acids in water. They include three acids that are often found as reagents in laboratories—hydrochloric acid, nitric acid, and sulfuric acid (with respect to the loss of one proton from each H_2SO_4 molecule). Most acids are weak in water. All carboxylic acids are weak in water.

Now consider strong and weak bases. The common strong bases are oxide ions and hydroxide ions, which are provided by the alkali metal and alkaline earth metal oxides and hydroxides, such as calcium oxide (see Table J.1). As we have seen, chemists

TABLE J.1 The Strong Acids and Bases in Water

Strong acids	Strong bases
hydrobromic acid, $HBr(aq)$	Group 1 hydroxides
hydrochloric acid, $HCl(aq)$	alkaline earth metal hydroxides*
hydroiodic acid, $HI(aq)$	Group 1 and Group 2 oxides
nitric acid, HNO_3	
perchloric acid, $HClO_4$	
chloric acid, $HClO_3$	
sulfuric acid, H_2SO_4 (to HSO_4^-)	

*$Ca(OH)_2$, $Sr(OH)_2$, $Ba(OH)_2$.

often refer to these oxides and hydroxides as "strong bases." When an oxide dissolves in water, the oxide ions, O^{2-}, accept protons to form hydroxide ions:

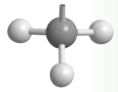
$$O^{2-}(aq) + H_2O(l) \longrightarrow 2\,OH^-(aq)$$

Hydroxide ions, such as those provided by sodium hydroxide and calcium hydroxide, are also strong bases in water:

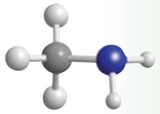
$$H_2O(l) + OH^-(aq) \longrightarrow OH^-(aq) + H_2O(l)$$

Even though a hydroxide ion is a strong base and is protonated in water, it effectively survives, because the H_2O molecule that donates a proton to OH^- becomes a hydroxide ion itself and takes its place!

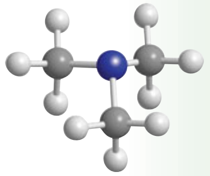
All other common bases are weak in water. For example, ammonia is a weak base in water. In its aqueous solutions, it exists almost entirely as NH_3 molecules, with just a small proportion—usually fewer than one in a hundred molecules at normal concentrations—of NH_4^+ cations and OH^- anions. Other common weak bases are the amines, the pungent compounds that are derived from ammonia by replacement of one or more of its hydrogen atoms by an organic group. For example, the replacement of one hydrogen atom in NH_3 by a methyl group, $—CH_3$ (**3**), results in methylamine, CH_3NH_2 (**4**). The replacement of all three hydrogen atoms in NH_3 by methyl groups results in trimethylamine, $(CH_3)_3N$ (**5**), a substance found in decomposing fish and on unwashed dogs.



3 Methyl group, $—CH_3$



4 Methylamine, CH_3NH_2



5 Trimethylamine, $(CH_3)_3N$

Strong acids (the acids listed in Table J.1) are completely deprotonated in solution; weak acids (most other acids) are not. Strong bases (the metal oxides and hydroxides listed in Table J.1) are completely protonated in solution. Weak bases (ammonia and its organic derivatives, the amines) are only partially protonated in solution.

J.3 Neutralization

The reaction between an acid and a base is called a **neutralization reaction,** and the ionic compound produced in the reaction is called a **salt.** The general form of a neutralization reaction of a strong acid and a metal hydroxide that provides the hydroxide ion, a strong base, in water is

$$\text{Acid} + \text{metal hydroxide} \longrightarrow \text{salt} + \text{water}$$

The name *salt* is taken from ordinary table salt, sodium chloride, the ionic product of the reaction between hydrochloric acid and sodium hydroxide:

$$HCl(aq) + NaOH(aq) \longrightarrow NaCl(aq) + H_2O(l)$$

In the neutralization reaction between an acid and a metal hydroxide, the cation of the salt is provided by the metal hydroxide, such as NaOH, and the anion is provided by the acid. Another example is the reaction between nitric acid and barium hydroxide:

$$2\,HNO_3(aq) + Ba(OH)_2(aq) \longrightarrow Ba(NO_3)_2(aq) + 2\,H_2O(l)$$

The barium nitrate remains in solution as Ba^{2+} and NO_3^- ions.

We saw in Section I that the net chemical change in a precipitation reaction is clarified by writing its net ionic equation. The same is true of neutralization reactions. First, we write the complete ionic equation for the neutralization reaction between nitric acid and barium hydroxide in water:

Although hydrogen ions are always attached to water molecules as hydronium ions, H_3O^+, or more complex species, we write them here as H^+ for simplicity. The (aq) should be taken to imply that the hydrogen ion is actually present as the hydronium ion.

$$2\,H^+(aq) + 2\,NO_3^-(aq) + Ba^{2+}(aq) + 2\,OH^-(aq) \longrightarrow Ba^{2+}(aq) + 2\,NO_3^-(aq) + 2\,H_2O(l)$$

The ions common to both sides now cancel,

$$2\,H^+(aq) + \cancel{2\,NO_3^-(aq)} + \cancel{Ba^{2+}(aq)} + 2\,OH^-(aq) \longrightarrow \cancel{Ba^{2+}(aq)} + \cancel{2\,NO_3^-(aq)} + 2\,H_2O(l)$$

and the net ionic equation of this reaction is therefore

$$2\,H^+(aq) + 2\,OH^-(aq) \longrightarrow 2\,H_2O(l)$$

which simplifies to

$$H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$$

The net outcome of any neutralization reaction between a strong acid and a strong base in water is the formation of water from hydrogen ions and hydroxide ions.

When we write the net ionic equation for the neutralization of a weak acid or a weak base, we use the molecular form of the weak acid or base, because molecules are the dominant species in solution. For example, we write the net ionic equation for the reaction of the weak acid HCN with the strong base NaOH in water (Fig. J.3) as

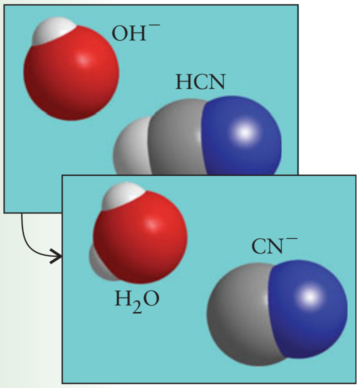


FIGURE J.3 The net ionic equation for the neutralization of HCN, a weak acid, by the strong base, NaOH, tells us that the hydroxide ion extracts a hydrogen ion from an acid molecule.

$$HCN(aq) + OH^-(aq) \longrightarrow H_2O(l) + CN^-(aq)$$

Similarly, the net ionic equation for the reaction of the weak base ammonia with the strong acid HCl in water is

$$NH_3(aq) + H^+(aq) \longrightarrow NH_4^+(aq)$$

Self-Test J.2A What acid and base solutions could you use to prepare rubidium nitrate? Write the chemical equation for the neutralization.

[*Answer:* $HNO_3(aq) + RbOH(aq) \longrightarrow RbNO_3(aq) + H_2O(l)$]

Self-Test J.2B Write the chemical equation for a neutralization reaction in which calcium phosphate is produced.

In a neutralization reaction in water, an acid reacts with a base to produce a salt (and water if the base is strong); the net outcome of the reaction between solutions of a strong acid and a metal hydroxide is the formation of water from hydrogen ions and hydroxide ions.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Describe the chemical properties of acids and bases (Section J.1).

❑ 2 Classify substances as acids or bases (Self-Test J.1).

❑ 3 Identify common strong acids and bases (Table J.1).

❑ 4 Predict the outcome of neutralization reactions and write their chemical equations (Self-Test J.2).

EXERCISES

J.1 Identify each compound as either a Brønsted acid or a Brønsted base: (a) NH_3; (b) HBr; (c) KOH; (d) H_2SO_3; (e) $Ca(OH)_2$.

J.2 Classify each compound as either a Brønsted acid or a Brønsted base: (a) H_2SeO_4; (b) $CH_3CH_2NH_2$, a derivative of ammonia; (c) HCOOH; (d) CsOH; (e) HIO_4.

J.3 Complete the overall equation, and write the complete ionic equation and the net ionic equation for each of the following acid–base reactions. If the substance is a weak acid or base, leave it in its molecular form in the equations.
(a) $HF(aq) + NaOH(aq) \longrightarrow$
(b) $(CH_3)_3N(aq) + HNO_3(aq) \longrightarrow$
(c) $LiOH(aq) + HI(aq) \longrightarrow$

J.4 Complete the overall equation, and write the complete ionic equation and the net ionic equation for each of the following acid–base reactions. If the substance is a weak acid or base, leave it in its molecular form in the equations.
(a) $H_3PO_4(aq) + KOH(aq) \longrightarrow$
(Phosphoric acid, H_3PO_4, is a triprotic acid. Write the equation for complete reaction with KOH.)
(b) $Ba(OH)_2(aq) + CH_3COOH(aq) \longrightarrow$
(c) $Mg(OH)_2(s) + HClO_3(aq) \longrightarrow$

J.5 Select an acid and a base for a neutralization reaction that results in the formation of (a) potassium bromide; (b) zinc nitrite; (c) calcium cyanide, $Ca(CN)_2$; (d) potassium phosphate. Write the balanced equation for each reaction.

J.6 Identify the salt that is produced from the acid–base neutralization reaction between (a) potassium hydroxide and acetic acid, CH_3COOH; (b) ammonia and phosphoric acid; (c) calcium hydroxide and bromous acid; (d) sodium hydroxide and hydrosulfuric acid, H_2S (both H atoms react). Write the complete ionic equation for each reaction.

J.7 Identify the acid and the base in each of the following reactions:
(a) $CH_3NH_2(aq) + H_3O^+(aq) \longrightarrow CH_3NH_3^+(aq) + H_2O(l)$
(b) $CH_3NH_2(aq) + CH_3COOH(aq) \longrightarrow CH_3NH_3^+(aq) + CH_3CO_2^-(aq)$
(c) $2\,HI(aq) + CaO(s) \longrightarrow CaI_2(aq) + H_2O(l)$

J.8 Identify the acid and the base in each of the following reactions:
(a) $HBrO_3(aq) + NaHCO_3(aq) \longrightarrow H_2CO_3(aq) + NaBrO_3(aq)$
(b) $(CH_3)_3N(aq) + HCl(aq) \longrightarrow (CH_3)_3NH^+(aq) + Cl^-(aq)$
(c) $O^{2-}(aq) + H_2O(l) \longrightarrow 2\,OH^-(aq)$

J.9 You are asked to identify compound X, which was extracted from a plant seized by customs inspectors. You run a number of tests and collect the following data. Compound X is a white, crystalline solid. An aqueous solution of X turns litmus red and conducts electricity poorly, even when X is present at appreciable concentrations. When you add sodium hydroxide to the solution a reaction takes place. A solution of the products of the reaction conducts electricity well. An elemental analysis of X shows that the mass percentage composition of the compound is 26.68% C and 2.239% H, with the remainder being oxygen. A mass spectrum of X yields a molar mass of 90.0 $g\cdot mol^{-1}$. (a) Write the empirical formula of X. (b) Write the molecular formula of X. (c) Write the balanced chemical equation and the net ionic equation for the reaction of X with sodium hydroxide. (Assume that X has two acidic hydrogen atoms.)

J.10 (a) White phosphorus, which has the formula P_4, burns in air to form compound A, in which the mass percentage of phosphorus is 43.64%, with the remainder oxygen. The mass spectrum of A yields a molar mass of 283.9 $g\cdot mol^{-1}$. Write the molecular formula of compound A. (b) Compound A reacts with water to form compound B, which turns litmus red and has a mass percentage composition of 3.087% H and 31.60% P, with the remainder oxygen. The mass spectrum of compound B yields a molar mass of 97.99 $g\cdot mol^{-1}$. Write the molecular formula of compound B. (c) Compound B reacts with an aqueous solution of calcium hydroxide to form compound C, a white precipitate. Write balanced chemical equations for the reactions in parts (a), (b), and (c).

J.11 In each of the following salts, either the cation or the anion is a weak acid or a weak base. Write the chemical equation for the proton transfer reaction of this cation or anion with water:
(a) NaC_6H_5O; (b) KClO; (c) C_5H_5NHCl; (d) NH_4Br.

J.12 $C_6H_5NH_3Cl$ is a chloride salt with an acidic cation. (a) If 50.0 g of $C_6H_5NH_3Cl$ is dissolved in water to make 150.0 mL of solution, what is the initial molarity of the cation? (b) Write the chemical equation for the proton transfer reaction of the cation with water. Identify the acid and the base in this reaction.

J.13 The anion in Na_3AsO_4 is a weak base that can accept more than one proton. (a) Write the chemical equations for the sequential proton transfer reactions of the anion with water. Identify the acid and the base in each reaction.
(b) If 35.0 g of Na_3AsO_4 is dissolved in water to make 250.0 mL of solution, how many moles of sodium cations are in the solution?

J.14 The anion in potassium sulfite, K_2SO_3, is a weak base that can accept more than one proton. (a) Write the chemical equations for the sequential proton transfer reactions of the anion with water. Identify the acid and the base in each reaction.
(b) If 0.054 g of K_2SO_3 is dissolved in water to make 200.0 mL of solution, what amount (in moles) of potassium cations are in the solution?

J.15 The oxides of nonmetallic elements are called acidic oxides because they form acidic solutions in water. Write the balanced chemical equations for the reaction of one mole of each acidic oxide with one mole of water molecules to form an oxoacid and name the acid formed: (a) CO_2; (b) SO_3.

J.16 The oxides of metallic elements are called basic oxides because they form basic solutions in water. Write the balanced chemical equations for the reaction of 1 mol of each basic oxide with 1 mol of water molecules to form a metal hydroxide: (a) BaO; (b) Li_2O.

K REDOX REACTIONS

K.1 Oxidation and Reduction
K.2 Oxidation Numbers: Keeping Track of Electrons
K.3 Oxidizing and Reducing Agents
K.4 Balancing Simple Redox Equations

Redox reactions constitute the third of the three major classes of chemical reactions treated here. The variety of these reactions is remarkable. Many common reactions, such as combustion, corrosion, photosynthesis, the metabolism of food, and the extraction of metals from their ores, appear to be completely different. However, when we consider these changes at the molecular level with a chemist's eye, we can see that they are all examples of a single type of process.

FIGURE K.1 An example of an oxidation reaction: magnesium burning brightly in air. Magnesium is so easily oxidized that it also burns brightly in water and carbon dioxide; consequently, magnesium fires are very difficult to extinguish.

Lab Video K.1

FIGURE K.2 When chlorine is bubbled through a solution of bromide ions, it oxidizes the ions to bromine, which colors the solution reddish brown.

K.1 Oxidation and Reduction

Let's examine some of these redox reactions and look for their common characteristic. First, consider the reaction between magnesium and oxygen, which produces magnesium oxide (Fig. K.1); this reaction is used in fireworks to produce white sparks. It is also used, less agreeably, in tracer ammunition and incendiary devices. The reaction of magnesium and oxygen is a classic example of an *oxidation reaction*, in the original sense of the term, "reaction with oxygen." In the course of the reaction, the Mg atoms in the solid magnesium lose electrons to form Mg^{2+} ions, and the O atoms in the molecular oxygen gain electrons to form O^{2-} ions:

$$2\,Mg(s) + O_2(g) \longrightarrow 2\,Mg^{2+}(s) + 2\,O^{2-}(s), \text{ as } 2\,MgO(s)$$

A similar reaction takes place when magnesium reacts with chlorine to produce magnesium chloride:

$$Mg(s) + Cl_2(g) \longrightarrow Mg^{2+}(s) + 2\,Cl^{-}(s), \text{ as } MgCl_2(s)$$

Because the *pattern* of reaction is the same, the second reaction is also regarded as an "oxidation" of magnesium even though no oxygen takes part. In each case, the common feature is the loss of electrons from magnesium and their transfer to another reactant. The loss of electrons from one species to another is now recognized as the essential event in an oxidation, and chemists now define **oxidation** as the loss of electrons, regardless of the species to which the electrons migrate.

We can often recognize loss of electrons by noting the increase in the charge of a species. This rule also applies to anions, as in the oxidation of bromide ions (charge −1) to bromine (charge 0) in a reaction such as the one used commercially to make bromine (Fig. K.2):

$$2\,NaBr(s) + Cl_2(g) \longrightarrow 2\,NaCl(s) + Br_2(l)$$

Here, the bromide ion (as sodium bromide) is oxidized to bromine by the chlorine gas.

The name *reduction* originally referred to the extraction of a metal from its oxide, often by reaction with hydrogen, carbon, or carbon monoxide. One example is the reduction of iron(III) oxide by carbon monoxide in the manufacture of steel:

$$Fe_2O_3(s) + 3\,CO(g) \longrightarrow 2\,Fe(l) + 3\,CO_2(g)$$

In this reaction, an oxide of an element is converted into the free element, the reverse of oxidation. In the reduction of iron(III) oxide, Fe^{3+} ions present in Fe_2O_3 are converted into uncharged Fe atoms when they gain electrons to neutralize their positive charges. That turns out to be the pattern common to all reductions: in a **reduction,** an atom *gains* electrons from another species. Whenever the charge on a species is decreased (as from Fe^{3+} to Fe), we say that reduction has taken place. The same rule applies if the charge is negative. For example, when chlorine is converted into chloride ions in the reaction

$$2\,NaBr(s) + Cl_2(g) \longrightarrow 2\,NaCl(s) + Br_2(l)$$

the charge decreases from 0 (in Cl_2) to −1 (in Cl^-), and we conclude that in this reaction chlorine has been reduced.

Self-Test K.1A Identify the species that have been oxidized or reduced in the reaction $3\,Ag^+(aq) + Al(s) \longrightarrow 3\,Ag(s) + Al^{3+}(aq)$.

[***Answer:*** Al(s) is oxidized, $Ag^+(aq)$ is reduced]

Self-Test K.1B Identify the species that have been oxidized or reduced in the reaction $2\,Cu^+(aq) + I_2(s) \longrightarrow 2\,Cu^{2+}(aq) + 2\,I^-(aq)$.

We have seen that oxidation is electron loss and reduction is electron gain. Electrons are real particles and cannot just be "lost." Therefore, *whenever a species is oxidized, another species must be reduced*. Oxidation or reduction taken separately is like one

hand clapping: one transfer must occur in conjunction with the other for reaction to take place. For instance, in the reaction between chlorine and sodium bromide, the bromide ions are oxidized and the chlorine molecules are reduced. Because oxidation is always accompanied by reduction, chemists speak of **redox reactions,** oxidation–reduction reactions, rather than simply oxidation reactions or reduction reactions.

Oxidation is electron loss; reduction is electron gain. Oxidation and reduction occur together in redox reactions.

K.2 Oxidation Numbers: Keeping Track of Electrons

We recognize redox reactions by noting whether electrons have migrated from one species to another. The loss or gain of electrons is easy to identify for monatomic ions, because we can monitor the charges of the species. Thus, when Br^- ions are converted into bromine atoms (which go on to form Br_2 molecules), we know that each Br^- ion must have lost an electron and hence that it has been oxidized. When O_2 forms oxide ions, O^{2-}, we know that each oxygen atom must have gained two electrons and therefore that it has been reduced. The difficulty arises when the transfer of electrons is accompanied by the transfer of atoms. For example, is chlorine gas, Cl_2, oxidized or reduced when it is converted into hypochlorite ions, ClO^-?

Chemists have found a way to keep track of electrons by assigning an "oxidation number" to each element. The **oxidation number**, N_{ox}, is defined so that

The concept of oxidation number was first introduced in Section D.

Oxidation corresponds to an *increase* in oxidation number.
Reduction corresponds to a *decrease* in oxidation number.

A redox reaction, therefore, is any reaction in which there are changes in oxidation numbers.

The oxidation number of the element as a monatomic ion is the same as its charge. For example, the oxidation number of magnesium is +2 when it is present as Mg^{2+} ions, and the oxidation number of chlorine is −1 when it is present as Cl^- ions. The oxidation number of the elemental form of an element is 0; so magnesium metal has oxidation number 0 and chlorine in the form of Cl_2 molecules also has oxidation number 0. When magnesium combines with chlorine, the oxidation numbers change as follows:

$$\overset{0}{Mg(s)} + \overset{2(0)}{Cl_2(g)} \longrightarrow \overset{+2\ \ 2(-1)}{MgCl_2(s)}$$

We see that magnesium has been oxidized and chlorine has been reduced. Similarly, in the reaction between sodium bromide and chlorine,

$$\overset{2(+1\ \ -1)}{2\,NaBr(s)} + \overset{2(0)}{Cl_2(g)} \longrightarrow \overset{2(+1\ \ -1)}{2\,NaCl(s)} + \overset{2(0)}{Br_2(l)}$$

In this reaction, bromine has been oxidized and chlorine has been reduced, but the sodium ions remain unchanged as Na^+.

When an element is part of a compound or a polyatomic ion, we assign its oxidation number by using the procedure in Toolbox K.1.

A note on good practice: You will hear chemists speaking of both "oxidation number" and "oxidation state." An oxidation *number* is the number assigned according to the rules in Toolbox K.1. An *oxidation state* is the actual condition of a species with a specified oxidation number. Thus, an element *has* a certain oxidation number and *is in* the corresponding oxidation state. For example, Mg^{2+} is the +2 oxidation state of magnesium; and, in that state, magnesium has oxidation number +2.

TOOLBOX K.1 HOW TO ASSIGN OXIDATION NUMBERS

CONCEPTUAL BASIS

To assign an oxidation number, we imagine that each atom in a molecule, formula unit, or polyatomic ion is present in ionic form (which it might not be). The oxidation number is then taken to be the charge on each "ion." The "anion" is usually oxygen as O^{2-} or the element farthest to the right in the periodic table (actually, the most *electronegative* element; see Section 2.12). We then assign to the other atoms charges that balance the charge on the "anions."

PROCEDURE

To assign an oxidation number $N_{ox}(E)$ to an element E, we start with two simple rules:

1 The oxidation number of an element uncombined with other elements is 0.
2 The sum of the oxidation numbers of all the atoms in a species is equal to its total charge.

The oxidation numbers of elements in most of the compounds in this text are assigned by using these two rules along with the following specific values:

- The oxidation number of hydrogen is +1 in combination with nonmetals and −1 in combination with metals.
- The oxidation number of elements in Groups 1 and 2 is equal to their group number.
- The oxidation number of all the halogens is −1 unless the halogen is in combination with oxygen or another halogen higher in the group. The oxidation number of fluorine is −1 in all its compounds.
- The oxidation number of oxygen is −2 in most of its compounds. Exceptions are its compounds with fluorine (in which case, the previous statement takes precedence) and its occurrence as peroxides (O_2^{2-}), superoxides (O_2^-), and ozonides (O_3^-).

This procedure is illustrated in Example K.1.

EXAMPLE K.1 Assigning oxidation numbers

Is the conversion of SO_2 to SO_4^{2-} oxidation or reduction?

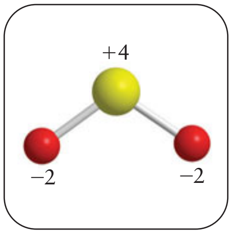
Anticipate Even though the product has acquired a negative charge, suggesting reduction, it has also acquired two more O atoms, so we can anticipate that overall the conversion is an oxidation.

PLAN The process is oxidation if the oxidation number of sulfur increases, reduction if it decreases. We need to assign the oxidation numbers of sulfur in SO_2 and SO_4^{2-}, then compare them. In each case, we represent the oxidation number of sulfur by $N_{ox}(S)$ and solve for $N_{ox}(S)$ after using the rules in Toolbox K.1. The oxidation number of oxygen is −2 in both compounds.

SOLVE SO_2: By rule 2, the sum of oxidation numbers of the atoms in the compound must be 0:

$$N_{ox}(S) + 2N_{ox}(O) = 0$$

$$\underbrace{N_{ox}(S)}_{\text{S}} + \underbrace{[2 \times (-2)]}_{\text{2 O}} = \underbrace{0}_{\text{zero charge on neutral molecule}}$$

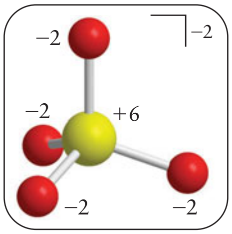


Therefore, the oxidation number of sulfur in SO_2 is +4.

SO_4^{2-} : By rule 2, the sum of oxidation numbers of the atoms in the ion is −2; so

$$N_{ox}(S) + 4N_{ox}(O) = -2$$

$$\underbrace{N_{ox}(S)}_{\text{S}} + \underbrace{[4 \times (-2)]}_{\text{4 O}} = \underbrace{-2}_{\text{total charge on ion}}$$



Therefore, the oxidation number of sulfur in SO_4^{2-} is +6.

Evaluate We conclude that sulfur is more highly oxidized in the sulfate ion than in sulfur dioxide. Therefore, as we suspected, the conversion of SO_2 to SO_4^{2-} is an oxidation.

Self-Test K.2A Find the oxidation numbers of sulfur, phosphorus, and chlorine in (a) H_2S; (b) P_4O_6; (c) ClO^-.

[***Answer:*** (a) −2; (b) +3; (c) +1]

Self-Test K.2B Find the oxidation numbers of sulfur, nitrogen, and chlorine in (a) SO_3^{2-}; (b) NO_2^-; (c) $HClO_3$.

Oxidation increases the oxidation number of an element; reduction decreases the oxidation number. Oxidation numbers are assigned by using the rules in Toolbox K.1.

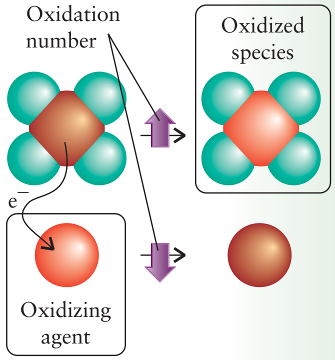


FIGURE K.3 The oxidizing agent (bottom) is the species containing the element that undergoes a decrease in oxidation number. Here we see how the oxidation number of the species on the top is driven upward as the oxidizing agent gains electrons.

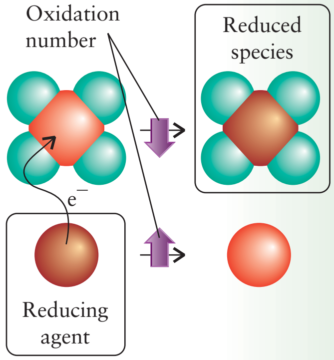

FIGURE K.4 The reducing agent (bottom) is the species containing the element that undergoes an increase in oxidation number. Here we see how the oxidation number of the species on the top is driven downward as it gains the electrons lost by the reducing agent.

K.3 Oxidizing and Reducing Agents

The species that *causes* oxidation is called the **oxidizing agent** (or "oxidant"). When an oxidizing agent acts, it accepts the electrons released by the species being oxidized. In other words, the oxidizing agent contains an element that undergoes a *decrease* in oxidation number (Fig. K.3). That is,

- The oxidizing agent in a redox reaction is the species that causes oxidation and in the process gets reduced.

For instance, oxygen removes electrons from magnesium. Because oxygen accepts those electrons, its oxidation number decreases from 0 to –2 (a reduction). Oxygen is therefore the oxidizing agent in this reaction. Oxidizing agents can be elements, ions, or compounds.

The species that brings about reduction is called the **reducing agent** (or "reductant"). Because the reducing agent supplies electrons to the species being reduced, the reducing agent loses electrons. That is, the reducing agent contains an element that undergoes an increase in oxidation number (Fig. K.4). In other words,

- The reducing agent in a redox reaction is the species that causes reduction and in the process gets oxidized.

For example, when magnesium metal supplies electrons to oxygen (reducing the oxygen atoms), the magnesium atoms lose electrons and the oxidation number of magnesium increases from 0 to +2 (an oxidation). It is the reducing agent in the reaction of magnesium and oxygen.

To identify the oxidizing and reducing agents in a redox reaction, we compare the oxidation numbers of the elements before and after the reaction to see which have changed. The reactant that contains an element that is reduced in the reaction is the oxidizing agent, and the reactant that contains an element that is oxidized is the reducing agent. For example, when a piece of zinc metal is placed in a copper(II) solution (Fig. K.5), the reaction is

$$\overset{0}{Zn}(s) + \overset{+2}{Cu}{}^{2+}(aq) \longrightarrow \overset{+2}{Zn}{}^{2+}(aq) + \overset{0}{Cu}(s)$$

The oxidation number of zinc changes from 0 to +2 (an oxidation), whereas that of copper decreases from +2 to 0 (a reduction). Therefore, because zinc is oxidized, zinc metal is the reducing agent in this reaction. Conversely, because copper is reduced, copper(II) ions are the oxidizing agent.

EXAMPLE K.2 Identifying oxidizing agents and reducing agents

Identify the oxidizing agent and the reducing agent in the following reaction:

$$Cr_2O_7^{2-}(aq) + 6\,Fe^{2+}(aq) + 14\,H^+(aq) \longrightarrow 6\,Fe^{3+}(aq) + 2\,Cr^{3+}(aq) + 7\,H_2O(l)$$

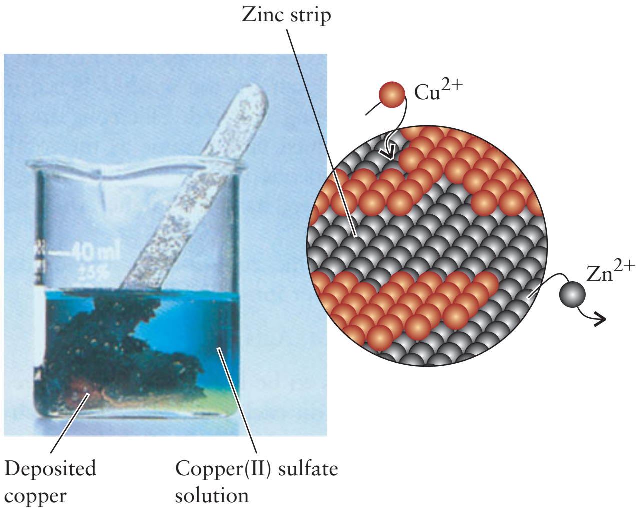

FIGURE K.5 When a strip of zinc is placed in a solution that contains Cu^{2+} ions, the blue solution slowly becomes colorless and copper metal is deposited on the zinc. The inset shows that, in this redox reaction, the zinc metal is reducing the Cu^{2+} ions to copper metal and the Cu^{2+} ions are oxidizing the zinc metal to Zn^{2+} ions.

Anticipate Because the charge on the iron cation has increased, it is being oxidized and we should expect it to be the reducing agent. Another clue is that a species with many O atoms can be suspected to act as an oxidizing agent, so we should expect the dichromate ion ($Cr_2O_7^{2-}$) to be the oxidizing agent.

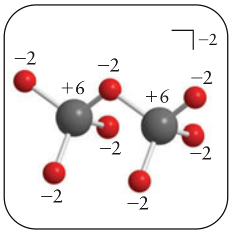
PLAN First, determine the oxidation numbers of the elements taking part in the reaction. The oxidizing agent is the species that contains an element that is reduced. Similarly, the reducing agent is the species that contains an element that is oxidized.

SOLVE The oxidation numbers of H and O have not changed, and so we concentrate on Cr and Fe.

Determine the oxidation numbers of chromium.

As a reactant (in $Cr_2O_7^{2-}$): let the oxidation number of Cr be $N_{ox}(Cr)$, then

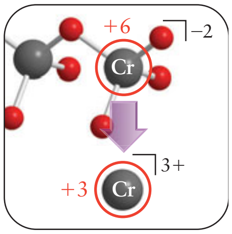
$$\underbrace{2N_{ox}(Cr)}_{Cr_2O_7^{2-}} + \underbrace{[7 \times (-2)]}_{Cr_2O_7^{2-}} = \underbrace{-2}_{Cr_2O_7^{2-}}, \quad \text{or} \quad 2N_{ox}(Cr) - 14 = -2$$



The oxidation number of Cr in $Cr_2O_7^{2-}$ is +6.
As a product (as Cr^{3+}): the oxidation number is +3.

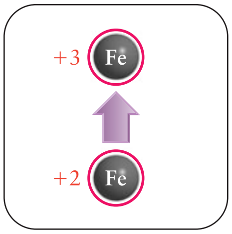
Decide whether Cr is oxidized or reduced.

Because $\overset{+6}{Cr_2}O_7^{2-} \longrightarrow 2\,\overset{+3}{Cr^{3+}}$, the oxidation number of Cr decreases from +6 to +3, so Cr is reduced and the dichromate ion is the oxidizing agent.



Determine the oxidation numbers of iron.

In Fe^{2+} (reactant): the oxidation number is +2.
In Fe^{3+} (product): the oxidation number is +3.



Decide whether Fe is oxidized or reduced.

The oxidation number of Fe increases from +2 to +3, so Fe is oxidized. Therefore, the Fe^{2+} ion is the reducing agent.

Evaluate As we anticipated, the dichromate ion is the oxidizing agent and Fe^{2+} is the reducing agent. The dichromate ion in acidic solution is a common laboratory oxidizing agent.

Self-Test K.3A In the Claus process for the recovery of sulfur from natural gas and petroleum, hydrogen sulfide reacts with sulfur dioxide to form elemental sulfur and water: $2\ H_2S(g) + SO_2(g) \longrightarrow 3\ S(s) + 2\ H_2O(l)$. Identify the oxidizing agent and the reducing agent.

[***Answer:*** SO_2 is the oxidizing agent, H_2S is the reducing agent]

Self-Test K.3B When sulfuric acid reacts with sodium iodide, sodium iodate and sulfur dioxide are produced. Identify the oxidizing and reducing agents in this reaction.

Oxidation is brought about by an oxidizing agent, a species that contains an element that undergoes reduction. Reduction is brought about by a reducing agent, a species that contains an element that undergoes oxidation.

K.4 Balancing Simple Redox Equations

Because electrons can be neither lost nor created in a chemical reaction, all the electrons lost by the species being oxidized must be transferred to the species being reduced. Because electrons are charged, the total charge of the reactants must be the same as the total charge of the products. Therefore, when balancing the chemical equation for a redox reaction, we have to balance the charges as well as the atoms.

For example, consider the net ionic equation for the oxidation of copper metal to copper(II) ions by silver ions (Fig. K.6):

$$Cu(s) + Ag^+(aq) \longrightarrow Cu^{2+}(aq) + Ag(s)$$

At first glance, the equation appears to be balanced, because it has the same number of each kind of atom on each side. However, the total charge of the products is different from that of the reactants. Each copper atom has lost two electrons, whereas each silver atom has gained only one. To balance the electrons, we have to balance the charge. Therefore, we need to write

$$Cu(s) + 2\ Ag^+(aq) \longrightarrow Cu^{2+}(aq) + 2\ Ag(s)$$

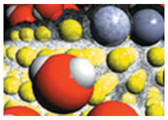
Self-Test K.4A When tin metal is placed in contact with a solution of Fe^{3+} ions, it reduces the iron to iron(II) and is itself oxidized to tin(II) ions. Write the net ionic equation for the reaction.

[***Answer:*** $Sn(s) + 2\ Fe^{3+}(aq) \longrightarrow Sn^{2+}(aq) + 2\ Fe^{2+}(aq)$]

Self-Test K.4B In aqueous solution, cerium(IV) ions oxidize iodide ions to solid diatomic iodine and are themselves reduced to cerium(III) ions. Write the net ionic equation for the reaction.

Some redox reactions, particularly those involving oxoanions, have complex chemical equations that require special balancing procedures. We meet examples and see how to balance them in Chapter 13.

When balancing the chemical equation for a redox reaction involving ions, the total charge on each side must be balanced.



(a) (b)

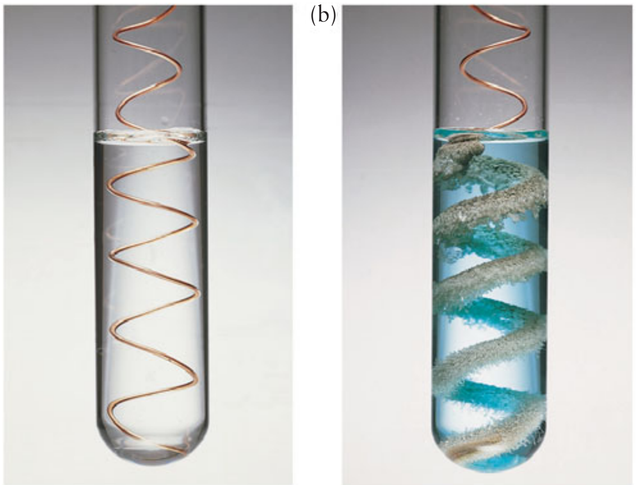


FIGURE K.6 (a) A silver nitrate solution is colorless. (b) Some time after the insertion of a copper wire, the solution shows the blue color of the copper(II) ion and the formation of crystals of silver metal on the surface of the wire.

Animation K.6

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Determine the oxidation number of an element (Toolbox K.1 and Example K.1).

❑ 2 Identify the oxidizing and reducing agents in a reaction (Example K.2).

❑ 3 Write and balance chemical equations for simple redox reactions (Self-Test K.4).

EXERCISES

K.1 Write a balanced equation for each of the following skeletal redox reactions:
(a) $NO_2(g) + O_3(g) \longrightarrow N_2O_5(g) + O_2(g)$
(b) $S_8(s) + Na(s) \longrightarrow Na_2S(s)$
(c) $Cr^{2+}(aq) + Sn^{4+}(aq) \longrightarrow Cr^{3+}(aq) + Sn^{2+}(aq)$
(d) $As(s) + Cl_2(g) \longrightarrow AsCl_3(l)$

K.2 Write a balanced equation for each of the following skeletal redox equations:
(a) $Hg^{2+}(aq) + Fe(s) \longrightarrow Hg_2{}^{2+}(aq) + Fe^{3+}(aq)$
(b) $Pt^{4+}(aq) + H_2(g) \longrightarrow Pt^{2+}(aq) + H^+(aq)$
(c) $Al(s) + Fe_2O_3(s) \longrightarrow Fe(s) + Al_2O_3(s)$
(d) $La(s) + Br_2(l) \longrightarrow LaBr_3(s)$

K.3 Write a balanced equation for each of the following redox reactions:
(a) Displacement of copper(II) ion from solution by magnesium metal: $Mg(s) + Cu^{2+}(aq) \longrightarrow Mg^{2+}(aq) + Cu(s)$
(b) Formation of iron(III) ion in the following reaction:
$Fe^{2+}(aq) + Ce^{4+}(aq) \longrightarrow Fe^{3+}(aq) + Ce^{3+}(aq)$
(c) Synthesis of hydrogen chloride from its elements:
$H_2(g) + Cl_2(g) \longrightarrow HCl(g)$
(d) Formation of rust (a simplified equation):
$Fe(s) + O_2(g) \longrightarrow Fe_2O_3(s)$

K.4 Determine the oxidation number of the italicized element in each of the following compounds: (a) $\mathit{S}OCl_2$; (b) $\mathit{Se}O_3$; (c) N_2O_5; (d) $\mathit{N}O_2$; (e) $H\mathit{Br}O_2$; (f) $\mathit{Xe}F_2$.

K.5 Determine the oxidation number of the italicized element in each of the following compounds: (a) $H_4\mathit{Si}O_4$; (b) $\mathit{Sn}O_2$; (c) N_2H_4; (d) P_4O_{10}; (e) S_2Cl_2; (f) P_4.

K.6 Determine the oxidation number of the italicized element in each of the following ions: (a) $\mathit{As}O_4{}^{3-}$; (b) $\mathit{N}_2O_2{}^{2-}$; (c) $\mathit{S}_2O_4{}^{2-}$; (d) $\mathit{Ti}F_6{}^{2-}$; (e) $\mathit{I}F_6{}^+$.

K.7 Determine the oxidation number of the italicized element in each of the following ions: (a) $\mathit{Zn}(OH)_4{}^{2-}$; (b) $\mathit{Pd}Cl_4{}^{2-}$; (c) $\mathit{U}O_2{}^{2+}$; (d) $\mathit{Si}F_6{}^{2-}$; (e) $\mathit{I}O^-$.

K.8 Some compounds of hydrogen and oxygen are exceptions to the common observation that H has oxidation number +1 and O has oxidation number −2. Assuming that each metal has the oxidation number of its most common ion, find the oxidation numbers of H and O in each of the following compounds: (a) KO_2; (b) $LiAlH_4$; (c) Na_2O_2; (d) NaH; (e) KO_3.

K.9 For each of the following redox reactions, identify the substance oxidized and the substance reduced by the change in oxidation numbers.
(a) $CH_3OH(aq) + O_2(g) \longrightarrow HCOOH(aq) + H_2O(l)$
(b) $2\ MoCl_5(s) + 5\ Na_2S(s) \longrightarrow 2\ MoS_2(s) + 10\ NaCl(s) + S(s)$
(c) $3\ Tl^+(aq) \longrightarrow 2\ Tl(s) + Tl^{3+}(aq)$

K.10 In each of the following reactions, use oxidation numbers to identify the substance oxidized and the substance reduced.
(a) Production of iodine from seawater:
$Cl_2(g) + 2\ I^-(aq) \longrightarrow I_2(aq) + 2\ Cl^-(aq)$
(b) Reaction to prepare bleach:
$Cl_2(g) + 2\ NaOH(aq) \longrightarrow NaCl(aq) + NaOCl(aq) + H_2O(l)$
(c) Reaction that destroys ozone in the stratosphere:
$NO(g) + O_3(g) \longrightarrow NO_2(g) + O_2(g)$

K.11 Which do you expect to be the stronger oxidizing agent? Explain your reasoning. (a) Cl_2 or Cl^-; (b) N_2O_5 or N_2O.

K.12 Which do you expect to be the stronger oxidizing agent? Explain your reasoning. (a) $NaClO_2$ or NaClO; (b) $Cr_2O_7{}^{2-}$ or Cr^{3+}.

K.13 Identify the oxidizing agent and the reducing agent in each of the following reactions:
(a) $Zn(s) + 2\ HCl(aq) \longrightarrow ZnCl_2(aq) + H_2(g)$, a simple means of preparing H_2 gas in the laboratory
(b) $2\ H_2S(g) + SO_2(g) \longrightarrow 3\ S(s) + 2\ H_2O(l)$, a reaction used to produce sulfur from hydrogen sulfide, the "sour gas" in natural gas
(c) $B_2O_3(s) + 3\ Mg(s) \longrightarrow 2\ B(s) + 3\ MgO(s)$, a preparation of elemental boron

K.14 Identify the oxidizing agent and the reducing agent in each of the following reactions:
(a) $2\ Al(l) + Cr_2O_3(s) \xrightarrow{\Delta} Al_2O_3(s) + 2\ Cr(l)$, an example of a thermite reaction used to obtain some metals from their ores
(b) $6\ Li(s) + N_2(g) \longrightarrow 2\ Li_3N(s)$, a reaction that shows the similarity of lithium and magnesium
(c) $2\ Ca_3(PO_4)_2(s) + 6\ SiO_2(s) + 10\ C(s) \longrightarrow P_4(g) + 6\ CaSiO_3(s) + 10\ CO(g)$, a reaction for the preparation of elemental phosphorus.

K.15 For each of the following incomplete reactions, would you choose an oxidizing agent or a reducing agent to make the conversion?
(a) $ClO_4{}^-(aq) \longrightarrow ClO_2(g)$
(b) $SO_4{}^{2-}(aq) \longrightarrow SO_2(g)$

K.16 For each of the following incomplete reactions, would you choose an oxidizing agent or a reducing agent to make the conversion?
(a) $H_3PO_3(aq) \longrightarrow P_4O_{10}(s)$
(b) CH_3CH_2OH (ethanol) $\longrightarrow CH_3CH_2COOH$ (acetic acid)

K.17 The Sabatier process has been used to remove CO_2 from artificial atmospheres, such as those in submarines and spacecraft. An advantage is that it produces methane, CH_4, which can be burned as a fuel, and water, which can be reused. Balance the equation for the process and identify the type of reaction:
$CO_2(g) + H_2(g) \longrightarrow CH_4(g) + H_2O(l)$.

K.18 The industrial production of sodium metal and chlorine gas makes use of the Downs process, in which molten sodium chloride is electrolyzed (Chapter 13). Write a balanced equation for the production of the two elements from molten sodium chloride. Which element is produced by oxidation and which by reduction?

K.19 Identify the oxidizing agent and the reducing agent for each of the following reactions:

(a) Production of tungsten metal from its oxide:
$WO_3(s) + 3\ H_2(g) \longrightarrow W(s) + 3\ H_2O(l)$
(b) Generation of hydrogen gas in the laboratory:
$Mg(s) + 2\ HCl(aq) \longrightarrow H_2(g) + MgCl_2(aq)$
(c) Production of metallic tin from tin(IV) oxide:
$SnO_2(s) + 2\ C(s) \xrightarrow{\Delta} Sn(l) + 2\ CO(g)$
(d) A reaction used to propel rockets:
$2\ N_2H_4(g) + N_2O_4(g) \longrightarrow 3\ N_2(g) + 4\ H_2O(g)$

K.20 Classify each of the following reactions as precipitation, acid–base neutralization, or redox. If a precipitation reaction, write a net ionic equation; if a neutralization reaction, identify the acid and the base; if a redox reaction, identify the oxidizing agent and the reducing agent.
(a) Reaction used to measure the concentration of carbon monoxide in a gas stream:
$5\ CO(g) + I_2O_5(s) \longrightarrow I_2(s) + 5\ CO_2(g)$
(b) Test for the amount of iodine in a sample:
$I_2(aq) + 2\ S_2O_3^{2-}(aq) \longrightarrow 2\ I^-(aq) + S_4O_6^{2-}(aq)$
(c) Test for bromide ions in solution:
$AgNO_3(aq) + Br^-(aq) \longrightarrow AgBr(s) + NO_3^-(aq)$
(d) Heating of uranium tetrafluoride with magnesium, one stage in the purification of uranium metal:
$UF_4(g) + 2\ Mg(s) \xrightarrow{\Delta} U(s) + 2\ MgF_2(s)$

K.21 Nitrogen in the air of spaceships is gradually lost through leakage and must be replaced. One method is to store the nitrogen in the form of hydrazine, $N_2H_4(l)$, from which nitrogen is readily obtained by heating. The ammonia also produced can be processed further to obtain even more nitrogen: $N_2H_4(l) \longrightarrow NH_3(g) + N_2(g)$. (a) Balance the equation. (b) Give the oxidation number of nitrogen in each compound. (c) Identify the oxidizing and reducing agent. (d) Given that 28 g of nitrogen gas occupies 24 L at room temperature and pressure, what volume of nitrogen gas can be obtained from 1.0 L of hydrazine? (The density of hydrazine is 1.004 $g \cdot cm^{-3}$ at room temperature.)

K.22 (a) Determine and tabulate the maximum (most positive) and minimum (most negative) oxidation numbers of the elements in the first seven main groups. *Hint*: Maximum oxidation numbers are often found in the oxoanion with the most oxygen atoms. For minimum oxidation numbers, consult Fig. C.7. (b) Describe any patterns you see in the data.

K.23 A mixture of 5.00 g of $Cr(NO_3)_2$ and 6.00 g of $CuSO_4$ is dissolved in sufficient water to make 250.0 mL of solution, where the cations react. In the reaction, copper metal is formed and each chromium ion loses one electron. (a) Write the net ionic equation. (b) What is the number of electrons transferred in the balanced equation written with the smallest whole-number coefficients? (c) What are the molar concentrations of the two anions in the final solution?

K.24 Silver tarnish is Ag_2S. (a) When silver metal is tarnished, is it oxidized or reduced? Answer this question by considering the oxidation numbers. (b) If a bar of silver is covered with 5.0 g of tarnish, what amount (in moles) of silver atoms was either oxidized or reduced? (c) What amount (in moles) of electrons was transferred in part (b)?

K.25 The following redox reactions are important in the refining of certain elements. Balance the equations and in each case, write the name of the source compound of the element (in bold face) and the oxidation state in that compound of the element that is being extracted:
(a) $\mathbf{SiCl_4}(l) + H_2(g) \longrightarrow Si(s) + HCl(g)$
(b) $\mathbf{SnO_2}(s) + C(s) \xrightarrow{1200°C} Sn(l) + CO_2$
(c) $\mathbf{V_2O_5}(s) + Ca(l) \xrightarrow{\Delta} V(s) + CaO(s)$
(d) $\mathbf{B_2O_3}(s) + Mg(s) \longrightarrow B(s) + MgO(s)$

K.26 Balance the following equations and identify the oxidizing and reducing agents in each:
(a) $CO(g) + H_2O(g) \longrightarrow CO_2(g) + H_2(g)$
(b) $ClO_2(g) + O_3(g) \longrightarrow Cl_2O_6(l) + O_2(g)$
(c) $Cl_2(g) + F_2(g) \longrightarrow ClF_3(g)$

K.27 Balance the following equations and identify the oxidizing and reducing agents in each:
(a) $Cl_2(g) + H_2O(l) \longrightarrow HClO(aq) + HCl(aq)$
(b) $NaClO_3(aq) + SO_2(g) + H_2SO_4(aq, dilute) \longrightarrow NaHSO_4(aq) + ClO_2(g)$
(c) $CuI(aq) \longrightarrow Cu(s) + I_2(s)$

FUNDAMENTALS

L REACTION STOICHIOMETRY

L.1 Mole-to-Mole Predictions
L.2 Mass-to-Mass Predictions
L.3 Volumetric Analysis

Chemistry is a part of the physical sciences, which means that it uses quantitative procedures as well as qualitative concepts. One of the most basic quantitative procedures in chemistry is the prediction of the masses of substances and volumes of solutions that are involved in chemical reactions. We develop these procedures here and will encounter them again throughout the text.

Sometimes we need to know how much product to expect from a reaction, or how much reactant we need to make a desired amount of product. To do this kind of calculation, we need the quantitative aspect of chemical reactions called **reaction stoichiometry**. The key to reaction stoichiometry is the balanced chemical equation. Recall from Section H that a stoichiometric coefficient in a chemical equation tells us the relative amount (number of moles) of a substance that reacts or is produced. Thus, the stoichiometric coefficients in

$$N_2(g) + 3\ H_2(g) \longrightarrow 2\ NH_3(g)$$

tell us that, if 1 mol N_2 reacts, then 3 mol H_2 will be consumed and 2 mol NH_3 will be produced. We summarize this information by writing

$$1\ mol\ N_2 \simeq 3\ mol\ H_2 \quad 1\ mol\ N_2 \simeq 2\ mol\ NH_3$$

FIGURE L.1 A technician studies a lightweight, efficient hydrogen–oxygen fuel cell of the type used in the space shuttle. The three fuel cells on the space shuttle provide life-support electricity and drinking water. Because they have no moving parts they have a long working life.

The sign $\simeq$ is read "is chemically equivalent to," and these expressions are called **stoichiometric relations**. The term *chemically equivalent* refers to a specific chemical reaction, and in general different reactions give rise to different stoichiometric relations.

L.1 Mole-to-Mole Predictions

Stoichiometry has important practical applications, such as predicting how much product can be formed in a reaction. For example, in the space shuttle fuel cell, oxygen reacts with hydrogen to produce water, which is used for life support (Fig. L.1). Let's look at the calculation space shuttle engineers would have to do to find out how much water is formed when 0.25 mol O_2 reacts with hydrogen gas.

First, we write the chemical equation for the reaction:

$$2\,H_2(g) + O_2(g) \longrightarrow 2\,H_2O(l)$$

Then we summarize the information that 1 mol O_2 reacts to form 2 mol H_2O by writing the stoichiometric relation between oxygen (the given substance) and water (the required substance):

$$1\text{ mol } O_2 \simeq 2\text{ mol } H_2O$$

Next, we use the stoichiometric relation to set up a conversion factor relating the given substance to the required substance:

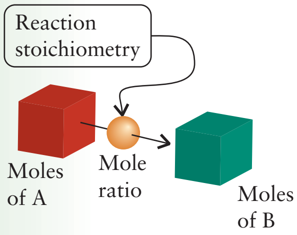
$$\frac{\text{Substance required}}{\text{Substance given}} = \frac{2\text{ mol } H_2O}{1\text{ mol } O_2}$$

Stoichiometric coefficients are exact numbers; therefore, they do not limit the significant figures of stoichiometric calculations (see Appendix 1C).

This ratio, which is commonly called the **mole ratio** for the reaction, allows us to relate the amount of O_2 molecules consumed to the amount of H_2O molecules produced. We use it in the same way that we use a conversion factor when we are converting units, as illustrated in Section A:

$$\begin{aligned}\text{Amount of } H_2O \text{ produced (mol)} &= (0.25\text{ mol } O_2) \times \frac{2\text{ mol } H_2O}{1\text{ mol } O_2}\\ &= 0.50\text{ mol } H_2O\end{aligned}$$

Note that the unit *mol* and the species (in this case, O_2 molecules) cancel. The general strategy for this type of calculation is summarized in diagram (**1**).



1

Self-Test L.1A What amount of NH_3 can be produced from 2.0 mol H_2 in the reaction $N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g)$?

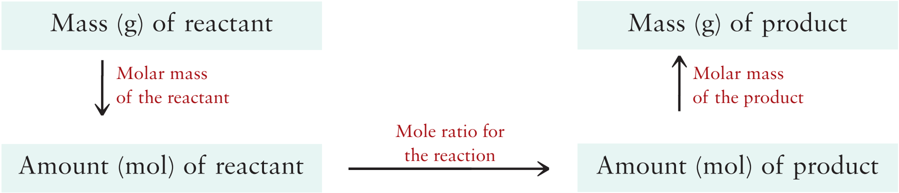
[***Answer:*** 1.3 mol NH_3]

Self-Test L.1B What amount of Fe atoms can be extracted from 25 mol Fe_2O_3?

The balanced chemical equation for a reaction is used to set up the mole ratio, a factor that is used to convert the amount of one substance into the amount of another.

L.2 Mass-to-Mass Predictions

To find out the mass of a product that can be formed from a known mass of a reactant, we first convert the grams of reactant into moles, use the mole ratio from the balanced equation, and then convert the moles of product formed into grams. Essentially, we go through three steps:



For example, in Section L.1 we saw that 0.50 mol H_2O can be produced from 0.25 mol O_2. If we want to know the mass of water that can be produced, we use the molar mass of water to convert this amount to mass by using $m = nM$:

$$\text{Mass of } H_2O \text{ produced (g)} = 0.50\ \cancel{\text{mol } H_2O} \times 18.02\ \text{g}\cdot(\cancel{\text{mol } H_2O})^{-1} = 9.0\ \text{g}$$

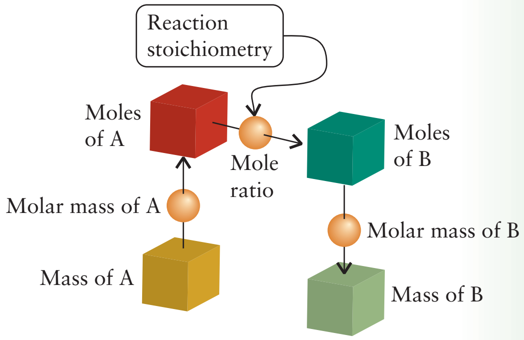
TOOLBOX L.1 HOW TO CARRY OUT MASS-TO-MASS CALCULATIONS

CONCEPTUAL BASIS

A chemical equation tells us the relations between the amounts (in moles) of each reactant and product. By using the molar masses as conversion factors, we can express these relations in terms of masses.

PROCEDURE

The general procedure for mass-to-mass calculations, summarized in diagram (**2**), requires that first we write the balanced chemical equation for the reaction. Then we perform the following calculations:



2

Step 1 Convert the given mass of one substance (A) in grams into amount in moles by using its molar mass.

$$n_A = \frac{m_A}{M_A}$$

If necessary, first convert the units of mass to grams (use 1 kg = 10^3 g, 1 mg = 10^{-3} g).

Step 2 Use the mole ratio derived from the stoichiometric coefficients in the balanced chemical equation to convert from the amount of one substance (A) into the amount in moles of the other substance (B).

For $aA \longrightarrow bB$ or $aA + bB \longrightarrow cC$, use

$$n_B = n_A \times \frac{b \text{ mol B}}{a \text{ mol A}}$$

Step 3 Convert from amount in moles of the second substance to mass (in grams) by using its molar mass.

$$m_B = n_B M_B$$

This procedure is illustrated in Example L.1.

EXAMPLE L.1 Calculating the mass of product that can be obtained from a given mass of reactant

(a) What mass of iron(III) oxide, Fe_2O_3, present in iron ore is required to produce 10.0 g of iron when it is reduced by carbon monoxide gas to metallic iron and carbon dioxide gas in a blast furnace? (b) The carbon dioxide produced as a by-product must also be monitored to protect the environment. What mass of carbon dioxide is released when 10.0 g of iron is produced?

Anticipate Because not all the matter in Fe_2O_3 is iron, expect to use more than 10.0 g of the ore to obtain 10.0 g of iron. To answer part (b) we have to do the calculation.

PLAN Follow the steps in Toolbox L.1.

SOLVE The chemical equation is

$$Fe_2O_3(s) + 3\ CO(g) \longrightarrow 2\ Fe(s) + 3\ CO_2(g)$$

which implies that

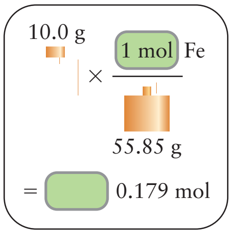
$$2 \text{ mol Fe} \simeq 1 \text{ mol } Fe_2O_3 \quad \text{and} \quad 2 \text{ mol Fe} \simeq 3 \text{ mol } CO_2$$

(a) The molar mass of iron is 55.85 g·mol^{-1} and that of iron(III) oxide is 159.69 g·mol^{-1}.

Step 1 Convert from mass into amount of product by using its molar mass ($n = m/M$).

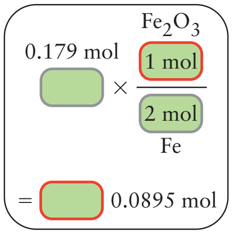
$$\text{Amount of Fe (mol)} = \frac{10.0\ \text{g}}{55.85\ \text{g}\cdot(\text{mol Fe})^{-1}}$$

$$= \frac{10}{55.85} \text{ mol Fe}$$



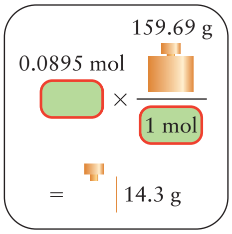
Step 2 Calculate the amount of reactant by using the mole ratio.

$$\text{Amount of } Fe_2O_3 \text{ (mol)} = \frac{10}{55.85} \text{ mol Fe} \times \frac{1 \text{ mol } Fe_2O_3}{2 \text{ mol Fe}}$$
$$= \frac{10}{55.85 \times 2} \text{ mol } Fe_2O_3$$



Step 3 Convert from amount into mass of reactant by using its molar mass ($n = m/M$).

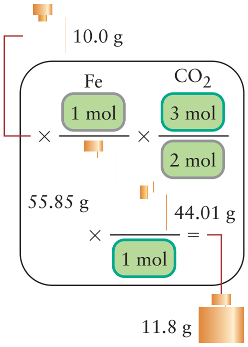
$$\text{Mass of } Fe_2O_3 \text{ (g)} = \frac{10}{55.85 \times 2} \text{ mol } Fe_2O_3$$
$$\times\ 159.69 \text{ g}\cdot(\text{mol } Fe_2O_3)^{-1}$$
$$= \frac{10 \times 159.69}{55.85 \times 2} \text{ g} = 14.3 \text{ g}$$



(b) The molar mass of carbon dioxide is 44.01 g·mol^{-1}.

Step 1 Convert from mass into amount of product by using its molar mass ($n = m/M$). First, find the amount of Fe produced, as above.

$$\text{Amount of Fe (mol)} = \frac{10.0 \text{ g}}{55.85 \text{ g}\cdot(\text{mol Fe})^{-1}} = \frac{10}{55.85} \text{ mol Fe}$$



Step 2 Calculate the amount of the product of interest by using the mole ratio.

$$\text{Amount of } CO_2 \text{ (mol)} = \frac{10}{55.85} \text{ mol Fe} \times \frac{3 \text{ mol } CO_2}{2 \text{ mol Fe}}$$
$$= \frac{10 \times 3}{55.85 \times 2} \text{ mol } CO_2$$

Step 3 Use molar mass to convert from amount into mass ($m = nM$).

$$\text{Mass of } CO_2 \text{ (g)} = \frac{10 \times 3}{55.85 \times 2} \text{ mol } CO_2 \times 44.01 \text{ g}\cdot(\text{mol } CO_2)^{-1}$$
$$= \frac{10 \times 3 \times 44.01}{55.85 \times 2} \text{ g} = 11.8 \text{ g}$$

Evaluate As we anticipated, more than 10 g of the ore is needed to obtain 10 g of iron.

A note on good practice: Note that although, as usual, we have left the numerical calculation to a single, final step, the same is not true for the units: canceling units does not introduce rounding errors and clarifies each step.

Self-Test L.2A Calculate the mass of potassium metal needed to react with 0.450 g of hydrogen gas to produce solid potassium hydride, KH.

[***Answer:*** 17.5 g]

Self-Test L.2B Carbon dioxide can be removed from power plant exhaust gases by combining it with an aqueous slurry of calcium silicate: $2\ CO_2(g) + H_2O(l) + CaSiO_3(s) \longrightarrow SiO_2(s) + Ca(HCO_3)_2(aq)$. What mass of $CaSiO_3$ (having molar mass 116.17 g · mol^{-1}) is needed to react completely with 0.300 kg of carbon dioxide?

FIGURE L.2 The apparatus typically used for a titration: magnetic stirrer; flask containing the analyte; clamp; buret containing the titrant—in this case, potassium hydroxide.

FIGURE L.3 An acid–base titration at the stoichiometric point. The indicator is phenolphthalein.

FUNDAMENTALS

In a mass-to-mass calculation, convert the given mass into amount in moles, apply the mole-to-mole conversion factor to obtain the amount required, and finally convert amount in moles into mass of the unknown substance.

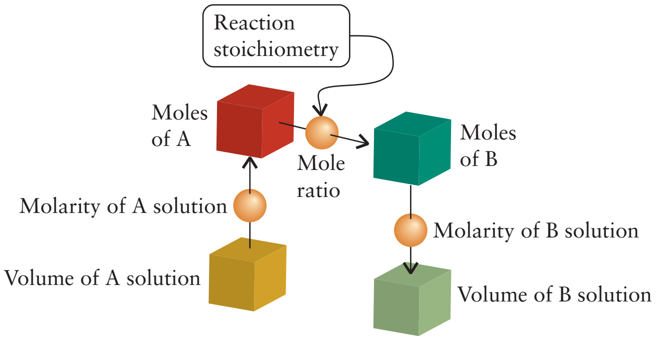
L.3 Volumetric Analysis

A common laboratory technique for determining the concentration of a solute is **titration** (Fig. L.2). Titrations are usually either **acid–base titrations**, in which an acid reacts with a base, or **redox titrations**, in which the reaction is between a reducing agent and an oxidizing agent. Titrations are widely used to monitor water purity and blood composition and for quality control in the food industry.

In a titration, the volume of one solution is known, and we measure the volume of the other solution required for complete reaction. The solution being analyzed is called the **analyte**, and a known volume is transferred into a flask, usually with a pipet. Then a solution containing a known concentration of reactant is measured into the flask from a buret until all the analyte has reacted. The solution in the buret is called the **titrant**, and the difference between the initial and final volume readings of the buret tells us the volume of titrant that has drained into the flask. The determination of concentration or amount by measuring volume is called **volumetric analysis**.

In an acid–base titration, the analyte is a solution of a base and the titrant is a solution of an acid or vice versa. An indicator, a water-soluble dye (Section J), is used to detect the **stoichiometric point**, the stage at which the volume of titrant added is exactly that required by the stoichiometric relation between titrant and analyte. For example, if we titrate hydrochloric acid containing a few drops of the indicator phenolphthalein, the solution is initially colorless. After the stoichiometric point, when excess base is present, the solution in the flask is basic and the indicator is pink. Because the indicator color change is sudden, it is easy to detect the stoichiometric point (Fig. L.3). Toolbox L.2 shows how to interpret a titration; the procedure is summarized in diagram (**3**), where A is the solute in the titrant and B is the solute in the analyte.

The stoichiometric point is also called the *equivalence point*.



3

TOOLBOX L.2 HOW TO INTERPRET A TITRATION

CONCEPTUAL BASIS

In a titration one reactant (the titrant) is added gradually in solution to another (the analyte). The goal is to determine the molarity of the reactant in the analyte or its mass. We use the molarity of the titrant to find the amount of reacting titrant species in the volume of titrant supplied.

PROCEDURE

Step 1 Calculate the amount (n_{titrant}, in moles) of titrant species added from the volume of titrant (V_{titrant},) and its molarity (c_{titrant}).

$$\overbrace{n_{\text{titrant}}}^{\text{mol titrant}} = \overbrace{c_{\text{titrant}}}^{(\text{mol titrant})\cdot\text{L}^{-1}} \times \overbrace{V_{\text{titrant}}}^{\text{L}}$$

Step 2 Calculate the amount of analyte: (a) Write the chemical equation for the reaction, (b) identify the mole ratio between the titrant species and the analyte species, and (c) use it to convert the amount of titrant into amount of analyte (n_{analyte}).

$$n_{\text{analyte}} = n_{\text{titrant}} \times \text{mole ratio}$$

Step 3 Calculate the initial molarity of the analyte (c_{analyte}) by dividing the amount of analyte species by the initial volume, $V_{analyte}$, of the analyte.

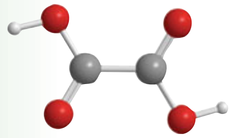
$$\overbrace{c_{\text{analyte}}}^{(\text{mol analyte})\cdot\text{L}^{-1}} = \frac{\overbrace{n_{\text{analyte}}}^{\text{mol analyte}}}{\underbrace{V_{\text{analyte}}}_{\text{L}}}$$

This procedure is illustrated in Example L.2.

If the mass of the analyte is required, instead of step 3, use the molar mass of the analyte to convert moles into grams.

This procedure is demonstrated in Example L.3.

A note on good practice. Because we need to keep track of the substances, we must be sure to indicate the exact species and concentration units, by writing, for example, 1.0 (mol HCl)·L^{-1} or 1.0 M HCl(aq).



4 Oxalic acid, $(COOH)_2$

EXAMPLE L.2 Determining the molarity of an acid by titration

Suppose that 25.00 mL of a solution of oxalic acid, $H_2C_2O_4$ (**4**), which has two acidic protons, is titrated with 0.100 M NaOH(aq) and that the stoichiometric point for reaction with both protons is reached when 38.0 mL of the solution of base is added. Find the molarity of the oxalic acid solution.

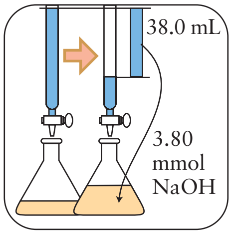
Anticipate If the acid were monoprotic, then because more than 25 mL of the alkali is needed to neutralize it, the molarity of the acid must be greater than the molarity of the base. However, the acid is in fact diprotic, so because each molecule of acid provides two acidic protons, its molarity would be half that of a monoprotic acid, so we can expect a molarity close to $\frac{1}{2} \times 1.5 \times 0.1$ M ≈ 0.08 M.

PLAN Proceed as in Toolbox L.2.

SOLVE

Step 1 Find the amount of NaOH added.

$$\begin{aligned} n_{\text{NaOH}} &= (38.0 \times 10^{-3}\,\text{L}) \times 0.100\,(\text{mol NaOH})\cdot\text{L}^{-1} \\ &= 38.0 \times 10^{-3} \times 0.100\,\text{mol NaOH} \end{aligned}$$

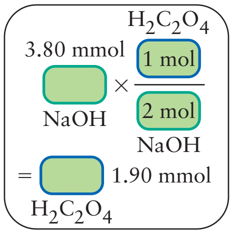


Step 2 (a) Write the chemical equation. (b) Identify the mole ratio. (c) Calculate the amount of acid present.

(a) $H_2C_2O_4(aq) + 2\,NaOH(aq) \longrightarrow Na_2C_2O_4(aq) + 2\,H_2O(l)$

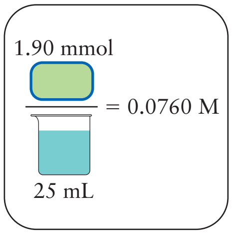
(b) 2 mol NaOH $\simeq$ 1 mol $H_2C_2O_4$

(c) $$\begin{aligned} n(H_2C_2O_4) &= (38.0 \times 10^{-3} \times 0.100\,\text{mol NaOH}) \\ &\quad \times \frac{1\,\text{mol}\,H_2C_2O_4}{2\,\text{mol NaOH}} \\ &= \tfrac{1}{2} \times 38.0 \times 10^{-3} \times 0.100\,\text{mol}\,H_2C_2O_4 \end{aligned}$$



Step 3 Calculate the molarity of the acid.

$$c(H_2C_2O_4) = \frac{\frac{1}{2} \times 38.0 \times 10^{-3} \times 0.100 \text{ mol } H_2C_2O_4}{25.00 \times 10^{-3} \text{ L}}$$
$$= 0.0760 \text{ (mol } H_2C_2O_4)\cdot L^{-1}$$



Evaluate The solution is 0.0760 M $H_2C_2O_4$(aq). As we expected, the acid is less concentrated than the base and has a molarity close to 0.08 M.

Self-Test L.3A A student used a sample of hydrochloric acid that was known to contain 0.020 mol of hydrogen chloride in 500.0 mL of solution to titrate 25.0 mL of a solution of calcium hydroxide. The stoichiometric point was reached when 15.1 mL of acid had been added. What was the molarity of the calcium hydroxide solution?

[***Answer:*** 0.012 M $Ca(OH)_2$(aq)]

Self-Test L.3B Many abandoned mines have exposed nearby communities to the problem of acid mine drainage. Certain minerals, such as pyrite (FeS_2), decompose when exposed to air, forming solutions of sulfuric acid. The acidic mine water then drains into lakes and creeks, killing fish and other animals. At a mine in Colorado, a 16.45-mL sample of mine water was completely neutralized with 25.00 mL of 0.255 M KOH(aq). What is the molar concentration of H_2SO_4 in the water?

EXAMPLE L.3 Determining the purity of a sample by means of a redox titration

The iron content of ores can be determined by titrating a sample with a solution of potassium permanganate, $KMnO_4$. The ore is first dissolved in hydrochloric acid, going into solution as iron(II) ions, which then react with MnO_4^- ions:

$$5\ Fe^{2+}(aq) + MnO_4^-(aq) + 8\ H^+(aq) \longrightarrow 5\ Fe^{3+}(aq) + Mn^{2+}(aq) + 4\ H_2O(l)$$

The stoichiometric point is reached when all the Fe^{2+} has reacted and is detected when the purple color of the permanganate ion persists. A sample of ore of mass 0.202 g was dissolved in hydrochloric acid, and the resulting solution needed 16.7 mL of 0.0108 M $KMnO_4$(aq) to reach the stoichiometric point. (a) What mass of iron(II) ions is present? (b) What is the mass percentage of iron in the ore sample?

Anticipate The mass of iron present must be less than the mass of ore used in the titration.

PLAN (a) To obtain the amount of iron(II) in the analyte, we use the volume and concentration of the titrant. We follow the first two steps of the procedure in Toolbox L.2. Then we convert moles of Fe^{2+} ions into mass by using the molar mass of Fe^{2+}: because the mass of electrons is so small, we use the molar mass of elemental iron for the molar mass of iron(II) ions. (b) To find the mass percentage, divide the mass of iron by the mass of the ore sample and multiply by 100%.

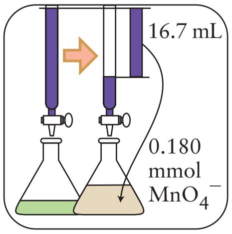
SOLVE (a) Find the mass of iron present in the sample. From the chemical equation, the stoichiometric relation between the iron and the permanganate ions is

$$5 \text{ mol } Fe^{2+} \simeq 1 \text{ mol } MnO_4^-$$

We can set up the mass calculation as follows:

Find the amount of MnO_4^- added from $n = cV$,

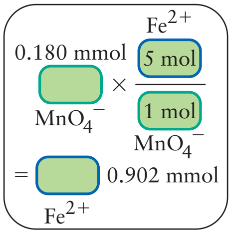
$$n(MnO_4^-) = \frac{0.0108 \text{ mol } MnO_4^-}{1 \text{ L}} \times (1.67 \times 10^{-2} \text{ L})$$
$$= (1.67 \times 10^{-2} \times 0.0108) \text{ mol } MnO_4^-$$



FUNDAMENTALS

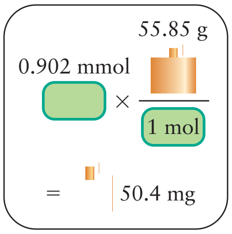
Find the amount of Fe^{2+} present from the mole ratio for the reaction,

$$n(Fe^{2+}) = (1.67 \times 10^{-2} \times 0.0108)\ \text{mol}\ MnO_4^- \times \frac{5\ \text{mol}\ Fe^{2+}}{1\ \text{mol}\ MnO_4^-}$$
$$= 1.67 \times 10^{-2} \times 0.0108 \times 5\ \text{mol}\ Fe^{2+}$$



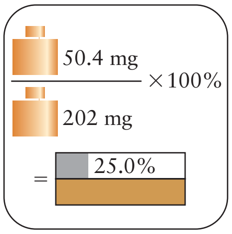
(a) Find the mass of iron from $m = nM$.

$$m(Fe) = (1.67 \times 10^{-2} \times 0.0108 \times 5\ \text{mol}\ Fe^{2+}) \times 55.85\ \text{g}\cdot(\text{mol}\ Fe^{2+})^{-1}$$
$$= 0.0504\ \text{g}$$



(b) Calculate the mass percentage of iron in the ore; from mass percentage = {(mass of iron)/(mass of sample)} × 100%,

$$\text{Mass percentage of iron} = \frac{0.0504\ \text{g}}{0.202\ \text{g}} \times 100\% = 25.0\%$$



Evaluate The sample contains 0.0504 g of iron (as we anticipated, that is necessarily smaller than the mass of ore) and is 25.0% iron by mass.

Self-Test L.4A A sample of clay of mass 20.750 g for use in making ceramics was analyzed to determine its iron content. The clay was washed with hydrochloric acid, and the iron converted into iron(II) ions. The resulting solution was titrated with cerium(IV) sulfate solution:

$$Fe^{2+}(aq) + Ce^{4+}(aq) \longrightarrow Fe^{3+}(aq) + Ce^{3+}(aq)$$

In the titration, 13.45 mL of 1.340 M Ce_2SO_4(aq) was needed to reach the stoichiometric point. What is the mass percentage of iron in the clay?

[***Answer:*** 4.85%]

Self-Test L.4B The amount of arsenic(III) oxide in a mineral can be determined by dissolving the mineral in acid and titrating it with potassium permanganate:

$$24\ H^+(aq) + 5\ As_4O_6(s) + 8\ MnO_4^-(aq) + 18\ H_2O(l) \longrightarrow 8\ Mn^{2+}(aq) + 20\ H_3AsO_4(aq)$$

A sample of industrial waste was analyzed for the presence of arsenic(III) oxide by titration with 0.0100 M $KMnO_4$. It took 28.15 mL of the titrant to reach the stoichiometric point. What mass of arsenic(III) oxide did the sample contain?

The stoichiometric relation between analyte and titrant species, together with the molarity of the titrant, is used in titrations to determine the molarity of the analyte.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Carry out stoichiometric calculations for any two species taking part in a chemical reaction (Toolbox L.1 and Example L.1).

❑ 2 Calculate the molar concentration (molarity) of a solute from titration data (Toolbox L.2 and Example L.2).

❑ 3 Calculate the mass of a solute from titration data (Toolbox L.2 and Example L.3).

EXERCISES

L.1 Compounds that can be used to store hydrogen in vehicles are being actively sought. One reaction being studied for hydrogen storage is $Li_3N(s) + 2\ H_2(g) \longrightarrow LiNH_2(s) + 2\ LiH(s)$ (a) How many moles of H_2 are needed to react with 1.5 mg of Li_3N? (b) Calculate the mass of Li_3N that will produce 0.650 mol LiH.

L.2 In research on the synthesis of superconductors the reaction $Tl_2O_3(l) + 2\ BaO(s) + 3\ CaO(s) + 4\ CuO(s) \longrightarrow Tl_2Ba_2Ca_3Cu_4O_{12}(s)$ is being studied: (a) How many moles of BaO are needed to react with 4.0 g of CaO? (b) Calculate the mass of CuO required to produce 0.10 mol of product.

L.3 The solid fuel in the booster stage of the space shuttle is a mixture of ammonium perchlorate and aluminum powder. On ignition, the reaction that takes place is $6\ NH_4ClO_4(s) + 10\ Al(s) \longrightarrow 5\ Al_2O_3(s) + 3\ N_2(g) + 6\ HCl(g) + 9\ H_2O(g)$. (a) What mass of aluminum should be mixed with 1.325 kg of NH_4ClO_4 for this reaction? (b) Determine the mass of Al_2O_3 (alumina, a finely divided white powder that is produced as billows of white smoke) formed in the reaction of 3.500×10^3 kg of aluminum.

L.4 The compound diborane, B_2H_6, was at one time considered for use as a rocket fuel. Its combustion reaction is

$$B_2H_6(g) + 3\ O_2(l) \longrightarrow 2\ HBO_2(g) + 2\ H_2O(l)$$

The fact that HBO_2, a reactive compound, was produced rather than the relatively inert B_2O_3 was a factor in the discontinuation of the investigation of diborane as a fuel. (a) What mass of liquid oxygen (LOX) would be needed to burn 257 g of B_2H_6? (b) Determine the mass of HBO_2 produced from the combustion of 106 g of B_2H_6.

L.5 The camel stores the fat tristearin, $C_{57}H_{110}O_6$, in its hump. As well as being a source of energy, the fat is also a source of water because, when it is used, the reaction $2\ C_{57}H_{110}O_6(s) + 163\ O_2(g) \longrightarrow 114\ CO_2(g) + 110\ H_2O(l)$ takes place. (a) What mass of water is available from 1.00 pound (454 g) of this fat? (b) What mass of oxygen is needed to oxidize this amount of tristearin?

L.6 Potassium superoxide, KO_2, is utilized in a closed-system breathing apparatus to remove carbon dioxide and water from exhaled air. The removal of water generates oxygen for breathing by the reaction $4\ KO_2(s) + 2\ H_2O(l) \longrightarrow 3\ O_2(g) + 4\ KOH(s)$. The potassium hydroxide removes carbon dioxide from the apparatus by the reaction $KOH(s) + CO_2(g) \longrightarrow KHCO_3(s)$. (a) What mass of potassium superoxide generates 85.0 g of O_2? (b) What mass of CO_2 can be removed from the apparatus by 67.0 g of KO_2?

L.7 When a hydrocarbon burns, water is produced as well as carbon dioxide. The density of gasoline is $0.79\ g{\cdot}mL^{-1}$. Assume gasoline to be represented by octane, C_8H_{18}, for which the combustion reaction is $2\ C_8H_{18}(l) + 25\ O_2(g) \longrightarrow 16\ CO_2(g) + 18\ H_2O(l)$. Calculate the mass of water produced from the combustion of 1.0 gallon (3.8 L) of gasoline.

L.8 The density of oak is $0.72\ g{\cdot}cm^{-3}$. Assuming oak to have the empirical formula CH_2O, calculate the mass of water produced when a log of dimensions 12 cm × 14 cm × 25 cm is completely burned to $CO_2(g)$ and $H_2O(l)$.

L.9 The stomach uses HCl to digest food. However, excess stomach acid can cause problems and must sometimes be neutralized by chewing antacid tablets containing a base such as $Mg(OH)_2$. Carbonates such as $CaCO_3$ are also used, because they can react as bases: $CaCO_3(s) + 2\ HCl(aq) \longrightarrow CaCl_2(aq) + CO_2(g) + H_2O(l)$. A popular antacid tablet contains 400. mg of $CaCO_3$ and 150. mg of $Mg(OH)_2$. What mass of HCl can it neutralize?

L.10 You have used up all the antacid tablets, so you decide to use sodium bicarbonate as an antacid, because it can act as a base: $NaHCO_3(s) + HCl(aq) \longrightarrow NaCl(aq) + H_2O(l) + CO_2(g)$. What mass of $NaHCO_3$ will you need to neutralize the same mass of acid neutralized by the antacid tablet in Exercise L.9?

L.11 A solution of sodium hydroxide of volume 15.00 mL was titrated to the stoichiometric point with 17.40 mL of 0.234 M HCl(aq). (a) What is the initial molarity of NaOH in the solution? (b) Calculate the mass of NaOH in the solution.

L.12 A solution of oxalic acid, $H_2C_2O_4$ (with two acidic protons), of volume 25.17 mL was titrated to the stoichiometric point with 26.72 mL of 0.327 M NaOH(aq). (a) What is the molarity of the oxalic acid? (b) Determine the mass of oxalic acid in the solution.

L.13 A sample of barium hydroxide of mass 9.670 g was dissolved and diluted to the mark in a 250.0-mL volumetric flask. It was found that 11.56 mL of this solution was needed to reach the stoichiometric point in a titration of 25.0 mL of a nitric acid solution. (a) Calculate the molarity of the HNO_3 solution. (b) What mass of HNO_3 is in the initial sample?

L.14 Suppose that 10.0 mL of 3.0 M KOH(aq) is transferred to a 250.0-mL volumetric flask and diluted to the mark. It was found that 38.5 mL of this diluted solution was needed to reach the stoichiometric point in a titration of 10.0 mL of a phosphoric acid solution according to the reaction $3\ KOH(aq) + H_3PO_4(aq) \longrightarrow K_3PO_4(aq) + 3\ H_2O(l)$. (a) Calculate the molarity of H_3PO_4 in the solution. (b) What mass of H_3PO_4 is in the initial sample?

L.15 In a titration, 3.25 g of an acid, HX, requires 68.8 mL of 0.750 M NaOH(aq) for complete reaction. What is the molar mass of the acid?

L.16 Suppose that 14.56 mL of 0.115 M NaOH(aq) was required to titrate 0.2037 g of an unknown acid, HX. What is the molar mass of the acid?

L.17 Excess NaI was added to 50.0 mL of aqueous $AgNO_3$ solution, and 1.76 g of AgI precipitate was formed. What was the molar concentration of $AgNO_3$ in the original solution?

L.18 An excess of $AgNO_3$ reacts with 25.0 mL of 5.0 M $K_2CrO_4(aq)$ to form a precipitate. What is the precipitate, and what mass of precipitate is formed?

L.19 A solution of hydrochloric acid was prepared by measuring 10.00 mL of the concentrated acid into a 1.000-L volumetric flask and adding water up to the mark. Another solution was prepared by adding 0.832 g of anhydrous sodium carbonate to a 100.0-mL volumetric flask and adding water up to the mark. Then, 25.00 mL of the carbonate solution was pipetted into a flask and titrated with the diluted acid. The stoichiometric point was reached after 31.25 mL of acid had been added. (a) Write a balanced equation for the reaction of HCl(aq) with $Na_2CO_3(aq)$. (b) What is the molarity of the original concentrated hydrochloric acid?

L.20 A tablet of vitamin C was analyzed to determine whether it did in fact contain, as the manufacturer claimed, 1.0 g of the

vitamin. One tablet was dissolved in water to form 100.00 mL of solution, and 10.0 mL of that solution was titrated with iodine (as potassium triiodide). It required 10.1 mL of 0.0521 M $I_3^-(aq)$ to reach the stoichiometric point in the titration. Given that 1 mol I_3^- reacts with 1 mol vitamin C in the reaction, is the manufacturer's claim correct? The molar mass of vitamin C is 176 $g\cdot mol^{-1}$.

L.21 Iodine is a common oxidizing agent, often used as the triiodide ion, I_3^-. Suppose that in the presence of HCl(aq), 25.00 mL of 0.120 M aqueous triiodide solution reacts completely with 30.00 mL of a solution containing 19.0 $g\cdot L^{-1}$ of an ionic compound containing tin and chlorine. The products are iodide ions and another compound of tin and chlorine. The reactant compound is 62.6% tin by mass. Write a balanced equation for the reaction.

L.22 A forensic laboratory is analyzing a mixture of the two solids calcium chloride dihydrate, $CaCl_2\cdot 2H_2O$, and potassium chloride, KCl. The mixture is heated to drive off the water of hydration: $CaCl_2 \xrightarrow{\Delta} 2H_2O(s)\ CaCl_2(s) + 2\ H_2O(g)$. A sample of the mixture weighed 2.543 g before heating. After heating, the resulting mixture of anhydrous $CaCl_2$ and KCl weighed 2.312 g. Calculate the mass percentage of each compound in the original sample.

L.23 Thiosulfate ions ($S_2O_3^{2-}$) "disproportionate" in acidic solution to give solid sulfur (S) and hydrogen sulfite ion (HSO_3^-):

$$2\ S_2O_3^{2-}(aq) + 2\ H_3O^+(aq) \longrightarrow 2\ HSO_3^-(aq) + 2\ H_2O(l) + 2\ S(s)$$

(a) A disproportionation reaction is a type of oxidation–reduction reaction. Which species is oxidized and which is reduced? (b) If 10.1 mL of 55.0% HSO_3^- by mass is obtained in the reaction, what mass of $S_2O_3^{2-}$ was present initially, assuming the reaction went to completion? The density of the HSO_3^- solution is 1.45 $g\cdot cm^{-3}$.

L.24 Suppose that 25.0 mL of 0.50 M $K_2CrO_4(aq)$ reacts with 15.0 mL of $AgNO_3(aq)$ completely. What mass of NaCl is needed to react completely with 45.0 mL of the same $AgNO_3$ solution?

L.25 The compound $XCl_2(NH_3)_2$ can be formed by reacting XCl_4 with NH_3. Suppose that 3.571 g of XCl_4 reacts with excess NH_3 to give Cl_2 and 3.180 g of $XCl_2(NH_3)_2$. What is the element X?

L.26 The reduction of iron(III) oxide to iron metal in a blast furnace is another source of atmospheric carbon dioxide. The reduction takes place in these two steps:

$$2\ C(s) + O_2(g) \longrightarrow 2\ CO(g)$$

$$Fe_2O_3(s) + 3\ CO(g) \longrightarrow 2\ Fe(l) + 3\ CO_2(g)$$

Assume that all the CO generated in the first step reacts in the second. (a) How many C atoms are needed to react with 600. Fe_2O_3 formula units? (b) What is the maximum volume of carbon dioxide (taken to have a density of 1.25 $g\cdot L^{-1}$) that can be generated in the production of 1.0 t of iron (1 t = 10^3 kg)? (c) Assuming a 67.9% yield, what volume of carbon dioxide is released to the atmosphere in the production of 1.0 t of iron? (d) How many kilograms of O_2 are required for the production of 5.00 kg of Fe?

L.27 Barium bromide, $BaBr_x$, can be converted into $BaCl_2$ by treatment with chlorine. It is found that 3.25 g of $BaBr_x$ reacts completely with an excess of chlorine to yield 2.27 g of $BaCl_2$. Determine the value of x and write the balanced chemical equation for the production of $BaCl_2$ from $BaBr_x$.

L.28 Sulfur is an undesirable impurity in coal and petroleum fuels. The mass percentage of sulfur in a fuel can be determined by burning the fuel in oxygen and dissolving the SO_3 produced in water to form aqueous sulfuric acid. In one experiment, 8.54 g of a fuel was burned, and the resulting sulfuric acid was titrated with 17.54 mL of 0.100 M NaOH(aq). (a) Determine the amount (in moles) of H_2SO_4 that was produced. (b) What is the mass percentage of sulfur in the fuel?

L.29 Sodium bromide, NaBr, which is used to produce AgBr for use in photographic film, can itself be prepared as follows.

$$Fe + Br_2 \longrightarrow FeBr_2$$

$$FeBr_2 + Br_2 \longrightarrow Fe_3Br_8$$

$$Fe_3Br_8 + Na_2CO_3 \longrightarrow NaBr + CO_2 + Fe_3O_4$$

How much iron, in kilograms, is needed to produce 2.50 t of NaBr? *Note that these equations must first be balanced!*

L.30 Silver nitrate is an expensive laboratory reagent that is often used for quantitative analysis of chloride ion. A student preparing to conduct a particular analysis needs 100.0 mL of 0.0750 M $AgNO_3(aq)$, but finds only about 60 mL of 0.0500 M $AgNO_3(aq)$. Instead of making up a fresh solution of the exact concentration desired (0.0750 M), the student decides to pipet 50.0 mL of the existing solution into a 100.0-mL flask, then add enough pure solid $AgNO_3$ to make up the difference and enough water to bring the volume of the resulting solution to exactly 100.0 mL. What mass of solid $AgNO_3$ must be added in the second step?

L.31 (a) How would you prepare 1.00 L of 0.50 M $HNO_3(aq)$ from "concentrated" (16 M) $HNO_3(aq)$? (b) How many milliliters of 0.20 M NaOH(aq) could be neutralized by 100. mL of the diluted solution?

L.32 You have been given a sample of an unknown diprotic acid. (a) Analysis of the acid shows that a 10.0-g sample contains 0.224 g of hydrogen, 2.67 g of carbon, and the rest oxygen. Determine the empirical formula of the acid. (b) A 0.0900-g sample of your unknown acid is dissolved in 30.0 mL of water and titrated to the endpoint with 50.0 mL of 0.040 M NaOH(aq). Determine the molecular formula of the acid. (c) Write a balanced chemical equation for the neutralization of the unknown acid with NaOH(aq).

L.33 A 1.50-g sample of metallic tin was placed in a 26.45-g crucible and heated until all the tin had reacted with the oxygen in air to form an oxide. The crucible and product together were found to weigh 28.35 g. (a) What is the empirical formula of the oxide? (b) Write the name of the oxide.

L.34 A 1.27-g sample of metallic copper was placed in a 26.32-g crucible and heated until all the copper had reacted with the oxygen in air to form an oxide. The crucible and product together were found to weigh 27.75 g. (a) What is the empirical formula of the oxide? (b) Write the name of the oxide.

L.35 A chemist is titrating a solution of KOH of unknown concentration with 0.0101 M HCl(aq); a number of events occur during the titration. Which of the following events will affect the reported concentration? If there is an effect, indicate whether the reported KOH concentration will be too high or too low.

(a) The flask used for the KOH solution was not dried and so contains a small amount of distilled water.
(b) The buret used for the HCl solution was not dried and so contains a small amount of distilled water.
(c) The walls of the buret were slightly oily and some water droplets stick to the sides as the level falls.
(d) The chemist misread the concentration of HCl as 0.0110 M HCl(aq).

L.36 A chemist is determining the mass percentage of iron in a sample of ore, using the method in Example L.3. After dissolving the ore in hydrochloric acid, it is discovered that some of the solid does not dissolve. Which of the following additional pieces of information will the chemist need to determine the mass percentage of iron in the ore?

(a) The mass of the insoluble solid.
(b) The percentage of the mass of the ore sample represented by the insoluble solid.
(c) The identity of the insoluble solid.
(d) Knowledge that the insoluble solid does not contain any iron.
(e) None of these pieces of information are necessary.

M LIMITING REACTANTS

M.1 Reaction Yield
M.2 The Limits of Reaction
M.3 Combustion Analysis

Stoichiometric calculations of the amount of product formed in a reaction are based on an ideal view of the world. They suppose, for instance, that all the reactants react exactly as described in the chemical equation. In practice, that might not be so. Some of the starting materials may be consumed in a **competing reaction**, a reaction taking place at the same time as the one in which we are interested and using some of the same reactants. Another possibility is that the reaction might not be complete at the time we make our measurements. A third possibility—of major importance in chemistry and covered in several chapters of this text—is that many reactions do not go to completion. They appear to stop once a certain proportion of the reactants has been consumed. Therefore, the actual amount of product may be less than what we would calculate from the reaction stoichiometry.

M.1 Reaction Yield

The **theoretical yield** of a reaction is the *maximum* quantity (amount, mass, or volume) of product that can be obtained from a given quantity of reactant. The quantities of products calculated from a given mass of reactant in Section L were all theoretical yields. The **percentage yield** is the fraction of the theoretical yield actually produced, expressed as a percentage:

$$\text{Percentage yield} = \frac{\text{actual yield}}{\text{theoretical yield}} \times 100\% \qquad \textbf{(1)*}$$

EXAMPLE M.1 Calculating the percentage yield of a product

Incomplete combustion of the fuel in a poorly tuned engine can produce toxic carbon monoxide along with the usual carbon dioxide and water. In a test of an off-road motorcycle engine, 1.00 L of octane (of mass 702 g) is burned and it was found that 1.84 kg of carbon dioxide is produced. What is the percentage yield of carbon dioxide?

Anticipate Apart from knowing that the percentage yield cannot exceed 100%, it is not possible to anticipate the actual value in this case.

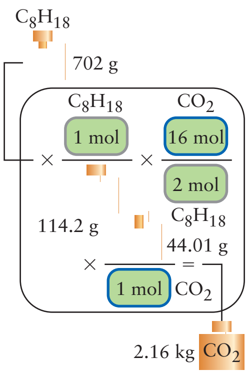
PLAN Begin by writing the chemical equation for the desired reaction. Then calculate the theoretical yield (in grams) of product by using the procedure in Toolbox L.1. To avoid rounding errors, do all the numerical work at the end of the calculation. To obtain the percentage yield, divide the actual mass produced by the theoretical mass of product and multiply by 100%.

SOLVE The molar mass of C_8H_{18} is 114.2 $g\cdot mol^{-1}$ and the molar mass of CO_2 is 44.01 $g\cdot mol^{-1}$. The chemical equation is

$$2\,C_8H_{18}(l) + 25\,O_2(g) \longrightarrow 16\,CO_2(g) + 18\,H_2O(l)$$

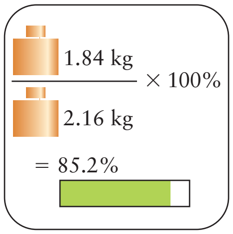
Calculate the theoretical yield of CO_2 for the combustion of 702 g of octane.

$$m(CO_2) = \frac{702\ \text{g}}{114.2\ \text{g}\cdot(\text{mol}\,C_8H_{18})^{-1}} \times \frac{16\ \text{mol}\ CO_2}{2\ \text{mol}\ C_8H_{18}}$$
$$\times\ 44.01\ \text{g}\cdot(\text{mol}\ CO_2)^{-1}$$
$$= 2.16 \times 10^3\ \text{g (or 2.16 kg)}$$



Calculate the percentage yield of carbon dioxide from the fact that only 1.84 kg was produced.

$$\text{Percentage yield of } CO_2 = \frac{1.84\ \text{kg}}{2.16\ \text{kg}} \times 100\% = 85.2\%$$



Evaluate The theoretical yield of 2.16 kg corresponds to about 8 kg of CO_2 per gallon of fuel. Although there are concerns about rising levels of CO_2, that the percentage yield of CO_2 is only 85.2% of the theroetical yield in this case is not a step in the right direction! It means that the fuel is being used inefficiently and that a lot of undesirable CO is being produced.

Self-Test M.1A When 24.0 g of potassium nitrate was heated with lead, 13.8 g of potassium nitrite was formed in the reaction $Pb(s) + KNO_3(s) \longrightarrow PbO(s) + KNO_2(s)$. Calculate the percentage yield of potassium nitrite.

[***Answer:*** 68.3%]

Self-Test M.1B Reduction of 15 kg of iron(III) oxide in a blast furnace produced 8.8 kg of iron. What is the percentage yield of iron?

The theoretical yield of a product is the maximum quantity that can be expected on the basis of the stoichiometry of a chemical equation. The percentage yield is the percentage of the theoretical yield actually achieved.

M.2 The Limits of Reaction

The **limiting reactant** in a reaction is the reactant that governs the maximum yield of product. A limiting reactant is like a part in short supply in a motorcycle factory. Suppose there are eight wheels and seven motorcycle frames. Because each frame requires two wheels, there are enough wheels for only four motorcycles, so the wheels play the role of the limiting reactant. When all the wheels have been used, three frames remain unused, because they were present in excess.

In some cases, we must determine by calculation which is the limiting reactant. For example, from the equation

$$N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g)$$

we see that, in the synthesis of ammonia, 1 mol $N_2 \simeq$ 3 mol H_2. To decide which reactant is the limiting one, we compare the number of moles of each reactant supplied with the stoichiometric coefficients. For example, suppose we had available 1 mol N_2 but only 2 mol H_2. Because this amount of hydrogen is less than is required by the stoichiometric relation, hydrogen would be the limiting reactant. Once we have identified the limiting reactant, we can calculate the amount of product that can be formed. We can also calculate the amount of excess reactant that remains at the end of the reaction.

TOOLBOX M.1 HOW TO IDENTIFY THE LIMITING REACTANT

CONCEPTUAL BASIS

The limiting reactant is the reactant that will be completely used up. All other reactants are in excess. Because the limiting reactant is the one that limits the amounts of products that can be formed, the theoretical yield is calculated from the amount of the limiting reactant.

PROCEDURE

There are two ways of determining which reactant is the limiting one.

Method 1

In this approach, we use the mole ratio from the chemical equation to determine whether there is enough of one reactant to react with another.

Step 1 Convert the mass of each reactant into an amount in moles, if necessary, by using the molar masses of the substances.

Step 2 Choose one of the reactants and use the stoichiometric relation to calculate the theoretical amount of the second reactant needed for complete reaction with the first.

Step 3 If the actual amount of the second reactant is greater than the amount needed (the value calculated in step 2), then the second reactant is present in excess; in this case, the first reactant is the limiting reactant. If the actual amount of the second reactant is less than that calculated, then all of it will react; so it is the limiting reactant and the first reactant is in excess.

This method is used in Example M.2.

Method 2

Calculate the theoretical molar yield of one of the products for each reactant separately, by using the procedure in Toolbox L.1. This method is a good one to use when there are more than two reactants. The reactant that would produce the smallest amount of product is the limiting reactant.

Step 1 Convert the mass of each reactant into an amount in moles, if necessary, by using the molar masses of the substances.

Step 2 Select one of the products. For each reactant, calculate how many moles of the product it can form.

Step 3 The reactant that can produce the least product is the limiting reactant.

This method is used in Example M.3.

EXAMPLE M.2 Identifying the limiting reactant

Calcium carbide, CaC_2, reacts with water to form calcium hydroxide and the flammable gas ethyne (acetylene). This reaction was once used for lamps on bicycles, because the reactants are easily transported. (a) Which is the limiting reactant when 100. g of water reacts with 100. g of calcium carbide? (b) What mass of ethyne can be produced? (c) What mass of excess reactant remains after reaction is complete? Assume that the calcium carbide is pure and that all the ethyne produced is collected. The chemical equation is

$$CaC_2(s) + 2\,H_2O(l) \longrightarrow Ca(OH)_2(aq) + C_2H_2(g)$$

Anticipate Because the molar mass of CaC_2 is so much greater than that of H_2O, we might suspect that there is a small amount of it present and therefore that it will be the limiting reactant. On the other hand, the mole ratio for the reaction indicates that the amount of H_2O required is twice that of the CaC_2, so we have to be cautious about that prediction.

PLAN We follow the procedure in Method 1 of Toolbox M.1. Molar masses are calculated by using the information in the periodic table inside the front cover or the alphabetical list of elements inside the back cover.

SOLVE

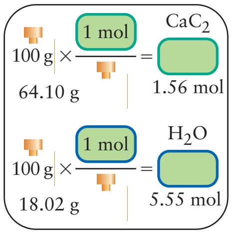
(a) First calculate the molar masses.

calcium carbide: $64.10\ g\cdot mol^{-1}$; water: $18.02\ g\cdot mol^{-1}$

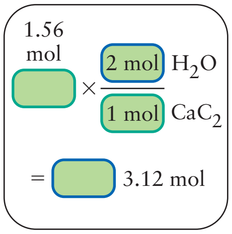
Step 1 Calculate the amount of each reactant.

$$n(CaC_2) = \frac{100.\ g}{64.10\ g\cdot(mol\ CaC_2)^{-1}} = \frac{100.}{64.10}\ mol\ CaC_2 = 1.56\ mol\ CaC_2$$

$$n(H_2O) = \frac{100.\ g}{18.02\ g\cdot(mol\ H_2O)^{-1}} = \frac{100.}{18.02}\ mol\ H_2O = 5.55\ mol\ H_2O$$



Step 2 Write the stoichiometric relation and calculate the amount of H_2O that is needed to react with the available amount of CaC_2.

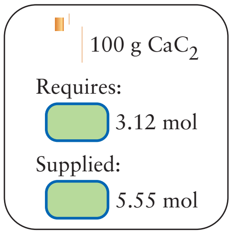


$$1 \text{ mol } CaC_2 \simeq 2 \text{ mol } H_2O$$

$$n(H_2O) = \left(\frac{100.}{64.10} \text{ mol } CaC_2\right) \times \frac{2 \text{ mol } H_2O}{1 \text{ mol } CaC_2}$$

$$= 3.12 \text{ mol } H_2O$$

Step 3 Determine which reactant is the limiting reactant.



Because 3.12 mol H_2O is required and 5.55 mol H_2O is supplied, all the calcium carbide can react; so the calcium carbide is the limiting reactant and water is present in excess.

(b) Because C_2H_2 is the limiting reactant and 1 mol $CaC_2 \simeq$ 1 mol C_2H_2, the mass of ethyne (of molar mass 26.04 $g \cdot mol^{-1}$) that can be produced is

$$m(CaC_2) = \left(\frac{100.}{64.10} \text{ mol } CaC_2\right) \times \frac{1 \text{ mol } C_2H_4}{1 \text{ mol } CaC_2} \times 26.04 \text{ g} \cdot (\text{mol } C_2H_4)^{-1}$$

$$= 40.6 \text{ g}$$

(c) The reactant in excess is water. Because 5.55 mol H_2O was supplied and 3.12 mol H_2O was consumed, the amount of H_2O remaining is $5.55 - 3.12$ mol $= 2.43$ mol. Therefore, the mass of the excess reactant remaining at the end of the reaction is

$$\text{Mass of } H_2O \text{ remaining} = (2.43 \text{ mol}) \times (18.02 \text{ g} \cdot \text{mol}^{-1}) = 43.8 \text{ g}$$

Evaluate The CaC_2 is the limiting reactant (as we anticipated), 40.6 g of ethyne can be produced, and 43.8 g of water remains unreacted.

Self-Test M.2A (a) Identify the limiting reactant in the reaction $6\,Na(l) + Al_2O_3(s) \longrightarrow 2\,Al(l) + 3\,Na_2O(s)$ when 5.52 g of sodium is heated with 5.10 g of Al_2O_3. (b) What mass of aluminum can be produced? (c) What mass of excess reactant remains at the end of the reaction?

[***Answer:*** (a) Sodium; (b) 2.16 g Al; (c) 1.02 g Al_2O_3]

Self-Test M.2B (a) What is the limiting reactant for the preparation of urea from ammonia in the reaction $2\,NH_3(g) + CO_2(g) \longrightarrow OC(NH_2)_2(s) + H_2O(l)$ when 14.5 kg of ammonia is available to react with 22.1 kg of carbon dioxide? (b) What mass of urea can be produced? (c) What mass of excess reactant remains at the end of the reaction?

EXAMPLE M.3 Calculating the percentage yield from a limiting reactant

An important step in the refining of aluminum metal is the manufacture of cryolite, Na_3AlF_6, from ammonium fluoride, sodium aluminate, and sodium hydroxide in aqueous solution:

$$6\,NH_4F(aq) + Na[Al(OH)_4](aq) + 2\,NaOH(aq) \longrightarrow Na_3AlF_6(s) + 6\,NH_3(aq) + 6\,H_2O(l)$$

Unfortunately, by-products can form, reducing the yield. In a laboratory investigation of the process, 100.0 g of NH_4F was mixed with 82.6 g of $Na[Al(OH)_4]$ and 80.0 g of NaOH. The mass of Na_3AlF_6 produced was 75.0 g. What was the percentage yield of the reaction?

Anticipate Apart from knowing that the percentage yield cannot exceed 100%, it is not possible to anticipate the actual value in this case.

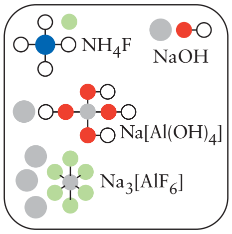
PLAN First, the limiting reactant must be identified (Toolbox M.1). This limiting reactant determines the theoretical yield of the reaction, and so we use it to calculate the theoretical amount of product by Method 2 in Toolbox L.1. The percentage yield is the ratio of the mass produced to the theoretical mass times 100%.

SOLVE

Find the molar masses.

Reactants: NH_4F: 37.04 g·mol^{-1}
$Na[Al(OH)_4]$: 118.00 g·mol^{-1}
NaOH: 80.00 g·mol^{-1}

Product: Na_3AlF_6: 209.95 g·mol^{-1}

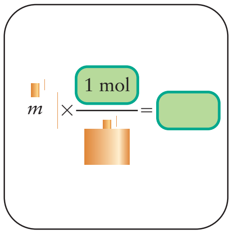


Step 1 Calculate the amount of each reactant from $n = m/M$.

$$n(NH_4F) = \frac{100.0\ \text{g}}{37.04\ \text{g}\cdot(\text{mol } NH_4F)^{-1}} = 2.700\ \text{mol } NH_4F$$

$$n(Na[Al(OH)_4]) = \frac{82.6\ \text{g}}{118.00\ \text{g}\cdot(\text{mol } Na[Al(OH)_4])^{-1}}$$
$$= 0.700\ \text{mol } Na[Al(OH)_4]$$

$$n(NaOH) = \frac{80.0\ \text{g}}{40.00\ \text{g}\cdot(\text{mol NaOH})^{-1}} = 2.00\ \text{mol NaOH}$$



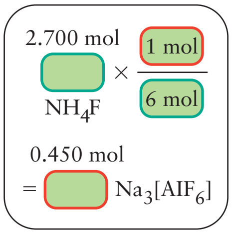
Step 2 Write the mole ratios for the reaction.

$6\ \text{mol } NH_4F \simeq 1\ \text{mol } Na_3AlF_6$; $1\ \text{mol } Na[Al(OH)_4] \simeq 1\ \text{mol } Na_3AlF_6$;
$2\ \text{mol NaOH} \simeq 1\ \text{mol } Na_3AlF_6$

Step 3 Identify as limiting reactant the reactant that can produce the least product.

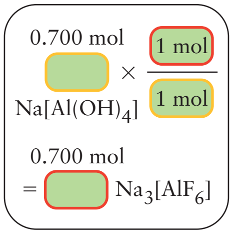
From NH_4F:

$$n(Na_3AlF_6) = 2.700\ \text{mol } NH_4F \times \frac{1\ \text{mol } Na_3AlF_6}{6\ \text{mol } NH_4F}$$
$$= 0.450\ \text{mol } Na_3AlF_6$$



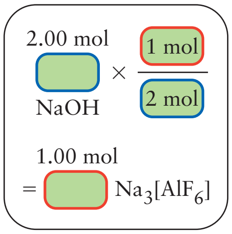
From $Na[Al(OH)_4]$:

$$n(Na_3AlF_6) = 0.700\ \text{mol } Na[Al(OH)_4] \times \frac{1\ \text{mol } Na_3AlF_6}{1\ \text{mol } Na[Al(OH)_4]}$$
$$= 0.700\ \text{mol } Na_3AlF_6$$



From NaOH:

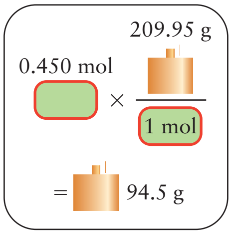
$$n(Na_3AlF_6) = 2.00\ \text{mol NaOH} \times \frac{1\ \text{mol } Na_3AlF_6}{2\ \text{mol NaOH}}$$
$$= 1.00\ \text{mol } Na_3AlF_6$$



NH_4F can produce only 0.450 mol Na_3AlF_6. Therefore, it is the limiting reactant.

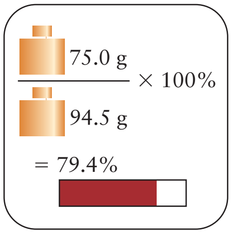
Calculate the theoretical yield as mass of Na_3AlF_6 from $m = nM$.

$$m(Na_3AlF_6) = 0.450 \text{ mol} \times 209.95 \text{ g·mol}^{-1} = 94.5 \text{ g}$$



Calculate the percentage yield from Eq. 1.

$$\text{Percentage yield of } Na_3AlF_6 = \frac{75.0 \text{ g}}{94.5 \text{ g}} \times 100\% = 79.4\%$$



Evaluate As expected, the yield (79.4%) is less than 100% on account of the formation of unwanted by-products.

Self-Test M.3A In the synthesis of ammonia, what is the percentage yield of ammonia when 100. kg of hydrogen reacts with 800. kg of nitrogen to produce 400. kg of ammonia?

[***Answer:*** 71.0%]

Self-Test M.3B Suppose that 28 g of NO_2 and 18 g of water are allowed to react to produce nitric acid and nitrogen monoxide. If 22 g of nitric acid are produced in the reaction, what is the percentage yield?

The limiting reactant in a reaction is the reactant supplied in an amount smaller than that required by the stoichiometric relation between the reactants.

M.3 Combustion Analysis

In Section F, we saw that one technique used in modern chemical laboratories to determine the empirical formulas of organic compounds is combustion analysis. We are now in a position to understand the basis of the technique, because it makes use of the concept of limiting reactant.

The sample is ignited and allowed to burn in a tube while a plentiful supply of oxygen passes through (Fig. M.1). The use of excess oxygen ensures that the sample is the limiting reactant. All the hydrogen in the compound is converted into water and all the carbon is converted into carbon dioxide. In the modern version of the technique, the product gases are separated chromatographically and their relative

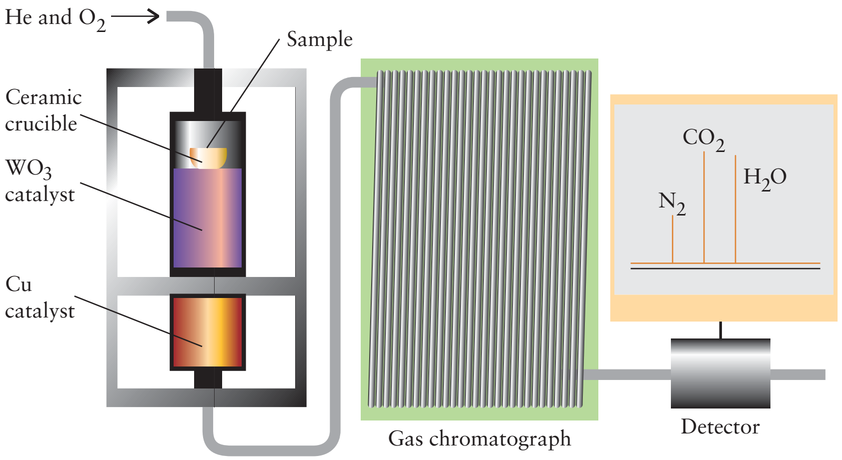


FIGURE M.1 The apparatus used for a combustion analysis. An oxygen–helium mixture is passed over the ceramic crucible containing the sample, which is oxidized. Product gases are passed through two filters. The WO_3 catalyst ensures that any CO produced is oxidized to CO_2; the Cu removes the excess oxygen. The masses of nitrogen, carbon dioxide, and water produced are obtained by separating the product gases and measuring their thermal conductivities.

amounts determined by measuring the thermal conductivity (the ability to conduct heat) of the gas streaming from the apparatus.

Let's see how to determine an empirical formula by analyzing the data, which are the initial mass of the compound and the masses of the water and carbon dioxide produced in the combustion of the compound. In the presence of excess oxygen, each carbon atom in the compound ends up in one molecule of carbon dioxide. Therefore, we can write

$$1 \text{ mol C in sample} \simeq 1 \text{ mol } CO_2 \text{ as product}$$

or, more briefly, 1 mol C $\simeq$ 1 mol CO_2. Hence, by measuring the mass of carbon dioxide produced and converting that mass into amount of C atoms, we can find the number of moles of C atoms in the original sample.

Similarly, in the presence of excess oxygen, each hydrogen atom in a compound contributes to a water molecule when the compound burns. We can infer that

$$2 \text{ mol H in sample} \simeq 1 \text{ mol } H_2O \text{ as product}$$

or, more briefly, 2 mol H $\simeq$ 1 mol H_2O. Therefore, if we measure the mass of water produced when the compound burns in plenty of oxygen, we can find the amount of H atoms (in moles) in the sample.

Many organic compounds also contain oxygen. Provided the compound contains only carbon, hydrogen, and oxygen, we can calculate the mass of oxygen originally present by subtracting the masses of carbon and hydrogen in the sample from the original mass of the sample. That mass of oxygen can be converted into amount of O atoms (in moles) by using the molar mass of oxygen atoms (16.00 $g \cdot mol^{-1}$). We can then calculate the empirical formula.

EXAMPLE M.4 Determining an empirical formula by combustion analysis

A combustion analysis was carried out on 1.621 g of a newly synthesized compound, which was known to contain only C, H, and O. The masses of water and carbon dioxide produced were 1.902 g and 3.095 g, respectively. What is the empirical formula of the compound?

Anticipate Only if we had carried out the synthesis with a specific product in mind could we anticipate the empirical formula.

PLAN We use the stoichiometric relations given earlier to find the amounts of carbon and hydrogen atoms in the sample and then convert those moles into masses. The mass of oxygen in the sample is obtained by subtracting the total mass of carbon and hydrogen from the mass of the original sample. It is then converted into the number of moles of O atoms. Finally, the relative numbers of atoms are expressed as an empirical formula.

SOLVE The molar masses that we need are

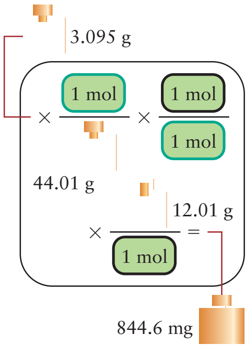
$$CO_2\text{: } 44.01 \text{ g}\cdot\text{mol}^{-1}\text{; H: } 1.008 \text{ g}\cdot\text{mol}^{-1}\text{; C: } 12.01 \text{ g}\cdot\text{mol}^{-1}\text{; } H_2O\text{: } 18.02 \text{ g}\cdot\text{mol}^{-1}$$

The mole ratio for the production of CO_2 is 1 mol C $\simeq$ 1 mol CO_2 and for the production of H_2O is 1 mol $H_2O \simeq$ 2 mol H.

Convert mass of CO_2 produced into amount of C in the sample.

$$n(\text{C}) = \frac{3.095 \text{ g}}{44.01 \text{ g}\cdot(\text{mol } CO_2)^{-1}} \times \frac{1 \text{ mol C}}{1 \text{ mol } CO_2} = \frac{3.095}{44.01} \text{ mol C}$$

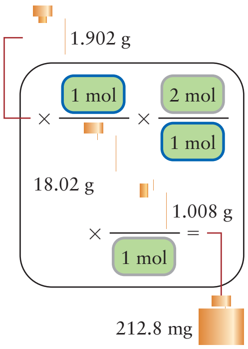
$$(= 0.0703 \text{ mol C})$$



Calculate the mass of carbon in the sample from $m = nM$.

$$m(\mathrm{C}) = \left(\frac{3.095}{44.01}\,\text{mol C}\right) \times 12.01\ \mathrm{g}\cdot(\text{mol C})^{-1} = 0.8446\ \mathrm{g}$$

Convert mass of H_2O produced into amount of H in the sample.



$$n(\mathrm{H}) = \frac{1.902\ \mathrm{g}}{18.02\ \mathrm{g}\cdot(\text{mol H}_2\text{O})^{-1}} \times \frac{2\ \text{mol H}}{1\ \text{mol H}_2\text{O}}$$

$$= \frac{1.902 \times 2}{18.02}\ \text{mol H}$$

$$(= 0.2111\ \text{mol H})$$

Calculate the mass of H in the sample.

$$m(\mathrm{H}) = \left(\frac{1.902 \times 2}{18.02}\,\text{mol H}\right) \times 1.008\ \mathrm{g}\cdot(\text{mol H})^{-1} = 0.2128\ \mathrm{g}$$

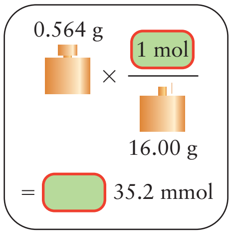
Find the total mass of C and H.

$$0.8446\ \mathrm{g} + 0.2128\ \mathrm{g} = 1.0574\ \mathrm{g}$$

Calculate the mass of oxygen in the sample from the difference between sample mass and the masses of C and H.

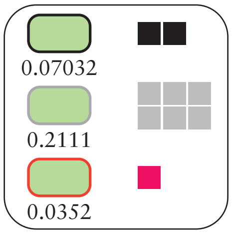
$$m(\mathrm{O}) = 1.621\ \mathrm{g} - 1.0574\ \mathrm{g} = 0.564\ \mathrm{g}$$

Convert mass of oxygen into amount of O atoms.



$$n(\mathrm{O}) = \frac{0.564\ \mathrm{g}}{16.00\ \mathrm{g}\cdot(\text{mol O})^{-1}} = 0.0352\ \text{mol O}$$

Write the ratios of the amount of each element in the sample. This ratio is the same as the relative numbers of atoms.



C:H:O = 0.070 32 : 0.2111 : 0.0352

Divide by the smallest number (0.0352).

C:H:O = 2.00 : 6.00 : 1.00

Evaluate We conclude that the empirical formula of the new compound is C_2H_6O.

Self-Test M.4A When 0.528 g of sucrose (a compound of carbon, hydrogen, and oxygen) is burned, 0.306 g of water and 0.815 g of carbon dioxide are formed. Deduce the empirical formula of sucrose.

[***Answer:*** $C_{12}H_{22}O_{11}$]

Self-Test M.4B When 0.236 g of aspirin is burned in oxygen, 0.519 g of carbon dioxide and 0.0945 g of water are formed. Deduce the empirical formula of aspirin.

In a combustion analysis, the amounts of C, H, and O atoms in a sample of a compound, and thus its empirical formula, are determined from the masses of carbon dioxide and water produced when the compound burns in excess oxygen.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Calculate the theoretical and percentage yields of the products of a reaction, given the mass of starting material (Example M.1).

❑ 2 Identify the limiting reactant of a reaction and use the limiting reactant to calculate the yield of a product and the amount of excess reactant remaining after reaction is complete (Toolbox M.1 and Example M.2).

❑ 3 Determine the empirical formula of an organic compound containing carbon, hydrogen, and oxygen by combustion analysis (Example M.3).

EXERCISES

M.1 When limestone, which is principally $CaCO_3$, is heated, carbon dioxide and quicklime, CaO, are produced by the reaction $CaCO_3(s) \xrightarrow{\Delta} CaO(s) + CO_2(g)$. If 17.5 g of CO_2 is produced from the thermal decomposition of 42.73 g of $CaCO_3$, what is the percentage yield of the reaction?

M.2 Phosphorus trichloride, PCl_3, is produced from the reaction of white phosphorus, P_4, and chlorine: $P_4(s) + 6\ Cl_2(g) \longrightarrow 4\ PCl_3(g)$. A sample of PCl_3 of mass 203.2 g was collected from the reaction of 51.24 g of P_4 with excess chlorine. What is the percentage yield of the reaction?

M.3 Solid boron can be extracted from solid boron oxide by reaction with magnesium metal at a high temperature. A second product is solid magnesium oxide. (a) Write a balanced equation for the reaction. (b) If 125 kg of boron oxide is heated with 125 kg of magnesium, what mass of boron can be produced?

M.4 The antiperspirant aluminum chloride is made by reacting solid aluminum oxide, solid carbon, and chlorine gas. Carbon monoxide gas is also produced in the reaction. (a) Write a balanced equation for the reaction. (b) If 185 kg of aluminum oxide is heated with 25 kg of carbon and 100 kg of chlorine, how much aluminum chloride can be produced?

M.5 Polychlorinated biphenyls (PCBs) were once widely used industrial chemicals but were found to pose a risk to health and the environment. PCBs contain only carbon, hydrogen, and chlorine. Aroclor 1254 is the trade name for a PCB with molar mass 360.88 $g\cdot mol^{-1}$. Combustion of 1.52 g of Aroclor 1254 produced 2.224 g of CO_2, and combustion of 2.53 g produced 0.2530 g of H_2O. How many chlorine atoms does an Aroclor 1254 molecule contain?

M.6 Slaked lime, $Ca(OH)_2$, is formed from quicklime, CaO, by the addition of water: $CaO(s) + H_2O(l) \longrightarrow Ca(OH)_2(s)$. What mass of slaked lime can be produced from a mixture of 25.0 g of CaO and 12.0 g of H_2O?

M.7 A reaction vessel contains 5.77 g of white phosphorus and 5.77 g of oxygen. The first reaction to take place is the formation of phosphorus(III) oxide, P_4O_6: $P_4(s) + 3\ O_2(g) \longrightarrow P_4O_6(s)$. If enough oxygen is present, the oxygen can react further with this oxide to produce phosphorus(V) oxide, P_4O_{10}: $P_4O_6(s) + 2\ O_2(g) \longrightarrow P_4O_{10}(s)$. (a) What is the limiting reactant for the formation of P_4O_{10}? (b) What mass of P_4O_{10} is produced? (c) How many grams of the excess reactant remain in the reaction vessel?

M.8 A mixture of 9.125 g of iron(II) oxide and 8.625 g of aluminum metal is placed in a crucible and heated in a high-temperature oven, where a reduction of the oxide takes place: $3\ FeO(s) + 2\ Al(l) \longrightarrow 3\ Fe(l) + Al_2O_3(s)$. (a) What is the limiting reactant? (b) Determine the maximum amount of iron (in moles of Fe) that can be produced. (c) Calculate the mass of excess reactant remaining in the crucible.

M.9 Copper(II) nitrate reacts with sodium hydroxide to produce a precipitate of light blue copper(II) hydroxide. (a) Write the net ionic equation for the reaction. (b) Calculate the maximum mass of copper(II) hydroxide that can be formed if 2.00 g of sodium hydroxide is added to 80.0 mL of 0.500 M $Cu(NO_3)_2(aq)$.

M.10 In the reaction of hydrogen gas (H_2) and oxygen gas (O_2) to form water vapor, which is the limiting reactant in each situation? What is the maximum quantity of water vapor that can be produced in each case? Report your answer using the units in parentheses. (a) 1.0 g of hydrogen gas and 0.25 mol $O_2(g)$ (in moles of H_2O); (b) 100 H_2 molecules and 40 O_2 molecules (in H_2O molecules).

M.11 The stimulant in coffee and tea is caffeine, a substance of molar mass 194 $g\cdot mol^{-1}$. When 0.376 g of caffeine was burned, 0.682 g of carbon dioxide, 0.174 g of water, and 0.110 g of nitrogen were formed. Determine the empirical and molecular formulas of caffeine, and write the equation for its combustion.

M.12 Nicotine, the stimulant in tobacco, causes a very complex set of physiological effects in the body. It is known to have a molar mass of 162 $g\cdot mol^{-1}$. When a sample of mass 0.385 g was burned, 1.072 g of carbon dioxide, 0.307 g of water, and 0.068 g of nitrogen were produced. What are the empirical and molecular formulas of nicotine? Write the equation for its combustion.

M.13 A compound found in the nucleus of a human cell was found to be composed of carbon, hydrogen, oxygen, and nitrogen. A combustion analysis of 1.35 g of the compound produced 2.20 g of CO_2 and 0.901 g of H_2O. When a separate 0.500-g sample of the compound was analyzed for nitrogen, 0.130 g of N_2 was produced. What is the empirical formula of the compound?

M.14 A compound produced as a by-product in an industrial synthesis of polymers was found to contain carbon, hydrogen, and iodine. A combustion analysis of 1.70 g of the compound

produced 1.32 g of CO_2 and 0.631 g of H_2O. The mass percentage of iodine in the compound was determined by converting the iodine in a 0.850-g sample of the compound into 1.15 g of lead(II) iodide. What is the empirical formula of the compound? Could the compound also contain oxygen? Explain your answer.

M.15 When aqueous solutions of calcium nitrate and phosphoric acid are mixed, a white solid precipitates. (a) What is the formula of the solid? (b) How many grams of the solid can be formed from 206 g of calcium nitrate and 150. g of phosphoric acid?

M.16 Small amounts of chlorine gas can be generated in the laboratory from the reaction of manganese(IV) oxide with hydrochloric acid: $4\,HCl(aq) + MnO_2(s) \longrightarrow 2\,H_2O(l) + MnCl_2(s) + Cl_2(g)$. (a) What mass of Cl_2 can be produced from 42.7 g of MnO_2 with an excess of HCl(aq)? (b) What volume of chlorine gas (of density 3.17 $g\cdot L^{-1}$) will be produced from the reaction of 300. mL of 0.100 M HCl(aq) with an excess of MnO_2? (c) Suppose only 150. mL of chlorine was produced in the reaction in part (b). What is the percentage yield of the reaction?

M.17 In addition to determining elemental composition of pure unknown compounds, combustion analysis can be used to determine the *purity* of known compounds. A sample of 2-naphthol, $C_{10}H_7OH$, which is used to prepare antioxidants to incorporate into synthetic rubber, was found to be contaminated with a small amount of LiBr. The combustion analysis of this sample gave the following results: 77.48% C and 5.20% H. Assuming that the only species present are 2-naphthol and LiBr, calculate the percentage purity by mass of the sample.

M.18 An organic compound with the formula $C_{14}H_{20}O_2N$ was recrystallized from 1,1,2,2-tetrachloroethane, $C_2H_2Cl_4$. A combustion analysis of the compound gave the following data: 68.50% C, 8.18% H by mass. Because the data were considerably different from that expected for pure $C_{14}H_{20}O_2N$, the sample was examined and found to contain a significant amount of 1,1,2,2-tetrachloroethane. Assuming that only these two compounds are present, what is the percentage purity by mass of the $C_{14}H_{20}O_2N$?

M.19 Tu-jin-pi is a root bark used in traditional Chinese medicines for the treatment of "athlete's foot." One of the active ingredients in tu-jin-pi is pseudolaric acid A, which is known to contain carbon, hydrogen, and oxygen. A chemist wanting to determine the molecular formula of pseudolaric acid A burned 1.000 g of the compound in an elemental analyzer. The products of the combustion were 2.492 g of CO_2 and 0.6495 g of H_2O. (a) Determine the empirical formula of the compound. (b) The molar mass was found to be 388.46 $g\cdot mol^{-1}$. What is the molecular formula of pseudolaric acid A?

M.20 A folk medicine used in the Anhui province of China to treat acute dysentery is cha-tiao-qi, a preparation of the leaves of *Acer ginnala*. Reaction of one of the active ingredients in cha-tiao-qi with water yields gallic acid, a powerful antidysenteric agent. Gallic acid is known to contain carbon, hydrogen, and oxygen. A chemist wanting to determine the molecular formula of gallic acid burned 1.000 g of the compound in an elemental analyzer. The products of the combustion were 1.811 g of CO_2 and 0.3172 g of H_2O. (a) Determine the empirical formula of the compound. (b) The molar mass was found to be 170.12 $g\cdot mol^{-1}$. What is the molecular formula of gallic acid?

M.21 An industrial by-product consists of C, H, O, and Cl. When 0.100 g of the compound was analyzed by combustion analysis, 0.0682 g of CO_2 and 0.0140 g of H_2O were produced. The mass percentage of Cl in the compound was found to be 55.0%. What are the empirical and molecular formulas of the compound?

M.22 A mixture of 4.94 g of 85.0% pure phosphine, PH_3, and 0.110 kg of $CuSO_4\cdot 5H_2O$ (of molar mass 249.68 $g\cdot mol^{-1}$) is placed in a reaction vessel. (a) Balance the chemical equation for the reaction that takes place, given the skeletal form $CuSO_4\cdot 5H_2O(s) + PH_3(g) \longrightarrow Cu_3P_2(s) + H_2SO_4(aq) + H_2O(l)$. (b) Name each reactant and product. (c) Determine the limiting reactant. (d) Calculate the mass (in grams) of Cu_3P_2 (of molar mass 252.56 $g\cdot mol^{-1}$) produced, given that the percentage yield of the reaction is 6.31%.

M.23 The acid HA (where A stands for an unknown group of atoms) has molar mass 231 $g\cdot mol^{-1}$. HA reacts with the base XOH (molar mass 125 $g\cdot mol^{-1}$) to produce H_2O and the salt XA. In one experiment, 2.45 g of HA react with 1.50 g of XOH to form 2.91 g of XA. What is the percentage yield of the reaction?

M.24 The acid H_2A' (where A′ stands for an unknown group of atoms) has molar mass 168 $g\cdot mol^{-1}$. H_2A' reacts with the base XOH (molar mass 125 $g\cdot mol^{-1}$) to produce H_2O and the salt X_2A'. In one experiment, 1.20 g of H_2A' react with 1.00 g of XOH to form 0.985 g of X_2A'. What is the percentage yield of the reaction?

M.25 Aluminum metal reacts with chlorine gas to produce aluminum chloride. In one preparation, 255 g of aluminum is placed in a container holding 535 g of chlorine gas. After reaction ceases, it is found that 300. g of aluminum chloride has been produced. (a) Write the balanced equation for the reaction. (b) What mass of aluminum chloride can be produced by these reactants? (c) What is the percentage yield of aluminum chloride?

ATOMS: THE QUANTUM WORLD

1.21 The General Properties of the Elements

What Are the Key Ideas? Matter is composed of atoms. The structures of atoms can be understood in terms of the theory of matter known as quantum mechanics, in which the properties of particles and waves merge together.

Why Do We Need to Know This Material? Atoms are the fundamental building blocks of matter. They are the currency of chemistry in the sense that almost all the explanations of chemical phenomena are expressed in terms of atoms. This chapter explores the periodic variation of atomic properties and shows how quantum mechanics is used to account for the structures and therefore the properties of atoms. This material is in fact the foundation for almost all explanations in chemistry.

What Do We Need to Know Already? We need to be familiar with the nuclear model of the atom and the general layout of the periodic table (Fundamentals Section B). We also need the concepts of kinetic and potential energy (Section A).

We need insight to think like a chemist. Chemical insight means that, when we look at an everyday object or a sample of a chemical, we can imagine the atoms that make it up. Not only that, we need to be able to plunge, in our mind's eye, deep into the center of matter and imagine the internal structure of atoms. To visualize this structure and how it relates to the chemical properties of elements, we need to understand the **electronic structure** of an atom, the description of how its electrons are arranged around the nucleus.

As soon as we start this journey into the atom, we encounter an extraordinary feature of our world. In the early twentieth century scientists expected to be able to use **classical mechanics,** the laws of motion proposed by Newton in the seventeenth century, to describe the structure of atoms (Section B). After all, classical mechanics had been tremendously successful for describing the motion of visible objects such as balls and planets. However, it soon became clear that classical mechanics fails when applied to electrons in atoms. New laws, which came to be known as **quantum mechanics,** had to be developed.

This chapter builds an understanding of atomic structure in four steps. First, we review the experiments that led to our current nuclear model of the atom and see how spectroscopy reveals information about the arrangement of electrons around the nucleus. Then we describe the experiments that led to the replacement of classical mechanics by quantum mechanics, introduce some of its central features, and illustrate them by considering a very simple system. Next, we apply those ideas to the simplest atom of all, the hydrogen atom. Finally, we extend these concepts to the atoms of all the elements and see the foundations of the periodic table.

INVESTIGATING ATOMS

Dalton pictured atoms as featureless spheres, like billiard balls. Today, we know that atoms have an internal structure: they are built from even smaller **subatomic particles.** In this book, we deal with the three major subatomic particles: the electron, the proton, and the neutron. By investigating the internal structure of atoms, we can come to see how one element differs from another and see how their properties are related to the structures of their atoms.

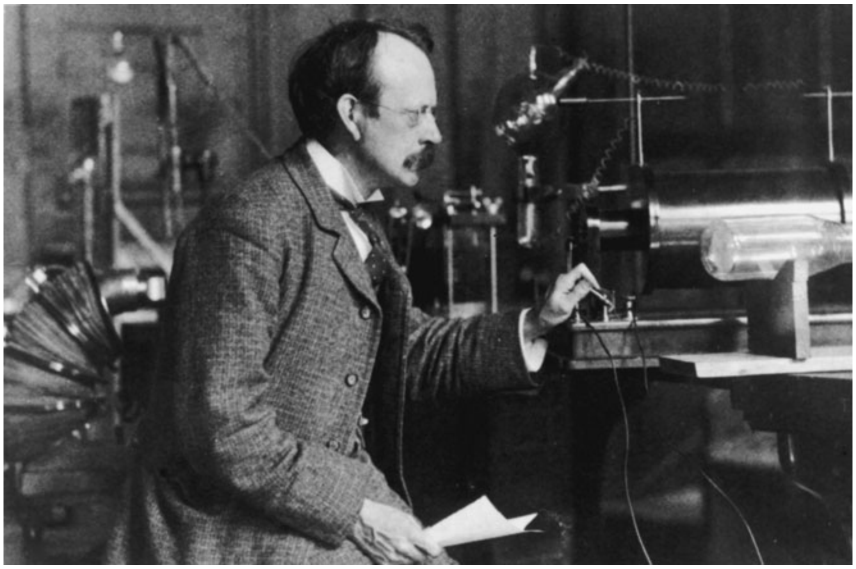

FIGURE 1.1 Joseph John Thomson (1856–1949), with the apparatus that he used to discover the electron.

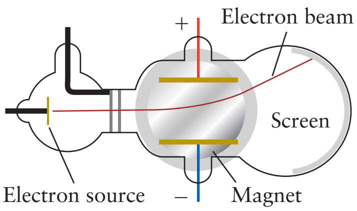

FIGURE 1.2 The apparatus used by Thomson to investigate the properties of electrons. An electric field is set up between the two plates and a magnetic field is applied perpendicular to the electric field.

1.1 The Nuclear Model of the Atom

The earliest experimental evidence for the internal structure of atoms was the discovery in 1897 of the first subatomic particle, the **electron.** The British physicist J. J. Thomson (Fig. 1.1) was investigating "cathode rays," the rays that are emitted when a high potential difference (a high voltage) is applied between two metal contacts called electrodes in an evacuated glass tube (Fig. 1.2). Thomson showed that cathode rays are streams of negatively charged particles. They came from inside the atoms that made up the negatively charged electrode, which is called the *cathode*. Thomson found that the charged particles, which came to be called "electrons," were the same regardless of the metal he used for the cathode. He concluded that they are part of the makeup of all atoms.

Thomson was able to measure the value of e/m_e, the ratio of the magnitude of the electron's charge e to its mass m_e. However, the values of e and m_e themselves were not known until later workers, most notably the American physicist Robert Millikan, carried out experiments that enabled them to determine the value of e. Millikan designed an ingenious apparatus in which he could observe tiny electrically charged oil droplets (Fig. 1.3). From the strength of the electric field required to overcome the pull of gravity on the droplets, he determined the values of the charges on the particles. Because each oil droplet contained more than one additional electron, he took the charge on one electron to be the smallest increment of charge between droplets. The modern value, which is obtained in a much more sophisticated way, is $e = 1.602 \times 10^{-19}$ C. A charge of $-e$ is considered to be "one unit" of negative charge, and e itself, which is called the **fundamental charge,** is taken to be "one unit" of positive charge. The mass of the electron was calculated by combining this charge with the value of e/m_e measured by Thomson; its modern value is 9.109×10^{-31} kg.

Recall that C stands for coulomb, the SI unit of electric charge (Section A).

Although electrons have a negative charge, atoms overall have zero charge. Therefore, an atom must contain enough positive charge to cancel the negative charge. But where was the positive charge? Thomson suggested a model of an atom as a blob of a positively charged, jellylike material, with the electrons suspended in it like raisins in pudding. However, this model was overthrown in 1908 by another experimental observation. Ernest Rutherford (Fig. 1.4) knew that some elements, including radon, emit

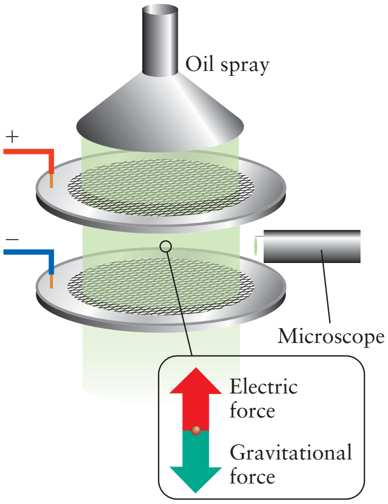

FIGURE 1.3 A schematic diagram of Millikan's oil-drop experiment. Oil is sprayed as a fine mist into a chamber containing a charged gas, and the location of an oil droplet is monitored by using a microscope. Charged particles (ions) are generated in the gas by exposing it to x-rays. The fall of the charged droplet is balanced by the electric field.

streams of positively charged particles, which he called **α particles** (alpha particles). He asked two of his students, Hans Geiger and Ernest Marsden, to shoot α particles toward a piece of platinum foil only a few atoms thick (Fig. 1.5). If atoms were indeed like blobs of positively charged jelly, then all the α particles would easily pass through the diffuse positive charge of the foil, with only occasional slight deflections in their paths.

Geiger and Marsden's observations astonished everyone. Although almost all the α particles did pass through and were deflected only very slightly, about 1 in 20 000 was deflected through more than 90°, and a few α particles bounced straight back in the direction from which they had come. "It was almost as incredible," said Rutherford, "as if you had fired a 15-inch shell at a piece of tissue paper and it had come back and hit you."

The results of the Geiger–Marsden experiment suggested the **nuclear model** of the atom, in which there is a dense pointlike center of positive charge, the **nucleus,** surrounded by a large volume of mostly empty space in which the electrons are located. Rutherford reasoned that when a positively charged α particle scored a direct hit on one of the minute but heavy platinum nuclei, the α particle was strongly repelled by the positive charge of the nucleus and deflected through a large angle, like a tennis ball bouncing off a stationary cannonball (Fig. 1.6). Later work showed that the nucleus of an atom contains particles called **protons,** each of which has a charge of $+e$, that are responsible for the positive charge, and **neutrons,** which are uncharged particles. The number of protons in the nucleus is different for each element and is called the **atomic number,** Z, of the element (Section B). The total charge on an atomic nucleus of atomic number Z is $+Ze$ and, for the atoms to be electrically neutral, there must be Z electrons around it.

In the nuclear model of the atom, all the positive charge and almost all the mass is concentrated in the tiny nucleus, and the negatively charged electrons surround the nucleus. The atomic number is the number of protons in the nucleus.

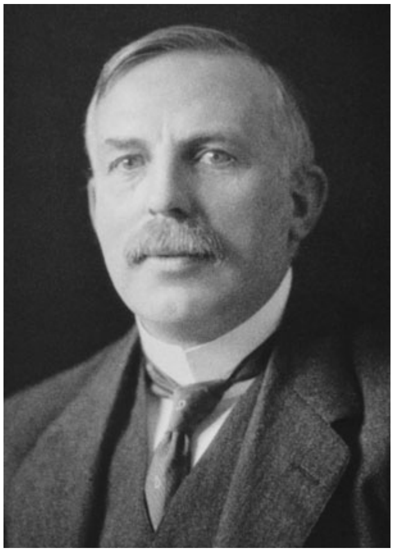

FIGURE 1.4 Ernest Rutherford (1871–1937), who was responsible for many discoveries about the structure of the atom and its nucleus.

1.2 The Characteristics of Electromagnetic Radiation

The question that scientists struggled with for years is how those Z electrons are arranged around the nucleus. To investigate the internal structures of objects as small as atoms, scientists observe them indirectly through the properties of the light the atoms emit when stimulated by heat or an electric discharge. The analysis of the light emitted or absorbed by substances is a hugely important branch of chemistry called **spectroscopy.** We shall see how atomic spectroscopy—spectroscopy applied to atoms—allowed scientists to propose a model of the electronic structure of atoms and to test their model against experiment. To do so, we need to understand the nature of light.

Light is a form of **electromagnetic radiation,** which consists of oscillating (time-varying) electric and magnetic fields that travel through empty space at about $3 \times 10^8\ \text{m·s}^{-1}$, or at just over 670 million miles per hour. This speed is denoted c and called the "speed of light." Visible light, radio waves, microwaves, and x-rays are all

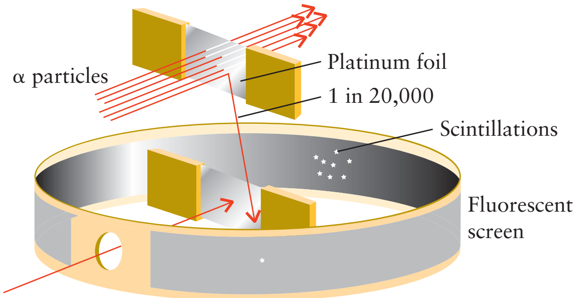

FIGURE 1.5 Part of the experimental arrangement used by Geiger and Marsden. The α particles came from a sample of the radioactive gas radon. They were directed through a hole into a cylindrical chamber with a zinc sulfide coating on the inside. The α particles struck the platinum foil mounted inside the cylinder, and their deflections were measured by observing flashes of light (scintillations) where they struck the screen. About 1 in 20 000 α particles was deflected through very large angles; most went through the thin foil with almost no deflection.

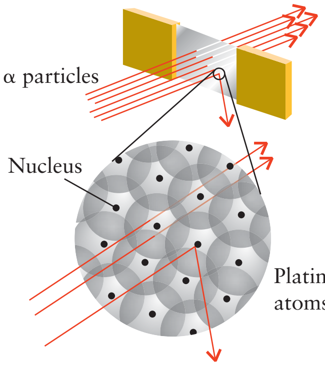

FIGURE 1.6 Rutherford's model of the atom explains why most α particles pass almost straight through the platinum foil, whereas a very few—those scoring a direct hit on the nucleus—undergo very large deflections. Most of the atom is nearly empty space thinly populated by the atom's electrons. The nuclei are much smaller relative to their atoms than shown here.

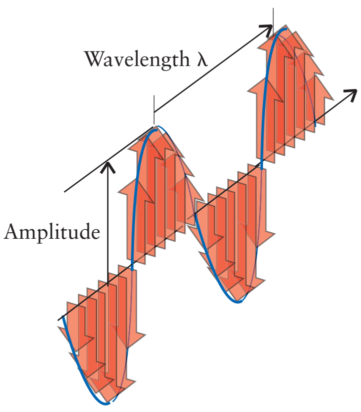

FIGURE 1.7 The electric field of electromagnetic radiation oscillates in space and time. This diagram represents a "snapshot" of an electromagnetic wave at a given instant. The length of an arrow at any point represents the strength of the force that the field exerts on a charged particle at that point. The distance between the peaks is the wavelength of the radiation, and the height of the wave above the center line is the amplitude.

types of electromagnetic radiation. All these forms of radiation transfer energy from one region of space to another. The warmth we feel from the Sun is carried to us through space as electromagnetic radiation.

As a light ray passes an electron, its electric field pushes the electron first in one direction and then in the opposite direction, over and over again. That is, the field oscillates in both direction and strength (Fig. 1.7). The number of cycles (complete reversals of direction away from and back to the initial strength and direction) per second is called the **frequency,** ν (the Greek letter nu), of the radiation. The unit of frequency, 1 hertz (1 Hz), is defined as 1 cycle per second:

$$1\ \text{Hz} = 1\ \text{s}^{-1}$$

Electromagnetic radiation of frequency 1 Hz pushes a charge in one direction, then the opposite direction, and returns to the original direction once per second. The frequency of electromagnetic radiation that we see as visible light is close to 10^{15} Hz, and so its electric field returns to its initial direction about a thousand trillion (10^{15}) times a second as it travels past a given point.

An instantaneous snapshot of a wave of electromagnetic radiation spread through space would look like Fig. 1.7. The wave is characterized by its amplitude and wavelength. The **amplitude** is the height of the wave above the center line. The square of the amplitude determines the **intensity,** or brightness, of the radiation. The **wavelength,** λ (the Greek letter lambda), is the peak-to-peak distance. The wavelengths of visible light are close to 500 nm. Although 500 nm is only half of one-thousandth of a millimeter (so you might *just* be able to imagine it), it is much longer than the diameters of atoms, which are typically close to 0.2 nm.

Different wavelengths of electromagnetic radiation correspond to different regions of the spectrum (see Table 1.1). Our eyes detect electromagnetic radiation with wavelengths in the range from 700 nm (red light) to 400 nm (violet light). Radiation in this range is called **visible light,** and the frequency of visible light determines its color. White light is a mixture of all wavelengths of visible light. The radiation from the Sun consists of white light and radiation of shorter and longer wavelengths called, respectively, ultraviolet and infrared radiation.

Now imagine the wave in Fig. 1.7 zooming along at its actual speed, the speed of light, c. If the wavelength of the light is very short, very many complete oscillations pass a given point in a second (Fig. 1.8a). If the wavelength is long, fewer complete oscillations pass the point in a second (Fig. 1.8b). A short wavelength therefore corresponds to high-frequency radiation and a long wavelength corresponds to low-frequency radiation. The precise relation is

A star next to an equation number signals that it appears in the list of Key Equations on the Web site for this book: www.freeman.com/chemicalprinciples5e.

$$\text{Wavelength} \times \text{frequency} = \text{speed of light, or } \lambda\nu = c \qquad \textbf{(1)*}$$

TABLE 1.1 Color, Frequency, and Wavelength of Electromagnetic Radiation

Radiation type	Frequency (10^{14} Hz)	Wavelength (nm, 2 sf)*	Energy per photon (10^{-19} J)
x-rays and γ-rays	$\geq 10^3$	≤ 3	$\geq 10^3$
ultraviolet	8.6	350	5.7
visible light			
violet	7.1	420	4.7
blue	6.4	470	4.2
green	5.7	530	3.8
yellow	5.2	580	3.4
orange	4.8	620	3.2
red	4.3	700	2.8
infrared	3.0	1000	2.0
microwaves and radio waves	$\leq 10^{-3}$	$\geq 3 \times 10^6$	$\leq 10^{-3}$

*The abbreviation sf denotes the number of significant figures in the data. The frequencies, wavelengths, and energies are typical values; they should not be regarded as precise.

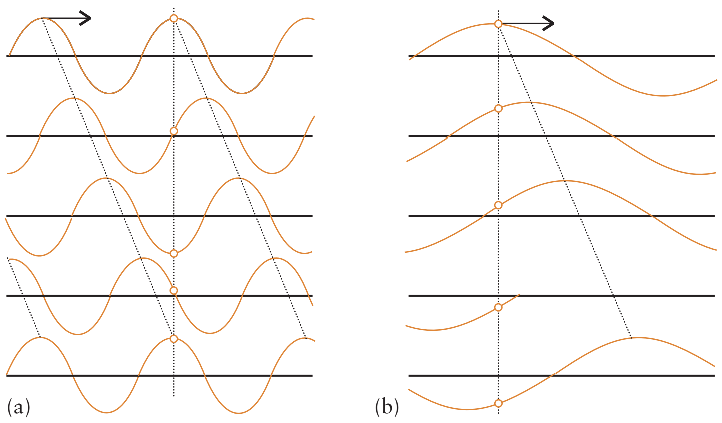

FIGURE 1.8 (a) Short-wavelength radiation: the vertical line shows how the electric field changes markedly at five successive instants, from top to bottom. (b) For the same five instants, the electric field of the long-wavelength radiation changes much less. The horizontal arrows in the uppermost images show that in each case the wave has traveled the same distance. Short-wavelength radiation has a high frequency, whereas long-wavelength radiation has a low frequency.

EXAMPLE 1.1 Calculating the wavelength of light of a known frequency

Which has the longer wavelength, red light of frequency 4.3×10^{14} Hz or blue light of frequency 6.4×10^{14} Hz?

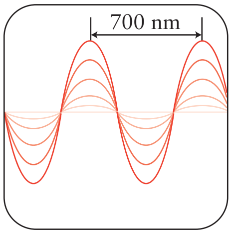
Anticipate Because long-wavelength waves result in fewer oscillations as they pass a given point, we associate long wavelength with low frequency. Therefore, because red light has a lower frequency than blue light, we should expect it to have the longer wavelength.

PLAN Use Eq. 1 to convert from frequency to wavelength.

SOLVE

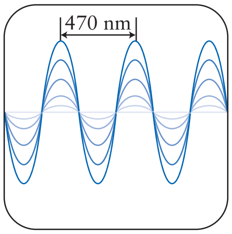
For red light: from $\lambda\nu = c$ written as $\lambda = c/\nu$,

$$\lambda = \frac{\overbrace{2.998 \times 10^{8}\ \text{m}\cdot\text{s}^{-1}}^{c}}{4.3 \times 10^{14}\ \underbrace{\text{s}^{-1}}_{\text{Hz}}} = \frac{2.998 \times 10^{8}}{4.3 \times 10^{14}}\ \text{m} = 7.0 \times 10^{-7}\ \text{m}$$



For blue light: from $\lambda\nu = c$ written as $\lambda = c/\nu$,

$$\lambda = \frac{\overbrace{2.998 \times 10^{8}\ \text{m}\cdot\text{s}^{-1}}^{c}}{6.4 \times 10^{14}\ \underbrace{\text{s}^{-1}}_{\text{Hz}}} = \frac{2.998 \times 10^{8}}{6.4 \times 10^{14}}\ \text{m} = 4.7 \times 10^{-7}\ \text{m}$$



Evaluate As predicted, red light has a longer wavelength (700 nm) than blue light (470 nm).

A note on good practice: It is a good idea to test your understanding with the self-tests that follow each worked example. Answers to the B self-tests can be found at the back of this book.

Self-Test 1.1A Calculate the wavelengths of the light from traffic signals as they change. Assume that the lights emit the following frequencies: green, 5.75×10^{14} Hz; yellow, 5.15×10^{14} Hz; red, 4.27×10^{14} Hz.

[***Answer:*** Green, 521 nm; yellow, 582 nm; red, 702 nm]

Self-Test 1.1B What is the wavelength of the signal from a radio station transmitting at 98.4 MHz?

Answer to all B self-tests are in the back of this book.

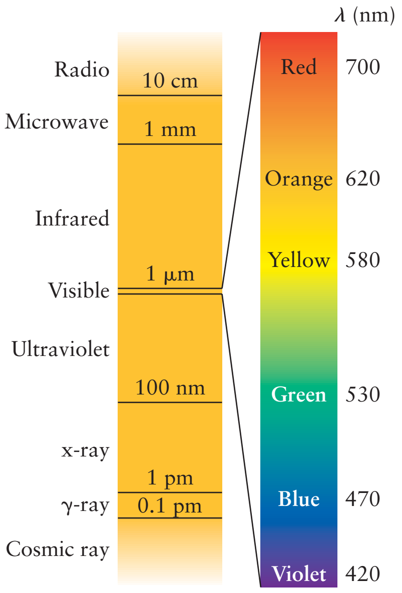


FIGURE 1.9 The electromagnetic spectrum and the names of its regions. The region we call "visible light" occupies a very narrow range of wavelengths. The regions are not drawn to scale.

As far as we know, there is neither an upper limit nor a lower limit to the wavelength of electromagnetic radiation (Fig. 1.9). **Ultraviolet radiation** is radiation at higher frequency than violet light; its wavelength is less than about 400 nm. This component of solar radiation is responsible for sunburn and tanning, but would destroy all living things on Earth if it were not largely prevented from reaching the surface of the Earth by the ozone layer. **Infrared radiation,** the radiation we experience as heat, has a lower frequency and longer wavelength than red light; its wavelength is greater than about 800 nm. Microwaves, which are used in radar and microwave ovens, have even longer wavelengths, in the millimeter-to-centimeter range.

Modern theories suggest that our concept of space breaks down on a scale of 10^{-34} m, so that may constitute a lower bound to the wavelength of electromagnetic radiation.

The color of light depends on its frequency and wavelength; long-wavelength radiation has a lower frequency than short-wavelength radiation.

1.3 Atomic Spectra

Now that we know some of the properties of electromagnetic radiation, we can begin to see how it provides information about atomic structure. In this section we focus on the hydrogen atom, as it contains only a single electron. When an electric current is passed through a low-pressure sample of hydrogen gas, the sample emits light. The electric current, which is like a storm of electrons, breaks up the H_2 molecules and excites the free hydrogen atoms to higher energies. These excited atoms quickly discard their excess energy by giving off electromagnetic radiation; then they combine to form H_2 molecules again.

When white light is passed through a prism, a continuous spectrum of light results because white light consists of all wavelengths of visible radiation (Fig. 1.10a). However, when the light emitted by excited hydrogen atoms is passed through a prism, the radiation is found to consist of a number of components, or **spectral lines** (Fig. 1.10b). The brightest line (at 656 nm) is red, and the excited atoms in the gas glow with this red light. Excited hydrogen atoms also emit ultraviolet and infrared radiation, which are invisible to the eye but can be detected electronically and photographically.

The components of different frequency or wavelength are called *lines* because, in the early spectroscopic experiments, the radiation from the sample was passed through a slit and then through a prism; the image of the slit was then focused on a photographic plate, where it appeared as a line.

The first person to identify a pattern in the lines of the visible region of the spectrum was Johann Balmer, a Swiss schoolteacher. In 1885, he noticed that the wavelengths of all the lines then known could be generated by the expression

$$\lambda \propto \frac{n^2}{n^2 - 4} \qquad n = 3,4,\ldots$$

Shortly after, the Swedish spectroscopist Johannes Rydberg suggested a form of this expression that was to prove much more revealing:

$$\frac{1}{\lambda} \propto \frac{1}{2^2} - \frac{1}{n^2} \qquad n = 3,4,\ldots$$

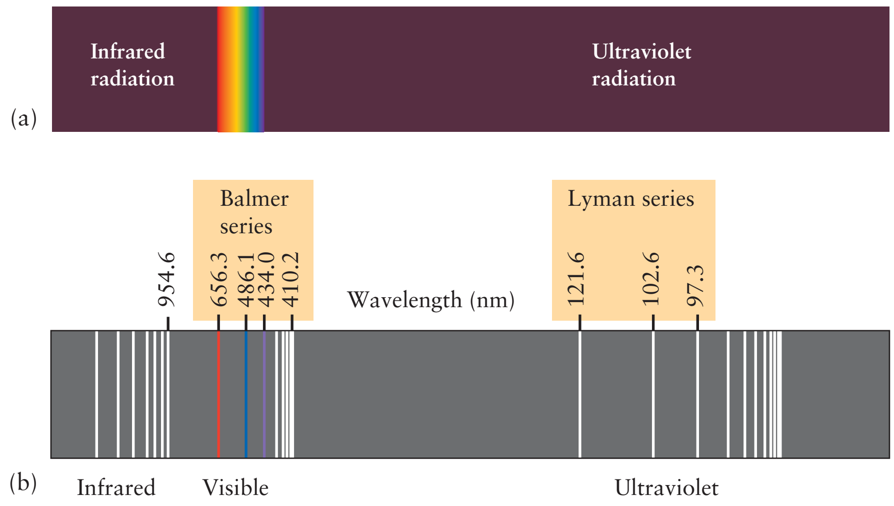

FIGURE 1.10 (a) The infrared, visible, and ultraviolet spectrum. (b) The complete spectrum of atomic hydrogen. The spectral lines have been assigned to various groups called series, two of which are shown with their names.

This expression is easily extended to account for other series of lines which soon came to be discovered, simply by replacing 2^2 by 3^2, 4^2, and so on. The modern form of the more general expression is often written in terms of the frequency $\nu = c/\lambda$ as

$$\nu = \mathcal{R}\left\{\frac{1}{n_1^2} - \frac{1}{n_2^2}\right\} \qquad n_1 = 1,2,\ldots, \qquad n_2 = n_1 + 1, n_1 + 2,\ldots \tag{2}$$

Here $\mathcal{R}$ is an empirical (experimentally determined) constant now known as the **Rydberg constant;** its value is 3.29×10^{15} Hz. The **Balmer series** is the set of lines with $n_1 = 2$ (and $n_2 = 3, 4, \ldots$). The **Lyman series,** a set of lines in the ultraviolet region of the spectrum, has $n_1 = 1$ (and $n_2 = 2, 3, \ldots$).

EXAMPLE 1.2 Identifying a line in the hydrogen spectrum

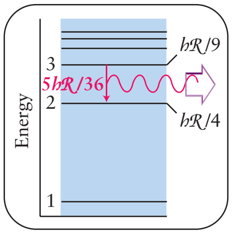
Calculate the wavelength of the radiation emitted by a hydrogen atom for $n_1 = 2$ and $n_2 = 3$. Identify the spectral line in Fig. 1.10b.

PLAN The frequency is given by Eq. 2. Convert frequency into wavelength by using Eq. 1. The wavelength should match one of the lines in the Balmer series in Fig. 1.10b.

SOLVE

From Eq. 2 with $n_1 = 2$ and $n_2 = 3$,

$$\nu = \mathcal{R}\left\{\frac{1}{2^2} - \frac{1}{3^2}\right\} = \frac{5}{36}\mathcal{R}$$

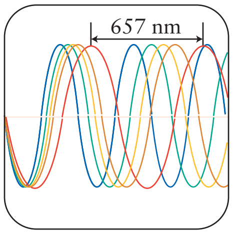


From $\lambda\nu = c$,

$$\lambda = \frac{c}{\nu} = \frac{c}{(5\mathcal{R}/36)} = \frac{36c}{5\mathcal{R}}$$

Now substitute the data:

$$\lambda = \frac{36 \times \overbrace{(2.998 \times 10^8\ \text{m}\cdot\text{s}^{-1})}^{c}}{5 \times \underbrace{(3.29 \times 10^{15}\ \text{s}^{-1})}_{\mathcal{R}}} = 6.57 \times 10^{-7}\ \text{m}$$



Evaluate This wavelength, 657 nm, corresponds to the red line in the Balmer series of lines in the spectrum.

Self-Test 1.2A Repeat the calculation for $n_1 = 2$ and $n_2 = 4$ and identify the spectral line in Fig. 1.10b.

[***Answer:*** 486 nm; blue line]

Self-Test 1.2B Repeat the calculation for $n_1 = 2$ and $n_2 = 5$ to and identify the spectral line in Fig. 1.10b.

If we pass white light through a vapor composed of the atoms of an element, we see its *absorption spectrum*, a series of dark lines on an otherwise continuous spectrum (Fig. 1.11). The absorption lines have the same frequencies as the lines in the emission spectrum and suggest that an atom can *absorb* radiation only of those same frequencies. Absorption spectra are used by astronomers to identify elements in the outer layers of stars.

We can begin to understand the presence of spectral lines if we suppose that an electron can exist with only certain energies when it is part of a hydrogen atom, and

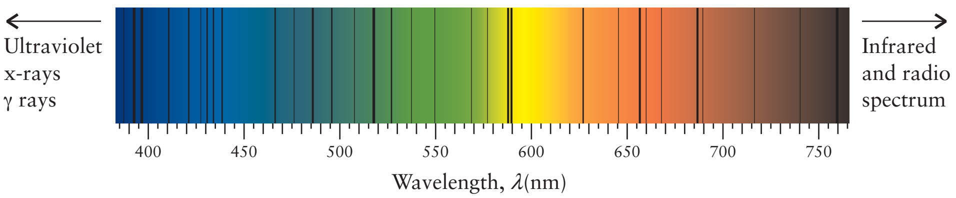


FIGURE 1.11 When white light shines through a vapor, radiation is absorbed by the atoms at frequencies that correspond to their excitation energies. In this small section of the spectrum of the Sun, it is possible to identify which atoms in its outer layers are absorbing the radiation from the incandescence below. Many of the lines have been ascribed to hydrogen, showing that hydrogen is present in the cooler outer layers of the Sun.

that a line in an emission spectrum arises from a **transition** between two of the allowed energies. The presence of spectral lines of specific frequencies suggests that the energy of an electron in an atom is restricted to a series of discrete values, called **energy levels.** The difference in the energies of two levels is carried away by the electromagnetic radiation emitted by the atom. If that is the case, then Rydberg's formula begins to suggest that the permitted energies are proportional to $\mathcal{R}/n^2$, for then the difference in energy of the two states involved in the transition would be given by an expression that resembled the right-hand side of Rydberg's formula. But why should the frequency of the emitted radiation be proportional to that energy difference? Furthermore, why does the Rydberg constant have the value that is observed?

The observation of discrete spectral lines suggests that an electron in an atom can have only certain energies.

QUANTUM THEORY

Toward the end of the nineteenth century, scientists became increasingly perplexed as they gathered more information about electromagnetic radiation that could not be explained by classical mechanics, and the lines in the spectrum of hydrogen remained deeply puzzling. Then, from 1900 on, a series of imaginative suggestions were made, and by 1927 the puzzles had been resolved, only to be replaced by new and even more intriguing puzzles. In this part of the chapter we describe these other puzzles and their resolution in terms of quantum mechanics. We shall then see some of the peculiar, revolutionary results from quantum mechanics that will help us to understand atomic structure, beginning with the hydrogen atom.

1.4 Radiation, Quanta, and Photons

Important clues to the nature of electromagnetic radiation came from observations of objects as they are heated. At high temperatures an object begins to glow—the phenomenon of **incandescence.** As the object is heated to higher temperatures it glows more brightly and the color of light it gives off changes from red through orange and yellow toward white. Those are *qualitative* observations. To understand what the color changes mean, scientists had to study the effect *quantitatively*. They measured the intensity of radiation at each wavelength and repeated the measurements at a variety of different temperatures. These experiments caused one of the greatest revolutions that has ever occurred in science. Figure 1.12 shows some of the experimental results. The "hot object" is known as a **black body** (even though it might be glowing white hot!). The name signifies that the object does not favor one wavelength over another in the sense of absorbing a particular wavelength preferentially or emitting one preferentially. The curves in Fig. 1.12 show the intensity of **black-body radiation,** the radiation emitted at different wavelengths by a heated black body, for a series of temperatures. Notice that as the temperature rises, the maximum intensity of the radiation emitted occurs at shorter and shorter wavelengths.

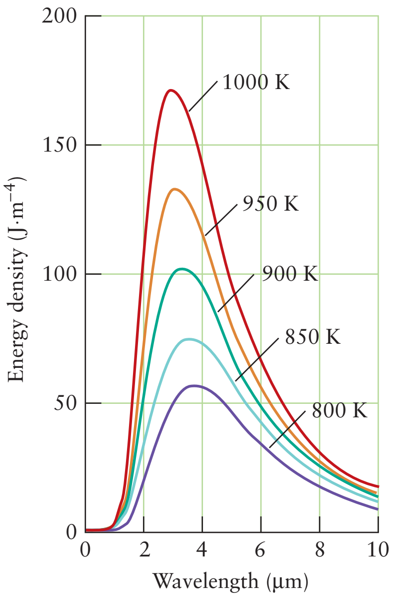

FIGURE 1.12 The intensity of radiation emitted by a heated black body as a function of wavelength. As the temperature increases, the total energy emitted (the area under the curve) increases sharply, and the maximum intensity of emission moves to shorter wavelengths. (To obtain the energy in a volume V and at wavelengths λ and $\lambda + \Delta\lambda$, multiply the energy density by V and $\Delta\lambda$.)

Thinking point: Why does a heated metal object first glow red hot and then white hot?

Two crucial pieces of experimental information about black-body radiation were discovered in the late nineteenth century. In 1879, Josef Stefan investigated the increasing brightness of a black body as it is heated and discovered that the total intensity of radiation emitted over all wavelengths increases as the fourth power of the absolute temperature (Fig. 1.13). This quantitative relation is now called the **Stefan–Boltzmann law** and is usually written

The name of the Stefan–Boltzmann law recognizes Ludwig Boltzmann's theoretical contribution.

$$\text{Total intensity} = \text{constant} \times T^4 \quad \textbf{(3a)}$$

The experimental value of the constant is $5.67 \times 10^{-8}\ \text{W}\cdot\text{m}^{-2}\cdot\text{K}^{-4}$, where W denotes watts ($1\ \text{W} = 1\ \text{J}\cdot\text{s}^{-1}$). A few years later, in 1893, Wilhelm Wien examined the shift in color of black-body radiation as the temperature increases and discovered that the wavelength corresponding to the maximum in the intensity, λ_{max}, is inversely proportional to the absolute temperature, $\lambda_{max} \propto 1/T$ (that is, as T increases the wavelength decreases), and therefore that $\lambda_{max} \times T$ is a constant (Fig. 1.14). This quantitative result is now called **Wien's law** and is normally written

$$T\lambda_{max} = \text{constant} \quad \textbf{(3b)}$$

The empirical (experimental) value of the constant in this expression is 2.9 K·mm.

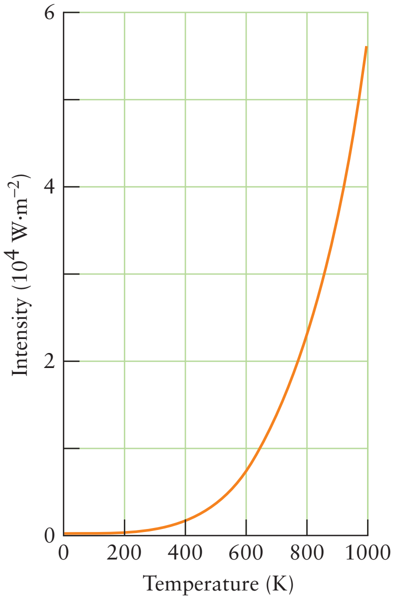

FIGURE 1.13 The total intensity of radiation emitted by a heated black body increases as the fourth power of the temperature, so a body at 1000 K emits more than 120 times as much energy as is emitted by the same body at 300 K.

EXAMPLE 1.3 Determining temperature from black-body radiation

A star can be regarded as a black body, so we can use the properties of black-body radiation to measure its temperature. The maximum intensity of solar radiation occurs at 490. nm. What is the temperature of the surface of the Sun?

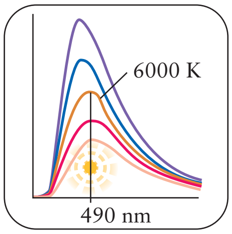
Anticipate We should be aware that objects glowing white hot are at temperatures of several thousand degrees.

PLAN Use Wien's law in the form $T = \text{constant}/\lambda_{max}$.

SOLVE

From $T = \text{constant}/\lambda_{max}$,

$$T = \frac{\overbrace{2.9 \times 10^{-3}\text{m}\cdot\text{K}}^{2.9\ \text{mm}}}{\underbrace{4.90 \times 10^{-7}\ \text{m}}_{490\ \text{nm}}} = \frac{2.9 \times 10^{-3}}{4.90 \times 10^{-7}}\ \text{K} = 5.9 \times 10^{3}\ \text{K}$$



Evaluate The surface temperature of the Sun is about 5900 K, in accord with our expectation.

Self-Test 1.3A In 1965, electromagnetic radiation with a maximum at 1.05 mm (in the microwave region) was discovered to pervade the universe. What is the temperature of "empty" space?

[***Answer:*** 2.76 K]

Self-Test 1.3B A red giant is a late stage in the evolution of a star. The average wavelength maximum at 700. nm shows that a red giant cools as it dies. What is the surface temperature of a red giant?

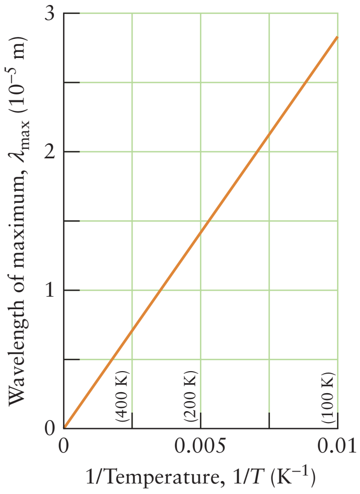


FIGURE 1.14 As the temperature is raised ($1/T$ decreases), the wavelength of maximum emission shifts to smaller values.

For nineteenth-century scientists, the obvious way to account for the laws of black-body radiation was to use classical physics to derive its characteristics. However, much to their dismay, they found that the characteristics they deduced did not match their observations. Worst of all was the **ultraviolet catastrophe:** classical physics predicted that any hot body should emit intense ultraviolet radiation and even x-rays and γ-rays! According to classical physics, a hot object would devastate the countryside with high-frequency radiation. Even a human body at 37°C would glow in the dark. There would, in fact, be no darkness.

The word *quantum* comes from the Latin for amount—literally, "How much?"

The suggestion that resolved the problem came in 1900 from the German physicist Max Planck. He proposed that the exchange of energy between matter and radiation occurs in **quanta,** or packets, of energy. Planck focused his attention on the hot, rapidly oscillating electrons and atoms of the black body. His central idea was that a charged particle oscillating at a frequency ν can exchange energy with its surroundings by generating or absorbing electromagnetic radiation only in discrete packets of energy

$$E = h\nu \qquad (4)^*$$

The constant h, now called **Planck's constant,** has the value 6.626×10^{-34} J·s. If the oscillating atom releases an energy E into the surroundings, then radiation of frequency $\nu = E/h$ will be detected.

Planck's hypothesis implies that radiation of frequency ν can be generated only if an oscillator of that frequency has acquired the minimum energy required to start oscillating. At low temperatures, there is not enough energy available to stimulate oscillations at very high frequencies, and so the object cannot generate high-frequency, ultraviolet radiation. As a result, the intensity curves in Fig. 1.12 die away at high frequencies (short wavelengths) and the ultraviolet catastrophe is avoided. In contrast, in classical physics it was assumed that an oscillator could oscillate with any energy and therefore, even at low temperatures, high-frequency oscillators could contribute to the emitted radiation. Planck's hypothesis is *quantitatively* successful, too, because not only was he able to use his proposal to derive the Stefan–Boltzmann and Wien laws but he was also able to calculate the variation of intensity with wavelength and to obtain a curve that matched the experimental curve almost exactly.

In fact, Planck struggled for years to keep classical mechanics alive, believing that his introduction of the quantum was just a mathematical trick. Einstein is often credited with establishing the physical reality of quantizaton.

To achieve this successful theory, Planck had discarded classical physics, which puts no restriction on how small an amount of energy may be transferred from one object to another. He had proposed instead that energy is transferred in discrete packets. To justify such a dramatic revolution, more evidence was needed. That evidence came from the **photoelectric effect,** the ejection of electrons from a metal when its surface is exposed to ultraviolet radiation (Fig. 1.15). The experimental observations were as follows:

1. No electrons are ejected unless the radiation has a frequency above a certain threshold value characteristic of the metal.
2. Electrons are ejected immediately, however low the intensity of the radiation.
3. The kinetic energy of the ejected electrons increases linearly with the frequency of the incident radiation.

A note on good practice: We say that a property y varies linearly with x if the relation between y and x can be written $y = b + mx$, where b and m are constants. When $y = mx$ (that is, when $b = 0$), we say that *y is proportional to x*. See Appendix 1E.

Albert Einstein found an explanation of these observations and, in the process, profoundly changed our conception of the electromagnetic field. He proposed that electromagnetic radiation consists of particles, which were later called **photons.** Each photon can be regarded as a packet of energy, and the energy of a single photon is related to the frequency of the radiation by Eq. 4 ($E = h\nu$). For example, ultraviolet photons are more energetic than photons of visible light, which has lower frequencies. According to this photon model of electromagnetic radiation, we can visualize a beam of red light as a stream of photons, each having the same energy, yellow light as a stream of photons, each of higher energy, and green light as a stream of photons, each of higher energy still. It is important to note that the intensity of radiation is an indication of the *number* of photons present, whereas $E = h\nu$ is a measure of the *energy* of each individual photon.

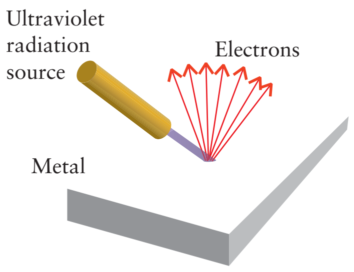

FIGURE 1.15 When a metal is illuminated with ultraviolet radiation, electrons are ejected, provided the frequency is above a threshold frequency that is characteristic of the metal.

EXAMPLE 1.4 Calculating the energy of a photon

What is (a) the energy of a single photon of blue light of frequency 6.4×10^{14} Hz; (b) the energy per mole of photons of the same frequency?

PLAN (a) Use Eq. 4 to find the energy of light of a given frequency. (b) Multiply the energy of one photon by the number of photons per mole, which is Avogadro's constant (Section E).

SOLVE

(a) From $E(1\text{ photon}) = h\nu$,

$$E(1\text{ photon}) = (6.626 \times 10^{-34}\text{ J·s}) \times (6.4 \times 10^{14}\text{ Hz}) = 4.2 \times 10^{-19}\text{ J}$$

(b) From $E(\text{per mole of photons}) = N_A E$,

$$\begin{aligned} E(\text{per mole of photons}) &= (6.022 \times 10^{23}\text{ mol}^{-1}) \times (4.2 \times 10^{-19}\text{ J}) \\ &= 2.5 \times 10^{5}\text{ J mol}^{-1}\text{, or } 250\text{ kJ mol}^{-1} \end{aligned}$$

To derive the energy in part (a), we have used $1\text{ Hz} = 1\text{ s}^{-1}$, so $\text{J·s} \times \text{Hz} = \text{J·s} \times \text{s}^{-1} = \text{J}$.

Self-Test 1.4A What is the energy of a photon of yellow light of frequency 5.2×10^{14} Hz?

[***Answer:*** 3.4×10^{-19} J]

Self-Test 1.4B What is the energy of a photon of orange light of frequency 4.8×10^{14} Hz?

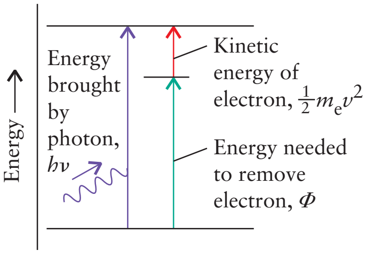

FIGURE 1.16 In the photoelectric effect, a photon with energy $h\nu$ strikes the surface of a metal and its energy is absorbed by an electron. If the energy of the photon is greater than the work function, Φ, of the metal, the electron absorbs enough energy to break away from the metal. The kinetic energy of the ejected electron is the difference between the energy of the photon and the work function: $\frac{1}{2}m_e v^2 = h\nu - \Phi$.

The characteristics of the photoelectric effect are easy to explain if we visualize electromagnetic radiation as consisting of a stream of photons. If the incident radiation has frequency ν, it consists of photons of energy $h\nu$. These particles collide with the electrons in the metal. The energy required to remove an electron from the surface of a metal is called the **work function** of the metal and denoted Φ (uppercase phi). If the energy of a photon is less than the energy required to remove an electron from the metal, then an electron will not be ejected, regardless of the intensity of the radiation (the rate at which the photons arrive). However, if the energy of the photon, $h\nu$, is greater than Φ, then an electron is ejected with a kinetic energy, $E_k = \frac{1}{2}m_e v^2$, equal to the difference between the energy of the incoming photon and the work function: $E_k = h\nu - \Phi$ (Fig. 1.16). It follows that

$$\underbrace{\tfrac{1}{2}m_e v^2}_{\substack{\text{Kinetic energy}\\ \text{of ejected}\\ \text{electron}}} = \underbrace{h\nu}_{\substack{\text{Energy}\\ \text{supplied}\\ \text{by photon}}} - \underbrace{\Phi}_{\substack{\text{Energy required}\\ \text{to eject photon}}} \qquad (5)$$

What does this equation tell us? Because the kinetic energy of the ejected electrons varies linearly with frequency, a plot of the kinetic energy against the frequency of the supplied radiation should look like the graph in Fig. 1.17, a straight line of slope h, the same for all metals, and have an extrapolated intercept with the vertical axis at $-\Phi$, different for each metal. The intercept with the horizontal axis (corresponding to zero kinetic energy of the ejected electron) is at Φ/h in each case.

We can now interpret the experimental observations of the photoelectric effect in light of Einstein's theory:

1. An electron can be driven out of the metal only if it receives from the photon during the collision at least a certain minimum energy equal to the work function, Φ. Therefore, the frequency of the radiation must have a certain minimum value if electrons are to be ejected. This minimum frequency depends on the work function and hence on the identity of the metal (as shown in Fig. 1.17).
2. Provided a photon has enough energy, a collision results in the immediate ejection of an electron.
3. The kinetic energy of the electron ejected from the metal increases linearly with the frequency of the incident radiation according to Eq. 5.

EXAMPLE 1.5 Analyzing the photoelectric effect

The speed of an electron emitted from the surface of a sample of potassium by a photon is 668 km·s^{-1}. (a) What is the kinetic energy of the ejected electron? (b) What is the wavelength of the radiation that caused photoejection of the electron? (c) What is the longest wavelength of electromagnetic radiation that could eject electrons from potassium? The work function of potassium is 2.29 eV.

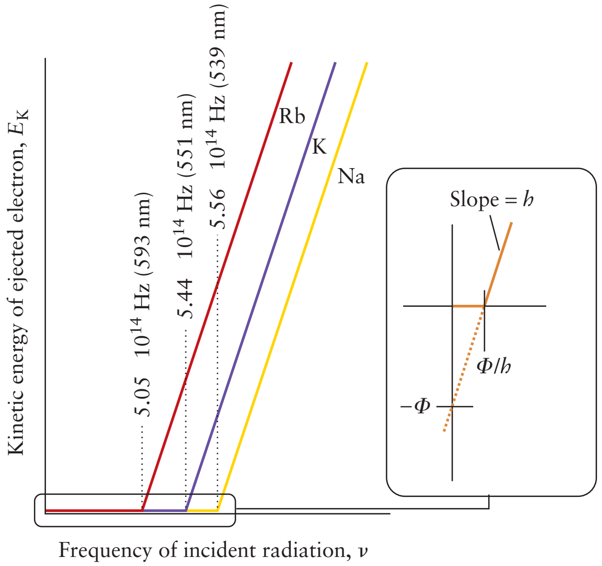

FIGURE 1.17 When photons strike a metal, no electrons are ejected unless the incident radiation has a frequency above a value characteristic of the metal. The kinetic energy of the ejected electrons varies linearly with the frequency of the incident radiation. The inset shows the relation of the slope and the two intercepts to the parameters in Eq. 5.

PLAN (a) Find the kinetic energy of the ejected electron from $E_k = \frac{1}{2}m_ev^2$. To use SI base units (which is often sensible in calculations), first convert the speed to meters per second. (b) The energy of the ejected electron is equal to the difference in energy of the incident radiation and the work function (Eq. 5). The photon needs to provide enough energy to eject the electron from the surface (the work function) as well as to cause it to move at 668 km·s^{-1}. Convert the value of the work function into joules and use Eq. 5 to determine the value of $h\nu$ for the photon. Then use $\lambda\nu = c$ to convert that energy to wavelength. Conversion factors and fundamental constants can be found inside the back cover of the book. (c) The longest wavelength of radiation that can eject electrons from a substance is the wavelength that results in the ejected electron having zero kinetic energy.

SOLVE

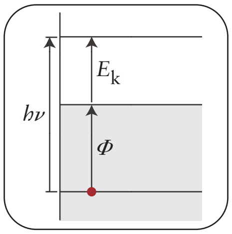
(a) From $E_k = \frac{1}{2}mv^2$,

$$E_k = \frac{1}{2} \times (9.109 \times 10^{-31}\ \text{kg}) \times (6.68 \times 10^5\ \text{m·s}^{-1})^2$$
$$= 2.03 \times 10^{-19}\ \text{J}$$

(b) Convert the work function from electronvolts to joules.

$$2.29\ \text{eV} \times \frac{1.602 \times 10^{-19}\ \text{J}}{1\ \text{eV}} = 3.67 \times 10^{-19}\ \text{J}$$

From $\frac{1}{2}m_ev^2 = h\nu - \Phi$, $h\nu = \Phi + \frac{1}{2}m_ev^2 = \Phi + E_k$,



$$h\nu = 3.67 \times 10^{-19}\ \text{J} + 2.03 \times 10^{-19}\ \text{J} = 5.70 \times 10^{-19}\ \text{J}$$

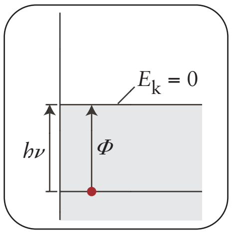
so

$$\nu = \frac{5.70 \times 10^{-19}\ \text{J}}{h}$$

Now use $\lambda = c/\nu$:

$$\lambda = \frac{(3.00 \times 10^8\ \text{m·s}^{-1}) \times (6.626 \times 10^{-34}\ \text{J·s})}{5.70 \times 10^{-19}\ \text{J}}$$
$$= 3.49 \times 10^{-7}\ \text{m} \quad \text{or} \quad 349\ \text{nm}$$

(c) To find the longest wavelength of radiation able to eject an electron, set $E_k = 0$ in Eq. 5, so $h\nu = \Phi$, and therefore $\lambda = ch/\Phi$.



$$\lambda = \frac{(3.00 \times 10^{8}\ \text{m·s}^{-1}) \times (6.626 \times 10^{-34}\ \text{J·s})}{3.67 \times 10^{-19}\ \text{J}}$$
$$= 5.42 \times 10^{-7}\ \text{m} \quad \text{or} \quad 542\ \text{nm}$$

Self-Test 1.5A The work function of zinc is 3.63 eV. What is the longest wavelength of electromagnetic radiation that could eject electrons from zinc?

[***Answer:*** 342 nm]

Self-Test 1.5B The speed of an electron that is emitted from the surface of a sample of zinc by a photon is 785 km·s^{-1}. (a) What is the kinetic energy of the ejected electron? (b) The work function of zinc is 3.63 eV. What is the wavelength of the radiation that caused photoejection of the electron?

The existence of photons and the relation between the energy and frequency of a photon helps to answer one of the questions posed by the spectrum of atomic hydrogen. At the end of Section 1.3 we started to form the view that a spectral line arises from a transition between two energy levels. Now we can see that if the energy difference is carried away as a photon, then the frequency of an individual line in a spectrum is related to the energy difference between two energy levels involved in the transition (Fig. 1.18):

$$h\nu = E_{\text{upper}} - E_{\text{lower}} \qquad \textbf{(6)*}$$

This relation is called the **Bohr frequency condition.** If the energies on the right of this expression are each proportional to $h\mathcal{R}/n^2$, then we have accounted for Rydberg's formula. We still have to explain why the energies have this form, but we have made progress.

Studies of black-body radiation led to Planck's hypothesis of the quantization of electromagnetic radiation. The photoelectric effect provides evidence of the particulate nature of electromagnetic radiation.

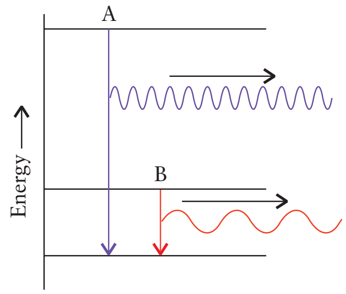


FIGURE 1.18 When an atom undergoes a transition from a state of higher energy to one of lower energy, it loses energy that is carried away as a photon. The greater the energy difference, the higher the frequency (and the shorter the wavelength) of the radiation emitted. Compare the high frequency of the emission during a transition from state A to that from state B.

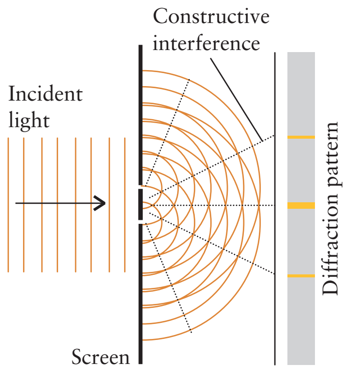

FIGURE 1.19 In this illustration, the peaks of the waves of electromagnetic radiation are represented by orange lines. When radiation coming from the left (the vertical lines) passes through a pair of closely spaced slits, circular waves are generated at each slit. These waves interfere with each other. Where they interfere constructively (as indicated by the positions of the dotted lines), a bright line is seen on the screen behind the slits; where the interference is destructive, the screen is dark.

1.5 The Wave–Particle Duality of Matter

The photoelectric effect strongly supports the view that electromagnetic radiation consists of photons that behave like particles. However, there is plenty of evidence to show that electromagnetic radiation behaves like waves! The most compelling evidence is the observation of **diffraction,** the pattern of high and low intensities generated by an object in the path of a ray of light (Fig. 1.19). A diffraction pattern results when the peaks and troughs of waves traveling along one path interfere with the peaks and troughs of waves traveling along another path. If the peaks coincide, the amplitude of the wave (its height) is enhanced; we call this enhancement **constructive interference** (Fig. 1.20a). If the peaks of one wave coincide with the troughs of another wave, the amplitude of the wave is diminished by **destructive interference** (Fig. 1.20b). This effect is the basis of a number of useful techniques for studying matter. For example, x-ray diffraction is one of the most important tools for studying the structures of molecules (see Major Technique 4, following Chapter 5).

You can appreciate why scientists were puzzled! The results of some experiments (the photoelectric effect) compelled them to the view that electromagnetic radiation is particlelike. The results of other experiments (diffraction) compelled them equally

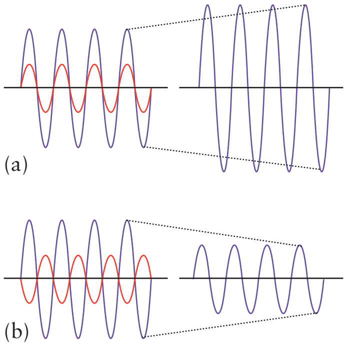

FIGURE 1.20 (a) Constructive interference. The two component waves (left) are "in phase" in the sense that their peaks and troughs coincide. The resultant (right) has an amplitude that is the sum of the amplitudes of the components. The wavelength of the radiation is not changed by interference, only the amplitude is changed. (b) Destructive interference. The two component waves are "out of phase" in the sense that the troughs of one coincide with the peaks of the other. The amplitude of the resultant is much lower than in the case of constructive interference of either component.

firmly to the view that electromagnetic radiation is wavelike. Thus we are brought to the heart of modern physics. Experiments oblige us to accept the **wave-particle duality** of electromagnetic radiation, in which the concepts of waves and particles blend together. In the wave model, the intensity of the radiation is proportional to the square of the amplitude of the wave. In the particle model, intensity is proportional to the number of photons present at each instant.

If electromagnetic radiation, which for a long time had been regarded as wavelike, has a dual character, could it be that matter, which since Dalton's day had been regarded as consisting of particles, also has wavelike properties? In 1925, the French scientist Louis de Broglie proposed that *all* particles should be regarded as having wavelike properties. He went on to suggest that the wavelength associated with the "matter wave" is inversely proportional to the particle's mass, m, and speed, v, and that

$$\lambda = \frac{h}{mv} \qquad \textbf{(7a)}$$

The product of mass and speed is called the **linear momentum,** p, of a particle, and so this expression is more simply written as the **de Broglie relation:**

$$\lambda = \frac{h}{p} \qquad \textbf{(7b)*}$$

EXAMPLE 1.6 Calculating the wavelength of a particle

In order to appreciate why the wavelike properties of particles had not been noticed, calculate the wavelength of a particle of mass 1 g traveling at 1 $m\cdot s^{-1}$.

Anticipate Because the particle is much heavier than any subatomic particle, we should expect a very short wavelength.

PLAN Use Eq. 7a to find the wavelength of a particle of known mass.

SOLVE

From $\lambda = h/mv$,

$$\lambda = \frac{6.626 \times 10^{-34}\ \text{J}\cdot\text{s}}{(1 \times 10^{-3}\,\text{kg}) \times (1\ \text{m}\cdot\text{s}^{-1})} = \frac{6.626 \times 10^{-34}}{1 \times 10^{-3}}\ \frac{\text{kg}\cdot\text{m}^2\cdot\text{s}^{-2}\cdot\text{s}}{\text{kg}\cdot\text{m}\cdot\text{s}^{-1}}$$

$$= 7 \times 10^{-31}\,\text{m}$$

Evaluate As expected, this wavelength is very—in fact, undetectably—small; the same is true for any macroscopic (visible) object traveling at normal speeds.

A note on good practice: Notice how, in the calculations, we kept all the units, writing them separately, and then canceling and multiplying them like ordinary numbers. We did not simply "guess" that the wavelength would turn out in meters. This procedure helps you to detect errors and ensures that your answer has the correct units.

Self-Test 1.6A Calculate the wavelength of an electron traveling at 1/1000 the speed of light (see the inside back cover of this book for the mass of an electron).

[***Answer:*** 2.43 nm]

Self-Test 1.6B Calculate the wavelength of a rifle bullet of mass 5.0 g traveling at twice the speed of sound (the speed of sound is 331 $m\cdot s^{-1}$).

The wavelike character of electrons was confirmed by showing that they could be diffracted. The experiment was first performed in 1925 by two American scientists, Clinton Davisson and Lester Germer, who directed a beam of fast electrons at a single

crystal of nickel. The regular array of atoms in the crystal, with centers separated by 250 pm, acts as a grid that diffracts waves; and a diffraction pattern was observed (Fig. 1.21). Since then, some molecules have been shown to undergo diffraction, and there is no doubt that particles have a wavelike character. Indeed, electron diffraction is now an important technique for determining the structures of molecules and exploring the structures of solid surfaces.

Electrons (and matter in general) have both wavelike and particlelike properties.

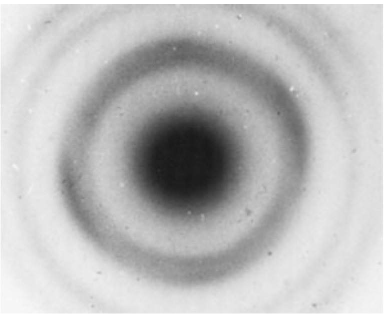

FIGURE 1.21 Davisson and Germer showed that electrons produce a diffraction pattern when reflected from a crystal. G. P. Thomson, working in Aberdeen, Scotland, showed that they also produce a diffraction pattern when they pass through a very thin gold foil. The latter is shown here. G. P. Thomson was the son of J. J. Thomson, who identified the electron (Section 1.1). Both received Nobel prizes: J. J. for showing that the electron is a particle and G. P. for showing that it is a wave.

1.6 The Uncertainty Principle

The discovery of wave–particle duality not only changes our understanding of electromagnetic radiation and matter, but also sweeps away the foundations of classical physics. In classical mechanics, a particle has a definite **trajectory,** or path on which location and linear momentum are specified at each instant. However, we cannot specify the precise location of a particle if it behaves like a wave: think of a wave in a guitar string, which is spread out all along the string, not localized at a precise point. A particle with a precise linear momentum has a precise wavelength; but, because it is meaningless to speak of the location of a wave, it follows that we cannot specify the location of a particle that has a precise linear momentum. Duality means that the electron in a hydrogen atom cannot be described as orbiting the nucleus with a definite trajectory. The popular picture of an electron in orbit around the nucleus is just plain wrong.

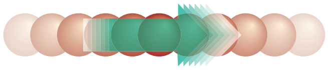
The difficulty will not go away. Wave–particle duality denies the possibility of specifying the location if the linear momentum is known, and so we cannot specify the trajectory of particles. If we know that a particle is *here* at one instant, we can say nothing about where it will be an instant later! The impossibility of knowing the precise position if the linear momentum is known precisely is an aspect of the **complementarity** of location and momentum—if one property is known the other cannot be known simultaneously. The **Heisenberg uncertainty principle**, which was formulated by the German scientist Werner Heisenberg in 1927, expresses this complementarity quantitatively. It states that, if the location of a particle is known to within an uncertainty Δx, then the linear momentum, p, parallel to the x-axis can be known simultaneously only to within an uncertainty Δp, where

$$\Delta p \Delta x \geq \tfrac{1}{2}\hbar \qquad (8)^*$$

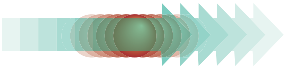
The symbol $\hbar$, which is read "h bar," means $h/2\pi$, a useful combination that is found widely in quantum mechanics.

What does this equation tell us? The product of the uncertainties in two simultaneous measurements cannot be less than a certain constant value. Therefore, if the uncertainty in position is very small (Δx very small), then the uncertainty in linear momentum must be large, and vice versa (Fig. 1.22).

The uncertainty principle has negligible practical consequences for macroscopic objects, but it is of profound importance for subatomic particles such as the electrons in atoms.



(a)



(b)

FIGURE 1.22 A representation of the uncertainty principle. (a) The location of the particle is ill defined, and so the momentum of the particle (represented by the arrow) can be specified reasonably precisely. (b) The location of the particle is well defined, and so the momentum cannot be specified very precisely.

EXAMPLE 1.7 Using the uncertainty principle

Estimate the minimum uncertainty in (a) the position of a marble of mass 1.0 g given that its speed is known to within $\pm 1.0\ \text{mm·s}^{-1}$ and (b) the speed of an electron confined to within the diameter of a typical atom (200. pm).

Anticipate We should expect the uncertainty in the position of an object as heavy as a marble to be very small but the uncertainty in the speed of an electron, which has a very small mass and is confined to a small region, to be very large.

PLAN (a) The uncertainty Δp is equal to $m\Delta v$, where Δv is the uncertainty in the speed; we use Eq. 8 to estimate the minimum uncertainty in position, Δx, along the direction of the

travel of the marble from $\Delta p \Delta x = \frac{1}{2}\hbar$ (the minimum value of the product of uncertainties). (b) We assume Δx to be the diameter of the atom and use Eq. 8 to estimate Δp; by using the mass of the electron inside the back cover, we find Δv from $\Delta p = m\Delta v$.

SOLVE (a) First we convert mass and speed into SI base units. The mass, m, is 1.0×10^{-3} kg, and the uncertainty in the speed, Δv, is $2 \times (1.0 \times 10^{-3}\ \text{m·s}^{-1})$. The minimum uncertainty in position, Δx, is then:

From $\Delta p \Delta x = \frac{1}{2}\hbar$ and $\Delta p = m\Delta v$,

$$m\Delta v \Delta x = \frac{\hbar}{2} \quad \text{or} \quad \Delta x = \frac{\hbar}{2m\Delta v}$$

From $\Delta x = \hbar/2m\Delta v$,

$$\Delta x = \frac{1.054\,57 \times 10^{-34}\ \text{J·s}}{2 \times \underbrace{(1.0 \times 10^{-3}\ \text{kg})}_{1.0\ \text{g}} \times \underbrace{(2.0 \times 10^{-3}\ \text{m·s}^{-1})}_{2.0\ \text{mm·s}^{-1}}}$$

$$= \frac{1.054\,57 \times 10^{-34}}{2 \times 1.0 \times 10^{-3} \times 2.0 \times 10^{-3}} \frac{\text{J·s}}{\text{kg·m·s}^{-1}}$$

$$= 2.6 \times 10^{-29} \frac{\text{kg·m}^2\text{·s}^{-2}\text{·s}}{\text{kg·m·s}^{-1}} = 2.6 \times 10^{-29}\ \text{m}$$

Evaluate As expected, this uncertainty is very small.

A note on good practice: Notice that to manipulate the units we have expressed derived units (J in this case) in terms of base units. Notice too that we are using the more precise values of the fundamental constants given inside the back cover (rather than the less precise values quoted in the text) to ensure reliable results.

(b) The mass of the electron is given inside the back cover; the diameter of the atom is $200. \times 10^{-12}$ m, or 2.00×10^{-10} m. The uncertainty in the speed, Δv, is equal to $\Delta p/m$:

From $\Delta p \Delta x = \frac{1}{2}\hbar$ and $\Delta p = m\Delta v$,

$$\Delta v = \frac{\Delta p}{m} \overset{\Delta p = \hbar/2\Delta x}{\widehat{=}} \frac{\hbar}{2m\Delta x}$$

From $\Delta x = \hbar/2m\Delta v$,

$$\Delta v = \frac{1.054\,57 \times 10^{-34}\ \text{J·s}}{2 \times \underbrace{(9.109\,39 \times 10^{-31}\ \text{kg})}_{m_e} \times \underbrace{(2.00 \times 10^{-10}\ \text{m})}_{200.\ \text{pm}}}$$

$$= \frac{1.054\,57 \times 10^{-34}}{2 \times 9.109\,39 \times 10^{-31} \times 2.0 \times 10^{-10}} \frac{\text{J·s}}{\text{kg·m}}$$

$$= 2.89 \times 10^{5} \frac{\overbrace{\text{kg·m}^2\text{·s}^{-2}}^{\text{J}}\text{·s}}{\text{kg·m}} = 2.89 \times 10^{5}\ \text{m·s}^{-1}$$

Evaluate As predicted, the uncertainty in the speed of the electron is very large, nearly $\pm 150\ \text{km·s}^{-1}$.

Self-Test 1.7A A proton is accelerated in a cyclotron to a very high speed that is known to within 3.0×10^2 km·s^{-1}. What is the minimum uncertainty in its position?

[*Answer:* 0.11 pm]

Self-Test 1.7B The police are monitoring an automobile of mass 2.0 t (1 t = 10^3 kg) speeding along a highway. They are certain of the location of the vehicle only to within 1 m. What is the minimum uncertainty in the speed of the vehicle?

The location and momentum of a particle are complementary; that is, the location and the momentum cannot both be known simultaneously with arbitrary precision. The quantitative relation between the precision of each measurement is described by the Heisenberg uncertainty principle.

FIGURE 1.23 Erwin Schrödinger (1887–1961).

1.7 Wavefunctions and Energy Levels

If they were to account for the spectrum of atomic hydrogen and then atoms of the other elements, scientists of the early twentieth century had to revise the nineteenth-century description of matter to take into account wave–particle duality. One of the first people to formulate a successful theory (in 1927) was the Austrian scientist Erwin Schrödinger (Fig. 1.23), who introduced a central concept of quantum theory. We shall illustrate the concept with a simple example (a particle trapped in a box) that reveals a number of important aspects of his approach. At the end of this section we shall be ready to move on to the hydrogen atom and see how the concepts apply to it and answer the remaining questions about its spectrum.

Because particles have wavelike properties, we cannot expect them to behave like pointlike objects moving along precise trajectories. Schrödinger's approach was to replace the precise trajectory of a particle by a **wavefunction,** ψ (the Greek letter psi), a mathematical function with values that vary with position. Some wavefunctions are very simple: shortly we shall meet one that is simply sin x; when we get to the hydrogen atom, we shall meet one that is like e^{-x}.

As you go on in quantum mechanics, you will see that wavefunctions may be "complex" in the technical sense of involving $i = \sqrt{(-1)}$. We ignore that possibility here.

The German physicist Max Born suggested how the wavefunction should be interpreted physically. The **Born interpretation** of the wavefunction is that *the probability of finding the particle in a region is proportional to the value of* ψ^2 (Fig. 1.24). To be precise, ψ^2 is a **probability density,** the probability that the particle will be found in a small region divided by the volume of the region. "Probability density" is the analog of the more familiar "mass density," the mass of a region divided by the volume of the region. To calculate the mass of a region, we multiply its mass density by the volume of the region. Likewise, to calculate the probability that a particle is in a region, we multiply the probability density by the volume of the region. For instance, if $\psi^2 = 0.1$ pm^{-3} at a point, then the probability of finding the particle in a region of volume 2 pm^3 located at that point would be (0.1 pm^{-3}) × (2 pm^3) = 0.2, or 1 chance in 5. Wherever ψ^2 is large, the particle has a high probability density; wherever ψ^2 is small, the particle has only a low probability density.

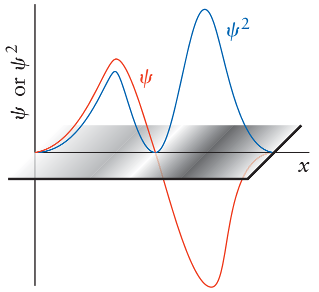


FIGURE 1.24 The Born interpretation of the wavefunction. The probability density (the blue line) is given by the square of the wavefunction and depicted by the density of shading in the band beneath. Note that the probability density is zero at a node. A node is a point where the wavefunction (the orange line) passes through zero, not merely approaches zero.

A note on good practice: Distinguish between *probability* and *probability density*: the former is unitless and lies between 0 (certainly not there) and 1 (certainly there), but the latter has the dimensions of 1/volume. To go from probability density to probability, multiply it by the volume of interest.

Because the square of any number is positive, we don't have to worry about ψ having a negative sign in some regions of space (as a function such as sin x has): probability density is never negative. Wherever ψ, and hence ψ^2, is zero, the particle has zero probability density. A location where ψ passes *through* zero (not just reaching zero) is called a **node** of the wavefunction; so we can say that a particle has zero probability density wherever the wavefunction has nodes.

Note the "passes through"; merely becoming zero is not enough to be considered a node.

To calculate the wavefunction for any particle we use Schrödinger's great contribution, the **Schrödinger equation.** Although we shall not use the equation directly (we shall need to know only the form of some of its solutions, not how those solutions are found),

The Schrödinger equation is a "differential equation," an equation that relates the "derivatives" of a function (in this case, a second derivative of ψ, $d^2\psi/dx^2$) to the value of the function at each point. Derivatives are reviewed in Appendix 1F.

it is appropriate at least to see what it looks like. For a particle of mass m moving in one dimension in a region where the potential energy is $V(x)$ the equation is

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} + V(x)\psi = E\psi \qquad \textbf{(9a)}$$

The term $d^2\psi/dx^2$ can be thought of as a measure of how sharply the wavefunction is curved. The left-hand side of the Schrödinger equation is commonly written $H\psi$, where H is called the **hamiltonian** for the system; then the equation takes the deceptively simple form

$$H\psi = E\psi \qquad \textbf{(9b)}$$

The Schrödinger equation is used to calculate both the wavefunction ψ and the corresponding energy E. To understand what is involved, we shall consider one of the simplest systems, a single particle of mass m confined in a one-dimensional box between two rigid walls a distance L apart, a so-called **particle in a box** (Fig. 1.25). The equation can be solved quite easily for this system (as we show below). The idea to keep in mind is that only certain wavelengths can exist in the box, just as a stretched string can support only certain wavelengths. Think of a guitar string: because it is tied down at each end, it can support only shapes like the ones shown in Fig. 1.25. The shapes of the wavefunctions for the particle in the box are the same as the displacements of a vibrating string. Their mathematical form is

$$\psi_n(x) = \left(\frac{2}{L}\right)^{1/2} \sin\left(\frac{n\pi x}{L}\right) \qquad n = 1, 2, \ldots \qquad \textbf{(10)}$$

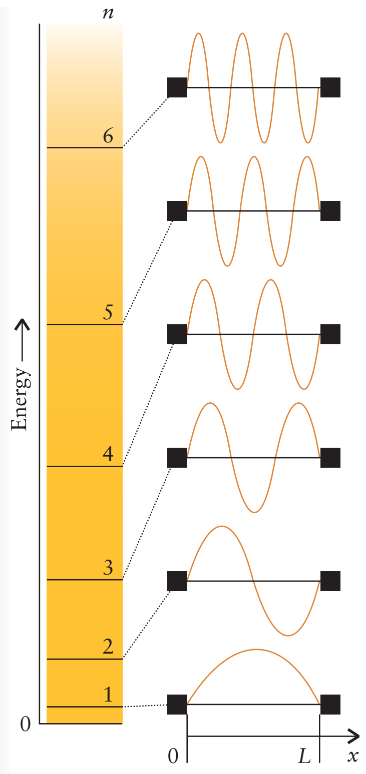

FIGURE 1.25 The arrangement known as "a particle in a box," in which a particle of mass m is confined between two impenetrable walls a distance L apart. The first six wavefunctions and their energies are shown. The numbers on the left are values of the quantum number n. Note that there is a zero-point energy because n cannot be zero.

Living Graph 1.25

The integer n labels the wavefunctions and is called a "quantum number." In general, a **quantum number** is an integer (or, in some cases, Section 1.10, a half-integer) that labels a wavefunction, specifies a state, and can be used to calculate the value of a property of the system. For example, we can use n to find an expression for the energy corresponding to each wavefunction.

HOW DO WE DO THAT (LEVEL 1)?

The kinetic energy of a particle of mass m is related to its speed, v, by $E_k = \frac{1}{2}mv^2$. We can relate this energy to the wavelength of the particle by noting that the linear momentum is $p = mv$ and then using the de Broglie relation (Eq. 7):

$$E_k = \frac{1}{2}mv^2 = \frac{1}{2}\frac{(mv)^2}{m} = \frac{p^2}{2m} = \frac{(h/\lambda)^2}{2m} = \frac{h^2}{2m\lambda^2}$$

We assume that the potential energy of the particle is zero everywhere inside the box, and so the total energy, E, is given by the expression for E_k alone.

At this point, we recognize that (like a guitar string) only whole-number multiples of half-wavelengths can fit into the box (see Fig. 1.25; the waves have one bulge, two bulges, three bulges, and so forth, with each "bulge" a half-wavelength). That is, the wavelengths possible for a particle in a box of length L must meet the condition that:

$$L = \frac{1}{2}\lambda, \lambda, \frac{3}{2}\lambda, \ldots = n \times \frac{1}{2}\lambda, \text{ with } n = 1, 2, \ldots$$

Therefore, the allowed wavelengths are

$$\lambda = 2L/n, \text{ with } n = 1, 2, \ldots$$

When this expression for λ is inserted into the expression for the energy, we obtain

$$E_n = \frac{h^2}{2m\lambda^2} = \frac{h^2}{2m(2L/n)^2} = \frac{n^2h^2}{8mL^2}$$

HOW DO WE DO THAT (LEVEL 2)?

The more sophisticated—and more general—way of finding the energy levels of a particle in a box is to use calculus to solve the Schrödinger equation. First, we note that the potential energy of the particle is zero everywhere inside the box; so $V(x) = 0$, and the equation that we have to solve is

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} = E\psi$$

Differential equations are commonly solved by recognizing that they have a particular form and then verifying that that form is a solution by substituting it into the original equation. An equation like this one has solutions of the form

$$\psi(x) = A \sin kx + B \cos kx$$

with A, B, and k constants. To verify that this is a solution, we substitute it into the differential equation and use $d(\sin kx)/dx = k \cos kx$ and $d(\cos kx)/dx = -k \sin kx$:

$$\begin{aligned}\frac{d^2\psi}{dx^2} &= \frac{d^2}{dx^2}(A \sin kx + B \cos kx) = \frac{d}{dx}(kA \cos kx - kB \sin kx)\\ &= -k^2A \sin kx - k^2B \cos kx = -k^2(A \sin kx + B \cos kx)\\ &= -k^2\psi\end{aligned}$$

This expression has the same form as the Schrödinger equation, and is exactly the same if $k^2 = 2mE/\hbar^2$. It follows that

$$E = \frac{k^2\hbar^2}{2m} = \frac{k^2(h/2\pi)^2}{2m} = \frac{k^2h^2}{8\pi^2 m}$$

Our next task is to find the constants A, B, and k that appear in $\psi(x)$ and E. One criterion for the acceptability of a wavefunction is that, like a guitar string, it varies smoothly. Like a guitar string, a wavefunction cannot drop from a nonzero value just inside the container to zero in the walls: to be continuous, ψ must be zero *at* the walls. Therefore, for a box of length L, $\psi(x)$ must be zero at the edges of the box, at $x = 0$ and $x = L$. We call these constraints "boundary conditions." If we set $x = 0$ and use $\sin 0 = 0$ and $\cos 0 = 1$ in $\psi(x) = A \sin kx + B \cos kx$, we find $\psi(0) = B$. However, $\psi(0) = 0$; so $B = 0$ and the wavefunction is

$$\psi(x) = A \sin kx$$

This expression already resembles that in Eq. 10. To find the value of k, we use the second boundary condition, that $\psi(L) = 0$; that is,

$$\psi(L) = A \sin kL = 0$$

Setting $A = 0$ is unacceptable, because then $\psi(x)$ would be zero everywhere, which would mean that the particle would be nowhere. Therefore, to guarantee that $\psi(L) = 0$, we use the relation $\sin n\pi = 0$ with $n = 1, 2, \ldots$, and set $kL = n\pi$. We now have

$$\psi(x) = A \sin\left(\frac{n\pi x}{L}\right) \quad n = 1, 2, \ldots$$

and, by substituting $k = n\pi/L$ into the expression for E, arrive at

$$E = \frac{k^2h^2}{8\pi^2 m} = \frac{(n\pi/L)^2h^2}{8\pi^2 m} = \frac{n^2h^2}{8mL^2}$$

exactly as we found in level 1. We see that the quantization of energy stems directly from the imposition of boundary conditions on the wavefunction.

To find the one remaining constant, A, we use the fact that the probability of finding the particle in a region of length dx at x is $\psi(x)^2dx$, and therefore the total probability of finding the particle between $x = 0$ and $x = L$ is the sum (integral) of these probabilities. Because that total probability must be equal to 1 (the particle must be somewhere in the box), we "normalize" the wavefunction; that is, we set the integral equal to 1:

$$\int_0^L \psi(x)^2 dx = A^2\int_0^L \sin^2\left(\frac{n\pi x}{L}\right)dx = 1$$

By convention, $\sin^2 x$ means $(\sin x)^2$.

The integral evaluates to $L/2$; so $A^2L/2 = 1$. Therefore, $A = (2/L)^{1/2}$ and the final form of the wavefunction is that given in Eq. 10.

We have established that the allowed energies of a particle of mass m in a one-dimensional box of length L are

$$E_n = \frac{n^2h^2}{8mL^2} \qquad n = 1, 2, \ldots \tag{11}$$

> ***What does this equation tell us?*** Because the mass, m, of the particle appears in the denominator, for a given length of box, the energy levels lie at lower values for heavy particles than for light particles. Because the length of the box appears in the denominator (as L^2), as the walls become more confining (L smaller), the energy levels are squeezed upward.

A striking implication of Eq. 11 is that because n can take only integral values, the energy of the particle is **quantized,** meaning that it is restricted to a series of discrete values, called **energy levels.** According to classical mechanics, an object can have any total energy—high, low, and anything in between. For example, a particle in a box could bounce from wall to wall with any speed and hence any kinetic energy. According to quantum mechanics, however, because only certain wavelengths fit into the box and each wavelength corresponds to a different energy, *energy is quantized*. The difference between the classical and quantum descriptions of energy is like the difference between the bulk and molecular descriptions of water: when we pour water from a bucket, the water seems to be a continuous fluid that can be transferred in any amount, no matter how small; however, the smallest amount of water that we can transfer is one H_2O molecule, one "quantum" of water.

As we saw in the derivation of Eq. 11, energy quantization stems from the **boundary conditions** on the wavefunction, the constraints that the wavefunction must satisfy at different points of space (such as fitting into a container correctly). Because an electron in an atom has a wavefunction that must satisfy certain constraints in three dimensions, only some solutions of the Schrödinger equation and their corresponding energies are acceptable. We can begin to see the origin of the quantized energy levels of an atom.

We can use Eq. 11 to calculate the energy separation between two neighboring levels with quantum numbers n and $n + 1$:

$$E_{n+1} - E_n = \frac{(n+1)^2h^2}{8mL^2} - \frac{n^2h^2}{8mL^2} = (2n+1)\frac{h^2}{8mL^2} \tag{12}$$

We see that, as L (the length of the box) or m (the mass of the particle) increases, the separation between neighboring energy levels decreases (Fig. 1.26). That is why no one noticed that energy is quantized until they investigated very small systems such as an electron in a hydrogen atom: the separation between levels is so small for ordinary particles in ordinary-sized vessels that it is completely undetectable. We can, in fact, ignore the quantization of the motion of the atoms of a gas in a typical flask.

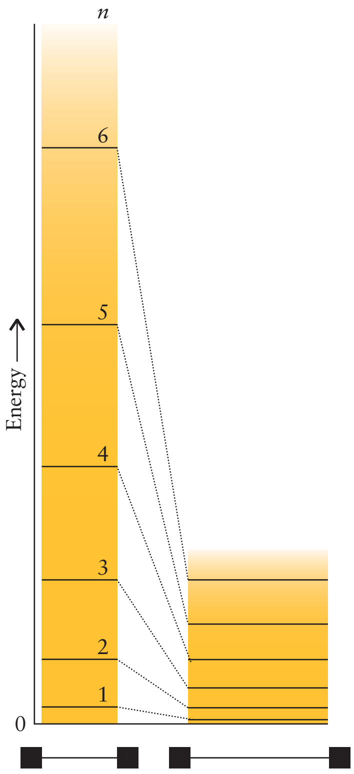

FIGURE 1.26 As the length of the box increases (compare boxes on left and right), the energy levels fall and move closer together.

EXAMPLE 1.8 Calculating the energies of a particle in a box

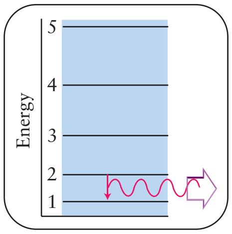
Very simple expressions can often be used to estimate the order of magnitude of a property without doing a detailed calculation. For example, treat a hydrogen atom as a one-dimensional box of length 150. pm (the approximate diameter of the atom) containing an electron and predict the wavelength of the radiation emitted when the electron falls to the lowest energy level from the next higher energy level.

PLAN The lowest energy level has $n = 1$, and so we can use Eq. 12 with $n = 1$ and $m = m_e$, the mass of the electron. The energy difference is carried away as a photon of radiation; so we set the energy difference equal to $h\nu$ and express ν in terms of the corresponding wavelength by using Eq. 1 ($\lambda = c/\nu$).

SOLVE The mass of the electron is found inside the back cover.

From Eq. 12 with $n = 1$, $2n + 1 = 3$,

$$E_2 - E_1 = \frac{3h^2}{8m_eL^2}$$



From $E_2 - E_1 = h\nu$,

$$h\nu = \frac{3h^2}{8m_eL^2}, \quad \text{so } \nu = \frac{3h}{8m_eL^2}$$

From $\lambda = c/\nu$,

$$\lambda = \frac{c}{(3h/8m_eL^2)} = \frac{8m_ecL^2}{3h}$$

Now substitute the data:

$$\lambda = \frac{8 \times \overbrace{(9.109\,39 \times 10^{-31}\text{ kg})}^{m_e} \times \overbrace{(2.998 \times 10^{8}\text{ m·s}^{-1})}^{c} \times \overbrace{(1.50 \times 10^{-10}\text{ m})^2}^{L = 150\text{ pm}}}{3 \times \underbrace{(6.626 \times 10^{-34}\text{ J·s})}_{h}}$$

$$= \frac{8 \times 9.109\,39 \times 10^{-31} \times 2.998 \times 10^{8} \times (1.50 \times 10^{-10})^2}{3 \times 6.626 \times 10^{-34}} \, \frac{\text{kg·m·s}^{-1}\text{·m}^2}{\underbrace{\text{kg·m}^2\text{·s}^{-2}}_{\text{J}}\text{·s}}$$

$$= 2.47 \times 10^{-8}\text{ m}$$

A note on good practice: Note once again how the complicated collection of units is treated: arriving at the correct units for the answer is a sign that you have set up the equation correctly. As usual, it is good practice to go as far as possible symbolically and then to insert numerical values at the last possible stage.

Evaluate This wavelength corresponds to 24.7 nm. The experimental value for the actual transition in a hydrogen atom is 122 nm. Although there is a big discrepancy, an atom does not have the hard boundaries that confine a particle in a box, and is three-dimensional. The fact that the predicted wavelength has nearly the same order of magnitude as the actual value suggests that a quantum theory of the atom, based on a more realistic three-dimensional model, should give good agreement.

Self-Test 1.8A Use the same model for helium but suppose that the box is 100. pm long, because the atom is smaller. Estimate the wavelength of the same transition.

[***Answer:*** 11.0 nm]

Self-Test 1.8B Use the same model for hydrogen and estimate the wavelength for the transition from the $n = 3$ energy level to the $n = 2$ level.

Another surprising implication of Eq. 11 is that *a particle in a container cannot have zero energy*. Because the lowest value of n is 1 (corresponding to a wave of one-half wavelength fitting into the box), the lowest energy is $E_1 = h^2/8mL^2$. This lowest possible energy is called the **zero-point energy.** The existence of a zero-point energy means that, according to quantum mechanics, a particle can never be perfectly still when it is confined between two walls: it must always possess an energy—in this case, a kinetic energy—of at least $h^2/8mL^2$. This result is consistent with the uncertainty principle. When a particle is confined between two walls, the uncertainty in its position cannot

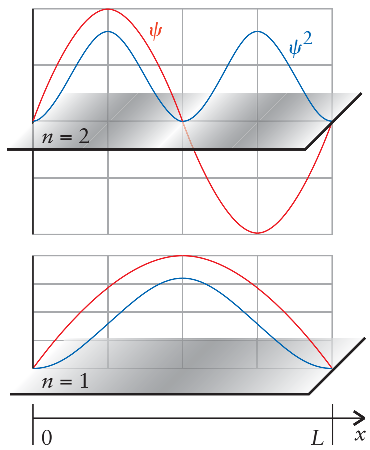


FIGURE 1.27 The two lowest energy wavefunctions (ψ, orange) for a particle in a box and the corresponding probability densities (ψ^2, blue). The probability densities are also shown by the density of shading of the bands beneath each wavefunction.

be larger than the distance between the two walls. Because the position is not *completely* uncertain, the linear momentum must be uncertain, too, and so we cannot say that the particle is completely still. The particle must therefore have some kinetic energy. The zero-point energy is a purely quantum mechanical phenomenon and is very small for macroscopic systems. For example, a billiard ball on a pool table has a completely negligible zero-point energy of about 10^{-67} J.

Finally, the shapes of the wavefunctions of a particle in a box also reveal some interesting information. Let's look at the two lowest energy wavefunctions, corresponding to $n = 1$ and $n = 2$. Figure 1.27 shows, by the density of shading, the likelihood of finding a particle: we see that when a particle is described by the wavefunction ψ_1 (and has energy $h^2/8mL^2$), then it is most likely to be found in the center of the box. Conversely, if the particle is described by the wavefunction ψ_2 (and has energy $h^2/2mL^2$), then it is most likely to be found in regions between the center and the walls and is unlikely to be found in the middle of the box. Remember that the wavefunction itself does not have any direct physical significance: we have to take the square of ψ before we can interpret it in terms of the probability of finding a particle somewhere.

The probability density for a particle at a location is proportional to the square of the wavefunction at that point; the wavefunction is found by solving the Schrödinger equation for the particle. When the equation is solved subject to the appropriate boundary conditions, it is found that the particle can possess only certain discrete energies.

THE HYDROGEN ATOM

We are now ready to build a quantum mechanical model of a hydrogen atom. Our task is to combine our knowledge that an electron has wavelike properties and is described by a wavefunction with the nuclear model of the atom, and explain the ladder of energy levels suggested by spectroscopy.

1.8 The Principal Quantum Number

An electron in an atom is like a particle in a box, in the sense that it is confined within the atom by the pull of the nucleus. We can therefore expect the electron's wavefunctions to obey certain boundary conditions, like the constraints we encountered when fitting a wave between the walls of a container. As we saw for a particle in a box, these constraints result in the quantization of energy and the existence of discrete energy levels. Even at this early stage, we can expect the electron to be confined to certain energies, just as the spectroscopic observations require.

Thinking point: How many quantum numbers do you think will be needed to specify the wavefunction of an electron in a hydrogen atom?

To find the wavefunctions and energy levels of an electron in a hydrogen atom, we must solve the appropriate Schrödinger equation. To set up this equation, which resembles the equation in Eq. 9 but allows for motion in three dimensions, we use the expression for the potential energy of an electron of charge $-e$ at a distance r from a nucleus of charge $+e$. As we saw in Section A, this "Coulomb" potential energy is

$$V(r) = \frac{(-e)(+e)}{4\pi\varepsilon_0 r} = -\frac{e^2}{4\pi\varepsilon_0 r} \qquad (13)$$

Solving the Schrödinger equation for a particle with this potential energy is difficult, but Schrödinger himself achieved it in 1927. He found that the allowed energy levels for an electron in a hydrogen atom are

$$E_n = -\frac{h\mathcal{R}}{n^2} \qquad \mathcal{R} = \frac{m_e e^4}{8h^3\varepsilon_0^2} \qquad n = 1, 2, \ldots \qquad (14a)$$

These energy levels have exactly the form suggested spectroscopically, but now we also have an expression for $\mathcal{R}$ in terms of more fundamental constants. When the

fundamental constants are inserted into the expression for $\mathcal{R}$, the value obtained is 3.29×10^{15} Hz, the same as the experimental value of the Rydberg constant. This agreement is a triumph for Schrödinger's theory and for quantum mechanics; it is easy to understand the thrill that Schrödinger must have felt when he arrived at this result. A very similar expression applies to other one-electron ions, such as He^+ and even C^{5+}, with atomic number Z:

$$E_n = -\frac{Z^2 h\mathcal{R}}{n^2} \qquad n = 1, 2, \ldots \qquad \textbf{(14b)*}$$

What does this equation tell us? All the energies are negative, meaning that the electron has a lower energy in the atom than when it is far from the nucleus. Because Z appears in the numerator, we see that the greater the value of the nuclear charge the more tightly the electron is bound to a nucleus. That n appears in the denominator shows that as n increases, the energy becomes less negative.

The dependence of the energy on Z^2 rather than on Z itself arises from two factors: first, a nucleus of atomic number Z and charge Ze gives rise to a field that is Z times stronger than that of a single proton; second, the electron is drawn in by the higher charge and is Z times closer to the nucleus than it is in hydrogen.

Figure 1.28 shows the energy levels calculated from Eq. 14a. We see that they come closer together as n increases. Each level is labeled by the integer n, which is called the **principal quantum number,** from $n = 1$ for the first (lowest, most negative) level, $n = 2$ for the second, continuing to infinity. The lowest energy possible for an electron in a hydrogen atom, $-h\mathcal{R}$, is obtained when $n = 1$. This lowest energy state is called the **ground state** of the atom. A hydrogen atom is normally found in its ground state, with its electron in the level with $n = 1$. When the bound electron is excited by absorbing a photon, its energy climbs up the ladder of levels as n increases. It reaches the top of the ladder, corresponding to $E = 0$ and freedom, when n reaches infinity. At that point, the electron has left the atom. This process is called **ionization.** The difference in energy between the ground state and the ionized state is the energy required to remove an electron from the neutral atom in its ground state. The "ionization energy" itself, which we discuss in more detail in Section 1.17, is the minimum energy needed to achieve ionization, with the electron removed from the orbital with $n = 1$ to a final state in which it has zero energy: in this final state it is free of the nucleus and has zero kinetic energy.

The ionization energy is discussed further in Section 1.17.

The energy levels of a hydrogen atom are defined by the principal quantum number, n = 1, 2, . . . , and form a converging series, as shown in Fig. 1.28.

1.9 Atomic Orbitals

We have found the energies and now need to find the corresponding wavefunctions. Knowing the form of the wavefunctions allows us to go beyond the information provided by spectroscopy and determine not only the allowed energies of the electron in a hydrogen atom but also how the electron is distributed around the nucleus.

The wavefunctions of electrons in atoms are called **atomic orbitals.** The name was chosen to suggest something less definite than an "orbit" of an electron around a nucleus and to take into account the wave nature of the electron. The mathematical expressions for atomic orbitals—which are obtained as solutions of the Schrödinger equation—are more complicated than the sine functions for the particle in a box, but their essential features are straightforward. Moreover, we must never lose sight of their interpretation, that the *square* of a wavefunction tells us the probability density of an electron at each point. To visualize this probability density, imagine a cloud centered on the nucleus. The density of the cloud at each point represents the probability of finding an electron there. Denser regions of the cloud therefore represent locations where the electron is more likely to be found.

To interpret the information in each atomic orbital, we need a way to identify the location of each point around a nucleus. It is most convenient to describe these

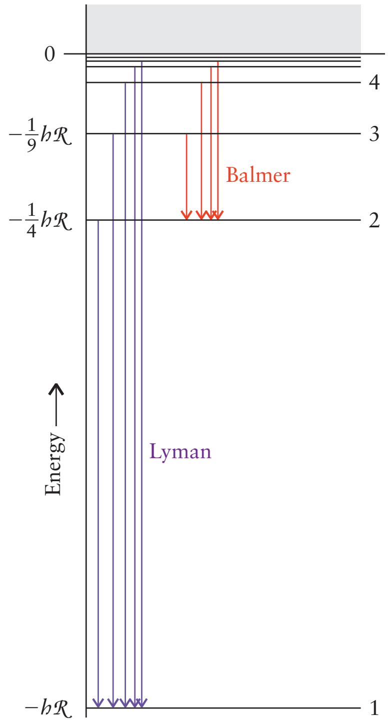

FIGURE 1.28 The permitted energy levels of a hydrogen atom as calculated from Eq. 14. The levels are labeled with the quantum number n, which ranges from 1 (for the lowest state) to infinity (for the separated proton and electron).

locations in terms of **spherical polar coordinates,** in which each point is labeled with three coordinates:

- r, the distance from the center of the atom;
- θ (theta), the angle from the positive z-axis (the "north pole"), which can be thought of as playing the role of the geographical "latitude"; and
- ϕ (phi), the angle about the z-axis, the geographical "longitude."

Geographical latitudes are measured from the equator, not the north pole. The technical name for θ is the colatitude.

These coordinates are shown in Fig. 1.29. Each wavefunction, which in general varies from point to point, can be written as a function of the coordinates, $\psi(r, \theta, \phi)$. It turns out, however, that all the wavefunctions can be written as the product of a function that depends only on r and another function that depends only on the angles θ and ϕ. That is,

$$\psi(r, \theta, \phi) = R(r)Y(\theta, \phi) \qquad \textbf{(15)*}$$

The function $R(r)$ is called the **radial wavefunction;** it tells us how the wavefunction varies as we move away from the nucleus in any direction. The function $Y(\theta, \phi)$ is called the **angular wavefunction;** it tells us how the wavefunction varies as the angles θ and ϕ change. For example, the wavefunction corresponding to the ground state of the hydrogen atom ($n = 1$) is

$$\psi(r, \theta, \phi) = \overbrace{\frac{2e^{-r/a_0}}{a_0^{3/2}}}^{R(r)} \times \overbrace{\frac{1}{2\pi^{1/2}}}^{Y(\theta,\phi)} = \frac{e^{-r/a_0}}{(\pi a_0^3)^{1/2}} \qquad a_0 = \frac{4\pi\varepsilon_0\hbar^2}{m_e e^2}$$

The quantity a_0 is called the **Bohr radius;** when the values of the fundamental constants are inserted, we find $a_0 = 52.9$ pm.

In an early model of the hydrogen atom proposed by Niels Bohr, the electron traveled in a circular orbit of radius a_0 around the nucleus. The uncertainty principle rules out this model.

What does this equation tell us? For this wavefunction, the angular wavefunction Y is a constant, $1/2\pi^{1/2}$, independent of the angles, which means that the wavefunction is the same in all directions. The radial wavefunction $R(r)$ decays exponentially toward zero as r increases, which means that the probability density is highest close to the nucleus ($e^0 = 1$). The Bohr radius tells us how sharply the wavefunction falls away with distance: when $r = a_0$, ψ has fallen to 1/e (37%) of its value at the nucleus.

All the higher energy levels have more than one wavefunction for each energy level. One of the wavefunctions for the next higher energy level, with $n = 2$ and $E_2 = -\frac{1}{4}h\mathcal{R}$, is

$$\psi(r, \theta, \phi) = \overbrace{\frac{1}{2\sqrt{6}}\frac{1}{a_0^{5/2}}re^{-r/2a_0}}^{R(r)} \times \overbrace{\left(\frac{3}{4\pi}\right)^{1/2}\sin\theta\cos\phi}^{Y(\theta,\phi)}$$
$$= \frac{1}{4}\left(\frac{1}{2\pi a_0^5}\right)^{1/2} re^{-r/2a_0}\sin\theta\cos\phi$$

What does this equation tell us? This wavefunction also falls exponentially toward zero as r increases. Notice, though, that the exponential function is multiplied by the factor r, so ψ is zero at the nucleus (at $r = 0$) as well as far away from it. We discuss the angular dependence shortly.

The expressions for a number of other atomic orbitals are shown in Table 1.2a (for R) and Table 1.2b (for Y). To understand these tables, we need to know, as we describe in more detail immediately below, that each wavefunction is labeled by *three* quantum numbers: n is related to the *size* and *energy* of the orbital, l is related to its *shape*, and m_l is related to its *orientation* in space.

When the Schrödinger equation is solved in detail, it turns out that *three* quantum numbers are needed to label each wavefunction (because the atom is three-dimensional). The three quantum numbers are designated n, l, and m_l. More surprisingly, it also turns out that, for a hydrogen atom, wavefunctions with the same value of n all have the same energy regardless of the values of the other two quantum numbers.

We have already encountered n, the principal quantum number, which specifies the energy of the orbital in a one-electron atom (through Eq. 14). In a one-electron

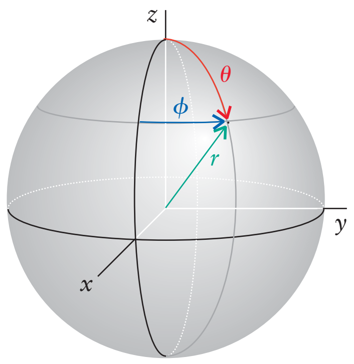

FIGURE 1.29 The spherical polar coordinates: r is the radius, which gives the distance from the center, θ is the colatitude, which gives the angle from the z-axis, and ϕ, the "longitude," is the azimuth, which gives the angle from the x-axis.

TABLE 1.2 Hydrogenlike Wavefunctions* (Atomic Orbitals), $\psi = RY$

(a) Radial wavefunctions			(b) Angular wavefunctions		
n	l	$R_{nl}(r)$	l	"m_l"†	$Y_{l,m_l}(\theta,\phi)$
1	0	$2\left(\frac{Z}{a_0}\right)^{3/2} e^{-Zr/a_0}$	0	0	$\left(\frac{1}{4\pi}\right)^{1/2}$
2	0	$\frac{1}{2\sqrt{2}}\left(\frac{Z}{a_0}\right)^{3/2}\left(2-\frac{Zr}{a_0}\right)e^{-Zr/2a_0}$	1	x	$\left(\frac{3}{4\pi}\right)^{1/2}\sin\theta\cos\phi$
	1	$\frac{1}{2\sqrt{6}}\left(\frac{Z}{a_0}\right)^{3/2}\left(\frac{Zr}{a_0}\right)e^{-Zr/2a_0}$		y	$\left(\frac{3}{4\pi}\right)^{1/2}\sin\theta\sin\phi$
3	0	$\frac{2}{9\sqrt{3}}\left(\frac{Z}{a_0}\right)^{3/2}\left(3-\frac{2Zr}{a_0}+\frac{2Z^2r^2}{9a_0^2}\right)e^{-Zr/3a_0}$		z	$\left(\frac{3}{4\pi}\right)^{1/2}\cos\theta$
	1	$\frac{2}{9\sqrt{6}}\left(\frac{Z}{a_0}\right)^{3/2}\left(2-\frac{Zr}{3a_0}\right)e^{-Zr/3a_0}$	2	xy	$\left(\frac{15}{16\pi}\right)^{1/2}\sin^2\theta\sin 2\phi$
	2	$\frac{4}{81\sqrt{30}}\left(\frac{Z}{a_0}\right)^{3/2}\left(\frac{Zr}{a_0}\right)^2 e^{-Zr/3a_0}$		yz	$\left(\frac{15}{4\pi}\right)^{1/2}\cos\theta\sin\theta\sin\phi$
				zx	$\left(\frac{15}{4\pi}\right)^{1/2}\cos\theta\sin\theta\cos\phi$
				x^2-y^2	$\left(\frac{15}{16\pi}\right)^{1/2}\sin^2\theta\cos 2\phi$
				z^2	$\left(\frac{5}{16\pi}\right)^{1/2}(3\cos^2\theta-1)$

*Note: In each case, $a_0 = 4\pi\varepsilon_0\hbar^2/m_e e^2$, or close to 52.9 pm; for hydrogen itself, $Z = 1$.

†In all cases except $m_l = 0$, the orbitals are sums and differences of orbitals with specific values of m_l.

atom, all atomic orbitals with the same value of the principal quantum number n have the same energy and are said to belong to the same **shell** of the atom. The name "shell" reflects the fact that as n increases, the region of greatest probability density is like a nearly hollow shell of increasing radius. The higher the number of the shell, the further away from the nucleus are the electrons in that shell.

The second quantum number needed to specify an orbital is l, the **orbital angular momentum quantum number.** This quantum number can take the values

$$l = 0, 1, 2, \ldots, n-1$$

There are n different values of l for a given value of n. For instance, when $n = 3$, l can have any of the three values 0, 1, and 2. The orbitals of a shell with principal quantum number n therefore fall into n **subshells,** groups of orbitals that have the same value of l. There is only one subshell in the $n = 1$ level ($l = 0$), two in the $n = 2$ level ($l = 0$ and 1), three in the $n = 3$ level ($l = 0$, 1, and 2), and so on. All orbitals with $l = 0$ are called **s-orbitals,** those with $l = 1$ are called **p-orbitals,** those with $l = 2$ are called **d-orbitals,** and those with $l = 3$ are called **f-orbitals:**

Value of l	0	1	2	3
Orbital type	s	p	d	f

The labels come from the fact that spectroscopic lines were once classified as sharp, principal, diffuse, and fundamental.

Although higher values of l (corresponding to g-, h-, . . . orbitals) are possible, the lower values of l (0, 1, 2, and 3) are the only ones that chemists need in practice.

Just as the value of n can be used to calculate the energy of an electron, the value of l can be used to calculate another physical property. As its name suggests, l tells us the **orbital angular momentum** of the electron, a measure of the rate at which (in classical terms) the electron "circulates" round the nucleus:

$$\text{Orbital angular momentum} = \{l(l+1)\}^{1/2}\hbar \qquad \textbf{(16)*}$$

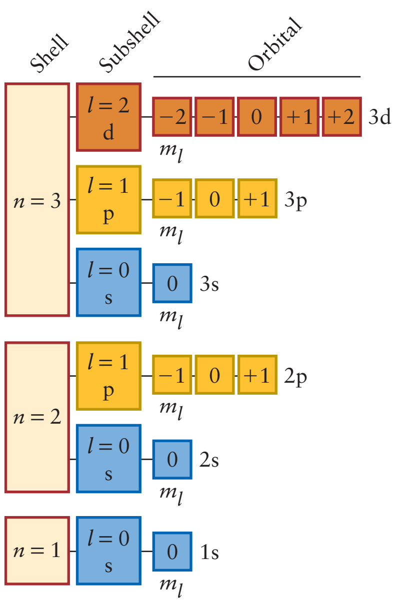

FIGURE 1.30 A summary of the arrangement of shells, subshells, and orbitals in an atom and the corresponding quantum numbers. Note that the quantum number m_l is an alternative label for the individual orbitals: in chemistry, it is more common to use *x*, *y*, and *z* instead, as shown in Figs. 1.36 through 1.38.

An electron in an s-orbital (an "s-electron"), for which $l = 0$, has zero orbital angular momentum. That means that we should imagine it not as circulating around the nucleus but simply as distributed evenly around it. An electron in a p-orbital ($l = 1$) has nonzero orbital angular momentum (of magnitude $2^{1/2}\hbar$; so it can be thought of as circulating around the nucleus. An electron in a d-orbital ($l = 2$) has a higher orbital angular momentum ($6^{1/2}\hbar$), one in an f-orbital ($l = 3$) has an even higher angular momentum ($12^{1/2}\hbar$), and so on.

An important feature of the hydrogen atom is that, as we have remarked, all the orbitals of a given shell have the same energy, regardless of the value of their orbital angular momentum (we see from Eq.14 that l does not appear in the expression for the energy). We say that the orbitals of a shell in a hydrogen atom are **degenerate,** which means that they all have the same energy. This degeneracy is true only of the hydrogen atom and one-electron ions (such as He^+ and C^{5+}).

The third quantum number required to specify an orbital is m_l, the **magnetic quantum number,** which distinguishes the individual orbitals within a subshell. This quantum number can take the values

$$m_l = l, l - 1, \ldots, -l$$

There are $2l + 1$ different values of m_l for a given value of l and therefore $2l + 1$ orbitals in a subshell of quantum number l. For example, when $l = 1$, $m_l = +1, 0, -1$; so there are three p-orbitals in a given shell. Alternatively, we can say that a subshell with $l = 1$ consists of three orbitals.

A note on good practice: Always write the + sign explicitly for positive values of m_l.

The magnetic quantum number tells us the orientation of the orbital motion of the electron. Specifically, it tells us that the orbital angular momentum around an arbitrary axis is equal to $m_l\hbar$, the rest of the orbital motion (to make up the full amount of $\{l(l+1)\}^{1/2}\hbar$) being around other axes. For instance, if $m_l = +1$, then the orbital angular momentum of the electron around the arbitrary axis is $+\hbar$, whereas, if $m_l = -1$, then the orbital angular momentum of the electron around the same arbitrary axis is $-\hbar$. The difference in sign simply means that the direction of motion is opposite, the electron in one state circulating clockwise and an electron in the other state circulating counterclockwise. If $m_l = 0$, then the electron is not circulating around the selected axis, but rather is evenly distributed around it.

The hierarchy of shells, subshells, and orbitals is summarized in Fig. 1.30 and Table 1.3. Each possible combination of the three quantum numbers specifies an individual orbital. For example, an electron in the ground state of a hydrogen atom has the specification $n = 1$, $l = 0$, $m_l = 0$. Because $l = 0$, the ground-state wavefunction is an example of an s-orbital and is denoted 1s. Each shell has one s-orbital, and the s-orbital in the shell with quantum number n is called an ***n*s-orbital.**

All s-orbitals are independent of the angles θ and ϕ, so we say that they are **spherically symmetrical** (Fig. 1.31). The probability density of an electron at the point (r, θ, ϕ) when it is in a 1s-orbital is given by the square of the corresponding wavefunction (which was given earlier, but can also be constructed as RY from the entries for R and Y in Tables 1.2a and 1.2b):

$$\psi^2(r, \theta, \phi) = \frac{e^{-2r/a_0}}{\pi a_0^3} \tag{17}$$

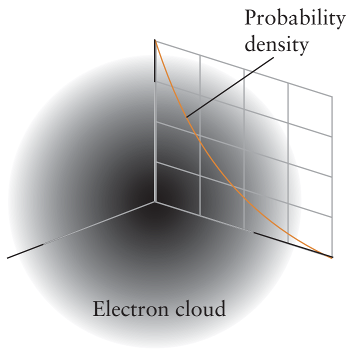

FIGURE 1.31 The three-dimensional electron cloud corresponding to an electron in a 1*s*-orbital of hydrogen. The density of shading represents the probability of finding the electron at any point. The superimposed graph shows how the probability varies with the distance of the point from the nucleus along any radius.

TABLE 1.3 Quantum Numbers for Electrons in Atoms

Name	Symbol	Values	Specifies	Indicates
principal	n	$1, 2, \ldots$	shell	size
orbital angular momentum*	l	$0, 1, \ldots, n-1$	subshell: $l = 0, 1, 2, 3, 4, \ldots$ s, p, d, f, g, . . .	shape
magnetic	m_l	$l, l-1, \ldots, -l$	orbitals of subshell	orientation
spin magnetic	m_s	$+\frac{1}{2}, -\frac{1}{2}$	spin state	spin direction

*Also called the azimuthal quantum number.

In this case, the probability density is independent of angle, and for simplicity is commonly written simply $\psi^2(r)$. In principle, the cloud representing the probability density never thins to exactly zero, no matter how large the value of r. So we could think of an atom as being bigger than the Earth! However, there is virtually no chance of finding an electron farther from the nucleus than about 250 pm, and so atoms are in fact very small. As we can see from the high density of the cloud at the nucleus, an electron in an s-orbital has a nonzero probability of being found right at the nucleus: because $l = 0$, there is no orbital angular momentum to fling the electron away from the nucleus.

Thinking point: How do you think a 1s-orbital in He^+ will differ from the same orbital in H?

EXAMPLE 1.9 Calculating the probability of finding an electron at a certain location

Suppose the electron is in a 1s-orbital of a hydrogen atom. What is the probability of finding the electron in a small region a distance a_0 from the nucleus relative to the probability of finding it in the same small region located right at the nucleus?

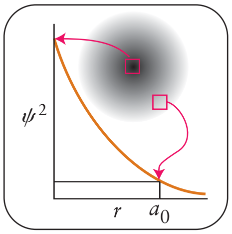
Anticipate We should expect a lower probability because the wavefunction decays exponentially with distance from the nucleus.

PLAN The probability density is independent of angle when $l = 0$. We need to compare the probability densities at the two locations. To do that, we take the ratio of the squares of the wavefunction at the two locations.

SOLVE

The ratio of the probability that the electron is found at the nucleus or at $r = a_0$ is:

$$\frac{\text{Probability density at } r = a_0}{\text{Probability density at } r = 0} = \frac{\psi^2(a_0)}{\psi^2(0)}$$



From $\psi^2(r, \theta, \phi) = (1/\pi a_0^3)e^{-2r/a_0}$,

$$\frac{\psi^2(a_0)}{\psi^2(0)} = \frac{(1/\pi a_0^3)\overbrace{e^{-2a_0/a_0}}^{e^{-2}}}{(1/\pi a_0^3)\underbrace{e^0}_{1}} = e^{-2} = 0.14$$

Evaluate As expected, the probability of finding the electron in a small region at a distance a_0 from the nucleus is lower than at the nucleus itself: the probability is only 14% of that of finding the electron in a region of the same volume located at the nucleus.

Self-Test 1.9A Calculate the same ratio but for the more distant point at $r = 2a_0$, twice as far from the nucleus.

[***Answer:*** 0.018]

Self-Test 1.9B Calculate the same ratio but for a point at $3a_0$ from the nucleus.

The value of ψ^2 lets us predict the probability of finding the electron in a given region at a distance r from the nucleus; but suppose we want to know the total probability of finding the electron at a distance r regardless of the direction. To calculate this probability we use the **radial distribution function,** P. Specifically, the probability that the electron will be found anywhere in a thin shell of radius r and thickness δr is given by $P(r)\delta r$ (Fig. 1.32), with

$$P(r) = r^2R^2(r) \qquad \textbf{(18a)}$$

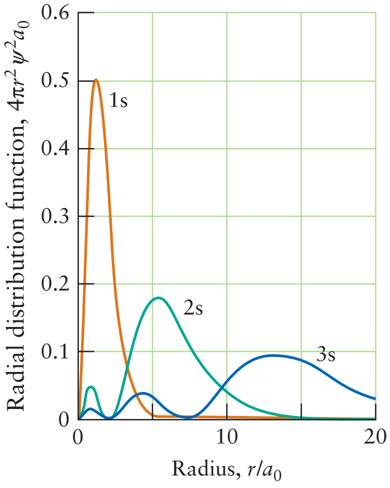


FIGURE 1.32 The radial distribution function tells us the probability density for finding an electron at a given radius summed over all directions. The graph shows the radial distribution function for the 1s-, 2s-, and 3s-orbitals in hydrogen. Note how the most probable radius (corresponding to the greatest maximum) increases as n increases.

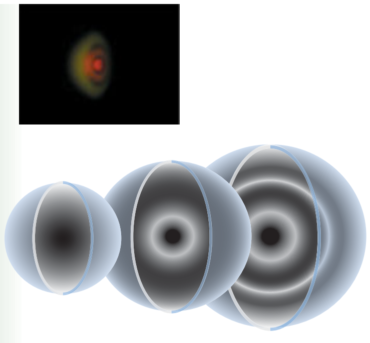

FIGURE 1.33 The three s-orbitals of lowest energy. The simplest way of drawing an atomic orbital is as a boundary surface, a surface within which there is a high probability (typically 90%) of finding the electron. We shall use blue to denote s-orbitals, but that color is only an aid to their identification. The shading within the boundary surfaces is an approximate indication of the electron density at each point. The darker the shading, the higher the probability of finding the electron at that distance from the nucleus.

Animation 1.33

For s-orbitals, $\psi = RY = R/2\pi^{1/2}$, so $R^2 = 4\pi\psi^2$, and this expression is then the same as

$$P(r) = 4\pi r^2\psi^2(r) \qquad \textbf{(18b)*}$$

and this expression is the form that you will normally see used; however, it applies only to s-orbitals, whereas Eq. 18a applies to any kind of orbital.

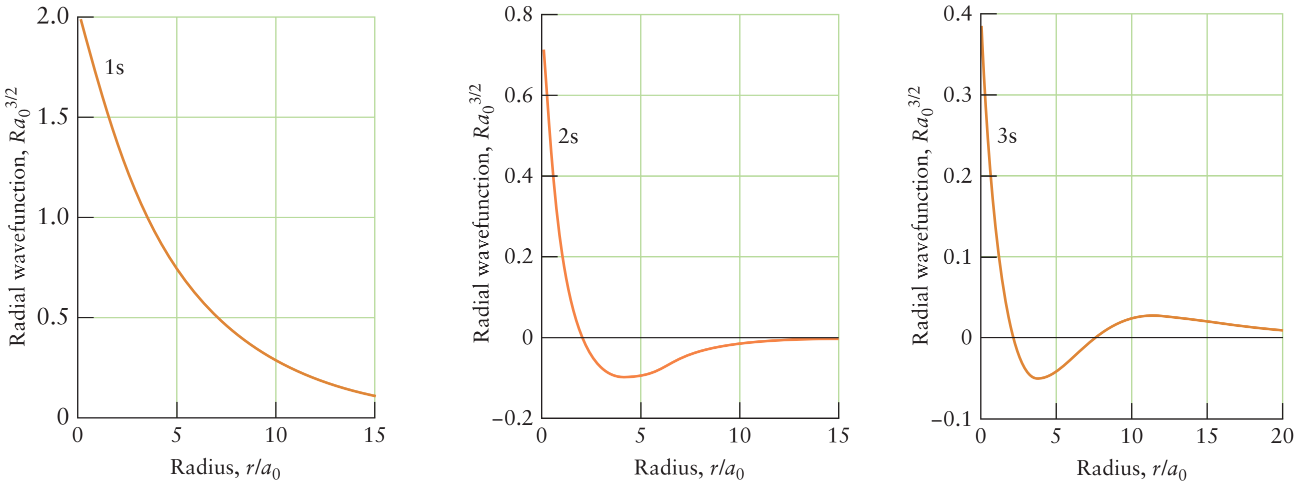
It is important to distinguish the radial distribution function from the wavefunction and its square, the probability density:

- The wavefunction itself tells us, through $\psi^2(r, \theta, \phi)\delta V$, the probability of finding the electron in the small volume δV at a particular location specified by r, θ, and ϕ.
- The radial distribution function tells us, through $P(r)\delta r$, the probability of finding the electron in the range of radii δr, at a particular value of the radius, summed over all values of θ and ϕ.

The radial distribution function for the population of the Earth, for instance, is zero up to about 6400 km from the center of the Earth, rises sharply, and then falls back to almost zero (the "almost" takes into account the small number of people who are on mountains or flying in airplanes).

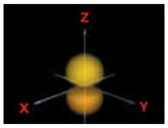
Note that for *all* orbitals, not just s-orbitals, P is zero at the nucleus, simply because the region in which we are looking for the electron has shrunk to zero size. (The probability density for an s-orbital is nonzero at the nucleus, but here we are multiplying it by a volume, $4\pi r^2\delta r$, that becomes zero at the nucleus, at $r = 0$.) As r increases, the value of $4\pi r^2$ increases (the shell is getting bigger), but, for a 1s-orbital, the square of the wavefunction, ψ^2, falls toward zero as r increases; as a result, the product of $4\pi r^2$ and ψ^2 starts off at zero, goes through a maximum, and then declines to zero. The value of P is a maximum at a_0, the Bohr radius. Therefore, the Bohr radius corresponds to the radius at which an electron in a 1s-orbital is most likely to be found.

Instead of drawing the s-orbital as a cloud, chemists usually draw its **boundary surface,** a smooth surface that encloses most of the cloud. However, although the boundary surface is easier to draw, it does not give the best picture of an atom; an atom has fuzzy edges and is not as smooth as the boundary surface might suggest. Despite this limitation, the boundary surface is useful, because an electron is likely to be found only inside the boundary surface of the orbital. An s-orbital has a spherical boundary surface (Fig. 1.33), because the electron cloud is spherical. s-Orbitals with higher energies have spherical boundary surfaces of greater diameter. They also have a more complicated radial variation, with nodes at locations that can be found by examining the wavefunctions (Fig. 1.34).



Living Graph 1.34

FIGURE 1.34 The radial wavefunctions of the first three s-orbitals of a hydrogen atom. Note that the number of radial nodes increases (as $n - 1$), as does the average distance of the electron from the nucleus (compare with Fig. 1.32). Because the probability density is given by ψ^2, all s-orbitals correspond to a nonzero probability density at the nucleus.



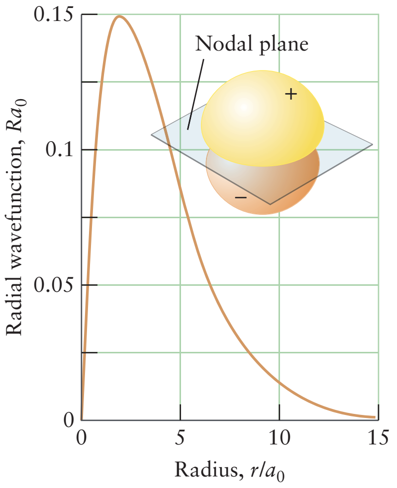


FIGURE 1.35 The boundary surface and the radial variation of a 2p-orbital along the (vertical) *z*-axis. All p-orbitals have boundary surfaces with similar shapes, including one nodal plane. Note that the orbital has opposite signs (as depicted by the depth of color) on each side of the nodal plane.

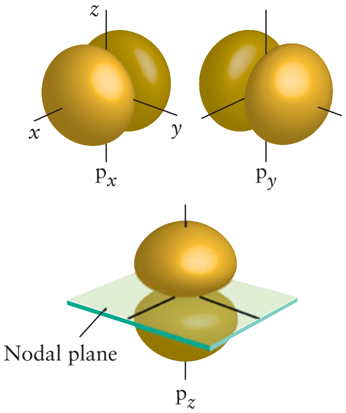

FIGURE 1.36 There are three p-orbitals of a given energy, and they lie along three perpendicular axes. We shall use yellow to indicate p-orbitals: dark and light shades denote different signs of the wavefunction.

Animation 1.36

The boundary surface of a p-orbital has two lobes (Fig. 1.35). These lobes are marked + and − to signify that the wavefunction has different signs in the two regions. For instance, the 2p-orbital discussed earlier is proportional to sin θ cos ϕ, and as ϕ increases from 0 to 2π as we travel around the "equator" of the atom, cos ϕ changes from +1 through 0 (at $\phi = \pi/2$) to −1 (at π) and then through zero and back to +1 again. Thus, in one hemisphere the wavefunction is positive and in the other it is negative, as depicted on the boundary surface in Fig. 1.35. The two lobes of a p-orbital are separated by a planar region called a **nodal plane,** which cuts through the nucleus and on which $\psi = 0$. A **p-electron,** an electron in a p-orbital, will never be found on the nodal plane. Nor will it be found at the nucleus on account of the factor r in the wavefunction. This difference from s-orbitals stems from the fact that an electron in a p-orbital has nonzero orbital angular momentum that flings it away from the nucleus.

There are three p-orbitals in each subshell, corresponding to the quantum numbers $m_l = +1, 0, -1$. However, chemists commonly refer to the orbitals according to the axes along which the lobes lie; hence, we refer to p_x, p_y, and p_z orbitals (Fig. 1.36).

There is no direct relation between the values of m_l and the *x*, *y*, *z* designation of the orbitals: the orbitals labeled with the axes are combinations of the orbitals labeled with the quantum number m_l.

A subshell with $l = 2$ consists of five d-orbitals. Each d-orbital has four lobes, except for the orbital designated d_{z^2}, which has a more complicated shape (Fig. 1.37). A subshell with $l = 3$ consists of seven f-orbitals with even more complicated shapes (Fig. 1.38).

The total number of orbitals in a shell with principal quantum number n is n^2. To confirm this rule, we need to recall that l has n integer values from 0 to $n - 1$ and that the number of orbitals in a subshell for a given value of l is $2l + 1$. For instance, for $n = 4$, there are four subshells with $l = 0, 1, 2,$ and 3, consisting of one s-orbital, three p-orbitals, five d-orbitals, and seven f-orbitals, respectively. There are therefore $1 + 3 + 5 + 7 = 16$, or 4^2, orbitals in the shell with $n = 4$ (Fig. 1.39).

The location of an electron in an atom is described by a wavefunction known as an atomic orbital; atomic orbitals are designated by the quantum numbers n, l, and m_l and fall into shells and subshells as summarized in Fig. 1.30.

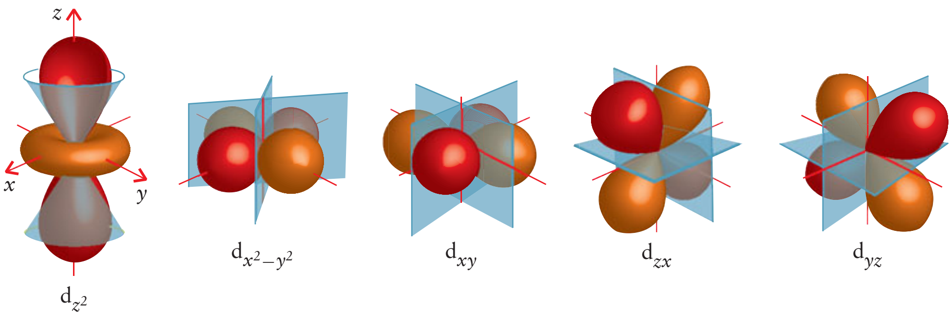

FIGURE 1.37 The boundary surface of a d-orbital is more complicated than that of an s- or a p-orbital. There are, in fact, five d-orbitals of a given energy; four of them have four lobes, one is slightly different. In each case, an electron that occupies a d-orbital will not be found at the nucleus. We shall use orange to indicate d-orbitals: dark and light shades denote different signs of the wavefunction.

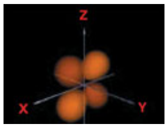

Animation 1.37

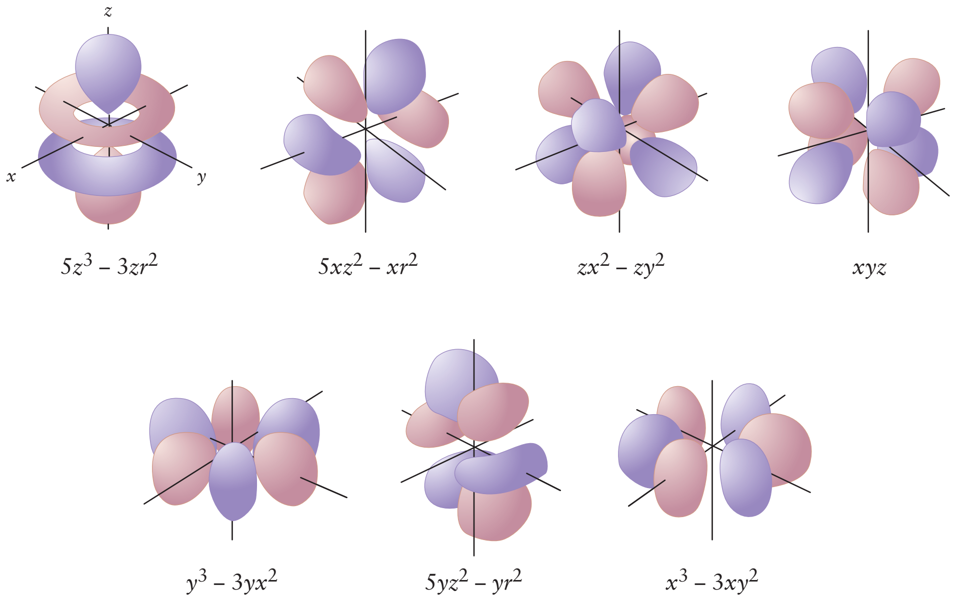

FIGURE 1.38 The seven f-orbitals (l = 3) of a shell have a very complex appearance. Their detailed form will not be used again in this text. However, their existence is important for understanding the periodic table, the presence of the lanthanoids and actinoids, and the properties of the later d-block elements. A darker color denotes a positive lobe, a lighter color a negative lobe.

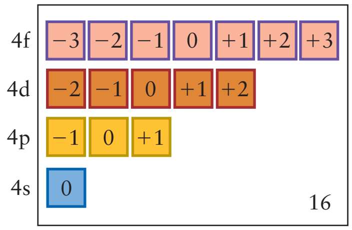

FIGURE 1.39 There are 16 orbitals in the shell with n = 4, each of which can hold two electrons (see Section 1.13), for a total of 32 electrons.

1.10 Electron Spin

Schrödinger's calculation of the energies of the hydrogen orbitals was a milestone in the development of modern atomic theory. Yet the observed spectral lines did not have exactly the frequencies he predicted. In 1925 (before Schrödinger's work but after Bohr had developed an earlier model of the atom), two Dutch–American physicists, Samuel Goudsmit and George Uhlenbeck, proposed an explanation for the tiny deviations that had been observed. They suggested that an electron behaves in some respects like a spinning sphere, something like a planet rotating on its axis. This property is called **spin.** Schrödinger's theory did not account for spin, but it emerged naturally when the British physicist Paul Dirac found a way (in 1928) to combine Einstein's theory of relativity with Schrödinger's approach.

According to quantum mechanics, an electron has two spin states, represented by the arrows ↑ (up) and ↓ (down) or the Greek letters α (alpha) and β (beta). We can think of an electron as being able to spin counterclockwise at a certain rate (the ↑ state) or clockwise at exactly the same rate (the ↓ state). These two spin states are distinguished by a fourth quantum number, the **spin magnetic quantum number,** m_s. This quantum number can have only two values: $+\frac{1}{2}$ indicates an ↑ electron and $-\frac{1}{2}$ indicates a ↓ electron (Fig. 1.40). Box 1.1 describes an experiment that confirmed these properties of electron spin.

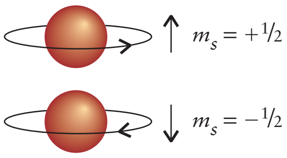

FIGURE 1.40 The two spin states of an electron can be represented as clockwise or counterclockwise rotation around an axis passing through the electron. The two states are identified by the quantum number m_s and depicted by the arrows shown on the right.

An electron has the property of spin; the spin is described by the quantum number m_s, which may have one of two values.

The magnitude of the spin angular momentum of an electron is described by the quantum number $s = \frac{1}{2}$ (the analog of l, but with an unchangeable value). Only the orientation of its spin is variable and specified by the quantum number m_s (the analog of m_l).

1.11 The Electronic Structure of Hydrogen

Let's review what we now know about the hydrogen atom by imagining first its ground state and then what happens to its electron as the atom acquires energy. Initially, the electron is in the lowest energy level, the ground state of the atom, with $n = 1$. The only orbital with this energy is the 1s-orbital; we say that the electron **occupies** a 1s-orbital or that it is a "1s-electron." The electron in the ground state of a hydrogen atom is described by the following values of the four quantum numbers:

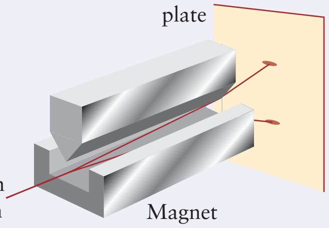
$$n = 1 \quad l = 0 \quad m_l = 0 \quad m_s = +\frac{1}{2} \text{ or } -\frac{1}{2}$$

The electron can have either spin state.

BOX 1.1 HOW DO WE KNOW . . . THAT AN ELECTRON HAS SPIN?

Electron spin was first detected experimentally by two German scientists, Otto Stern and Walter Gerlach, in 1920. Because a moving electric charge generates a magnetic field, they predicted that a spinning electron should behave like a tiny bar magnet.

In their experiment (see the illustration), Stern and Gerlach removed all the air from a container and set up a highly nonuniform magnetic field across it. They then shot a narrow stream of silver atoms through the container toward a detector. As explained in Section 1.13, a silver atom has one unpaired electron, with its remaining 46 electrons paired. The atom therefore behaves like a single unpaired electron riding on a heavy platform, the rest of the atom.



A schematic representation of the apparatus used by Stern and Gerlach. In the experiment, a stream of atoms splits into two as it passes between the poles of a magnet. The atoms in one stream have an odd ↑ electron, and those in the other an odd ↓ electron.

If a spinning electron behaved like a spinning ball, the axis of spin could point in any direction. The electron would behave like a bar magnet that could have any orientation relative to the applied magnetic field. In that case, a broad band of silver atoms should appear at the detector, because the field would push the silver atoms by different amounts according to the orientation of the spin. Indeed, that is exactly what Stern and Gerlach observed when they first carried out the experiment.

However, the first results were misleading. The experiment is difficult because the atoms collide with one another in the beam. An atom moving in one direction might easily be knocked by its neighbors into a different direction. When Stern and Gerlach repeated their experiment, they used a much less dense beam of atoms, thereby reducing the number of collisions between the atoms. They now saw only two narrow bands. One band consisted of atoms flying through the magnetic field with one orientation of their spin; the other band consisted of the atoms with opposite spin. The two narrow bands confirmed not only that an electron has spin but also that it can have only two orientations.

Electron spin is the basis of the experimental technique called *electron paramagnetic resonance* (EPR), which is used to study the structures and motions of molecules and ions that have unpaired electrons. This technique is based on detecting the energy needed to flip an electron between its two spin orientations. Like Stern and Gerlach's experiment, it works only with ions or molecules that have an unpaired electron.

When the atom acquires enough energy (by absorbing a photon of radiation, for instance) for its electron to reach the shell with $n = 2$, it can occupy any of the four orbitals in that shell. There are one 2s- and three 2p-orbitals in this shell; in hydrogen, they all have the same energy. When an electron is described by one of these wavefunctions, we say that it "occupies a 2s-orbital" or one of the 2p-orbitals or that it is "a 2s- or 2p-electron." The average distance of an electron from the nucleus when it occupies any of the orbitals in the shell with $n = 2$ is greater than when $n = 1$, and so we can think of the atom as swelling up as it is excited energetically. When the atom acquires even more energy, the electron moves into the shell with $n = 3$; the atom is now even larger. In this shell, the electron can occupy any of nine orbitals (one 3s-, three 3p-, and five 3d-orbitals). More energy moves the electron still farther from the nucleus to the $n = 4$ shell, where sixteen orbitals are available (one 4s-, three 4p-, five 4d-, and seven 4f-orbitals). Eventually, enough energy is absorbed so that the electron can escape the pull of the nucleus and leaves the atom.

Self-Test 1.10A The three quantum numbers for an electron in a hydrogen atom in a certain state are $n = 4$, $l = 2$, and $m_l = -1$. In what type of orbital is the electron located?

[***Answer:*** 4d]

Self-Test 1.10B The three quantum numbers for an electron in a hydrogen atom in a certain state are $n = 3$, $l = 1$, and $m_l = -1$. In what type of orbital is the electron located?

The state of an electron in a hydrogen atom is defined by the four quantum numbers n, l, m_l, and m_s; as the value of n increases, the size of the atom increases.

MANY-ELECTRON ATOMS

A many-electron atom is also called a *polyelectron atom.*

A neutral atom other than a hydrogen atom has more than one electron and is known as a **many-electron atom.** In the next three sections, we build on what we have learned about the hydrogen atom to see how the presence of more than one electron affects the energies of atomic orbitals. The resulting electronic structures are the key to the periodic properties of the elements and the abilities of atoms to form chemical bonds. This material therefore underlies almost every aspect of chemistry.

1.12 Orbital Energies

The electrons in a many-electron atom occupy orbitals like those of hydrogen. However, the energies of these orbitals are not the same as those for a hydrogen atom. The nucleus of a many-electron atom is more highly charged than the hydrogen nucleus, and the greater charge attracts electrons more strongly and hence lowers their energy. However, the electrons also repel one another; this repulsion opposes the nuclear attraction and raises the energies of the orbitals. In a helium atom, for instance, with two electrons, the charge of the nucleus is $+2e$ and the total potential energy is given by three terms:

$$V = \underbrace{-\frac{2e^2}{4\pi\varepsilon_0 r_1}}_{\text{Attraction of electron 1 to the nucleus}} \underbrace{-\frac{2e^2}{4\pi\varepsilon_0 r_2}}_{\text{Attraction of electron 2 to the nucleus}} + \underbrace{\frac{e^2}{4\pi\varepsilon_0 r_{12}}}_{\text{Repulsion between the two electrons}} \quad (19)$$

Along with code breakers, weather forecasters, and molecular biologists, chemists are now among the heaviest users of computers, which they use to calculate the detailed electronic structures of atoms and molecules (see Major Technique 5, following Chapter 14).

where r_1 is the distance of electron 1 from the nucleus, r_2 is the distance of electron 2 from the nucleus, and r_{12} is the distance between the two electrons. The two terms with negative signs (indicating that the potential energy *falls* as r_1 or r_2 decreases when either electron gets closer to the nucleus) represent the attractions between the nucleus and the two electrons. The term with a positive sign (indicating an *increase* in energy as r_{12} decreases) represents the repulsion between the two electrons. The Schrödinger equation based on this potential energy is impossibly difficult to solve exactly, but highly accurate numerical solutions can be obtained by using computers.

The hydrogen atom, with one electron, has no electron–electron repulsions and all the orbitals of a given shell are degenerate. For instance, the 2s-orbital and all three 2p-orbitals have the same energy. In many-electron atoms, however, the results of spectroscopic experiments and calculations show that electron–electron repulsions cause the energy of a 2p-orbital to be higher than that of a 2s-orbital. Similarly, in the $n = 3$ shell, the three 3p-orbitals lie higher than the 3s-orbital, and the five 3d-orbitals lie higher still (Fig. 1.41). How can we explain these energy differences?

As well as being attracted to the nucleus, each electron in a many-electron atom is repelled by the other electrons present. As a result, it is less tightly bound to the nucleus than it would be if those other electrons were absent. We say that each electron is **shielded** from the full attraction of the nucleus by the other electrons in the atom. The shielding effectively reduces the pull of the nucleus on an electron. The **effective nuclear charge,** $Z_{eff}e$, experienced by the electron is always less than the actual nuclear charge, Ze, because the electron–electron repulsions work against the pull of the nucleus. A *very* approximate form of the energy of an electron in a many-electron atom is a version of Eq. 14b in which the true atomic number is replaced by the effective atomic number:

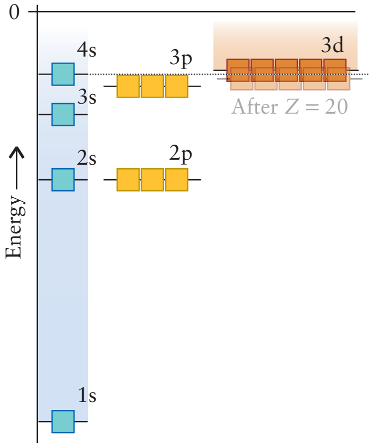


FIGURE 1.41 The relative energies of the shells, subshells, and orbitals in a many-electron atom. Each of the boxes can hold at most two electrons. Note the change in the order of energies of the 3d- and 4s-orbitals after $Z = 20$.

$$E_n = -\frac{Z_{eff}^2 h\mathcal{R}}{n^2} \quad (20)$$

Note that the other electrons do not "block" the influence of the nucleus; they simply provide additional repulsive coulombic interactions that partly counteract the pull of the nucleus. For example, the pull of the nucleus on an electron in the helium atom is less than its charge of $+2e$ would exert but greater than the net charge of $+e$ that we would expect if each electron balanced one positive charge exactly.

An s-electron of any shell can be found very close to the nucleus (remember that ψ^2 for an s-orbital is nonzero at the nucleus), and so we say that it can **penetrate** through the inner shells. A p-electron penetrates much less because its orbital angular momentum prevents it from approaching close to the nucleus (Fig. 1.42). We have seen that its wavefunction vanishes at the nucleus, and so there is zero probability density for finding a p-electron there. Because a p-electron penetrates less than an s-electron through the inner shells of the atom, it is more effectively shielded from the nucleus and hence experiences a smaller effective nuclear charge than an s-electron does. In other words, an s-electron is bound more tightly than a p-electron and has a slightly lower (more negative) energy. A d-electron is bound less tightly than a p-electron of the same shell because its orbital angular momentum is higher and it is therefore even less able to approach the nucleus closely. That is, d-electrons are higher in energy than p-electrons of the same shell, which are in turn higher in energy than s-electrons of that shell.

The effects of penetration and shielding can be large. A 4s-electron generally has a much lower energy than that of a 4p- or 4d-electron; it may even have lower energy than that of a 3d-electron of the same atom (see Fig. 1.41). The precise ordering of orbitals depends on the number of electrons in the atom, as we shall see in the next section.

In a many-electron atom, because of the effects of penetration and shielding, the order of energies of orbitals in a given shell is s < p < d < f.

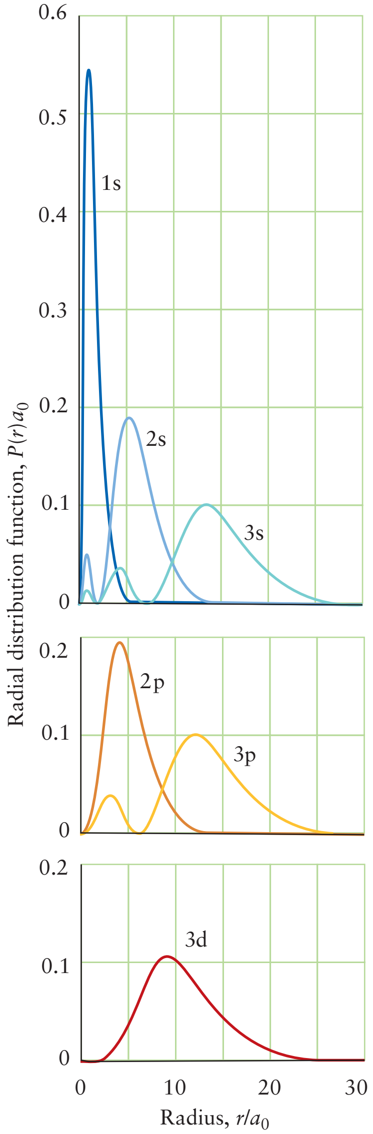

FIGURE 1.42 The radial distribution functions for s-, p-, and d-orbitals in the first three shells of a hydrogen atom. Note that the probability maxima for orbitals of the same shell are close to each other; however, note that an electron in an *n*s-orbital has a higher probability of being found close to the nucleus than does an electron in an *n*p-orbital or an *n*d-orbital.

1.13 The Building-Up Principle

The electronic structure of an atom determines its chemical properties, and so we need to be able to describe that structure. To do so, we write the **electron configuration** of the atom—a list of all its occupied orbitals, with the numbers of electrons that each one contains. In the ground state of a many-electron atom, the electrons occupy atomic orbitals in such a way that the total energy of the atom is a minimum. At first sight, we might expect an atom to have its lowest energy when all its electrons are in the lowest energy orbital (the 1s-orbital), but except for hydrogen and helium, which have no more than two electrons, that can never happen. In 1925, the Austrian scientist Wolfgang Pauli discovered a general and very fundamental rule about electrons and orbitals that is now known as the **Pauli exclusion principle:**

No more than two electrons may occupy any given orbital. When two electrons do occupy one orbital, their spins must be paired.

The spins of two electrons are said to be **paired** if one is ↑ and the other ↓ (Fig. 1.43). Paired spins are denoted ↑↓, and electrons with paired spins have spin magnetic quantum numbers of opposite sign. Because an atomic orbital is designated by three quantum numbers (n, l, and m_l) and the two spin states are specified by a fourth quantum number, m_s, another way of expressing the Pauli exclusion principle for atoms is

No two electrons in an atom can have the same set of four quantum numbers.

The exclusion principle implies that each atomic orbital can hold no more than two electrons.

The hydrogen atom in its ground state has one electron in the 1s-orbital. To show this structure, we place a single arrow in the 1s-orbital in a "box diagram," which shows each orbital as a box that can be occupied by no more than two electrons (see diagram **1**, which is a fragment of Fig. 1.41). We then report its **configuration** as $1s^1$ ("one s one"). In the ground state of a helium (He) atom ($Z = 2$), both electrons are in a 1s-orbital, which is reported as $1s^2$ ("one s two"). As we see in (**2**), the two electrons are paired. At this point, the 1s-orbital and the shell with $n = 1$ are fully occupied. We say that the helium atom has a **closed shell,** a shell containing the maximum number of electrons allowed by the exclusion principle.

1 H $1s^1$

2 He $1s^2$

A note on good practice: When a single electron occupies an orbital we write $1s^1$, for instance, not simply 1s.

Lithium ($Z = 3$) has three electrons. Two electrons occupy the 1s-orbital and complete the $n = 1$ shell. The third electron must occupy the next available orbital up the ladder

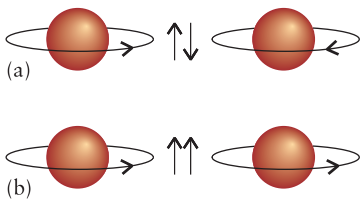

FIGURE 1.43 (a) Two electrons are said to be paired if they have opposite spins (one clockwise, the other counterclockwise). (b) Two electrons are classified as having parallel spins if their spins are in the same direction; in this case, both ↑.

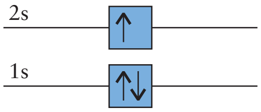
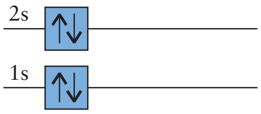
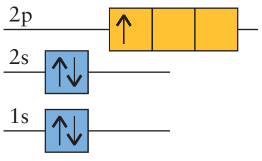
The outermost electrons are used in the formation of chemical bonds (Chapter 2), and the theory of bond formation is called *valence theory*; hence the name of these electrons.



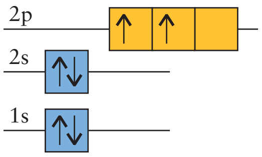
3 Li $1s^22s^1$, $[He]2s^1$



4 Be $1s^22s^2$, $[He]2s^2$



5 B $1s^22s^22p^1$, $[He]2s^22p^1$



6 C $1s^22s^22p^2$, $[He]2s^22p^2$

The building-up principle is also commonly called the *Aufbau principle*, from the German word for "building up."

of energy levels, the 2s-orbital (see Fig. 1.41). The ground state of a lithium (Li) atom is therefore $1s^22s^1$ (**3**). We can think of this atom as consisting of a **core,** the electrons in filled orbitals, and the valence electrons. In the case of lithium the core is made up of the inner heliumlike closed shell, the $1s^2$ core, which we denote [He]. The core is surrounded by an outer shell containing a higher-energy electron. Therefore, the electron configuration of lithium is $[He]2s^1$. Electrons in the outermost shell are called **valence electrons.** In general, only valence electrons can be lost in chemical reactions, because core electrons (those in lower-energy orbitals) are too tightly bound. Thus, lithium loses only one electron when it forms compounds; it forms Li^+ ions, rather than Li^{2+} or Li^{3+} ions.

The element with $Z = 4$ is beryllium (Be), with four electrons. The first three electrons form the configuration $1s^22s^1$, like lithium. The fourth electron pairs with the 2s-electron, giving the configuration $1s^22s^2$, or more simply $[He]2s^2$ (**4**). A beryllium atom therefore has a heliumlike core surrounded by a valence shell of two paired electrons. Like lithium—and for the same reason—a Be atom can lose only its valence electrons in chemical reactions. Thus, it loses both 2s-electrons to form a Be^{2+} ion.

Boron ($Z = 5$) has five electrons. Two enter the 1s-orbital and complete the $n = 1$ shell. Two enter the 2s-orbital. The fifth electron occupies an orbital of the next available subshell, which Fig. 1.41 shows is a 2p-orbital. This arrangement of electrons is reported as the configuration $1s^22s^22p^1$ or $[He]2s^22p^1$ (**5**), showing that boron has three valence electrons around a heliumlike core.

We need to make another decision at carbon ($Z = 6$): does the sixth electron join the one already in the 2p-orbital or does it enter a different 2p-orbital? (Remember, there are three p-orbitals in the subshell, all of the same energy.) To answer this question, we note that electrons are farther from each other and repel each other less when they occupy different p-orbitals than when they occupy the same orbital. So the sixth electron goes into an empty 2p-orbital, and the ground state of carbon is $1s^22s^22p_x^{\ 1}2p_y^{\ 1}$ (**6**). We write out the individual orbitals like this only when we need to emphasize that electrons occupy different orbitals within a subshell. In most cases, we can write the shorter form, $[He]2s^22p^2$. Note that in the orbital diagram we have drawn the two 2p-electrons with **parallel spins** (↑↑), indicating that they have the same spin magnetic quantum numbers. For reasons based in quantum mechanics, electrons with parallel spins tend to avoid each other. Therefore, this arrangement has slightly lower energy than that of a paired arrangement. However, it is allowed only when the electrons occupy different orbitals.

The procedure that we have been using is called the **building-up principle.** It can be summarized by two rules. To predict the ground-state configuration of a neutral atom of an element with atomic number Z with its Z electrons:

1. Add Z electrons, one after the other, to the orbitals in the order shown in Fig. 1.44 but with no more than two electrons in any one orbital.
2. If more than one orbital in a subshell is available, add electrons with parallel spins to different orbitals of that subshell rather than pairing two electrons in one of the orbitals.

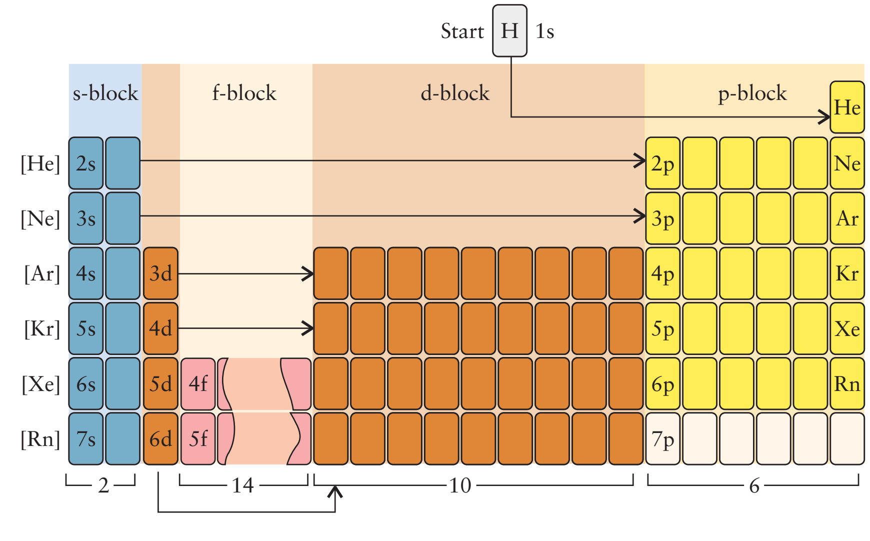


FIGURE 1.44 The names of the blocks of the periodic table indicate the last subshell being occupied according to the building-up principle. The numbers of electrons that each type of orbital can accommodate are shown by the numbers across the bottom of the table. The colors of the blocks match the colors that we are using for the corresponding orbitals.

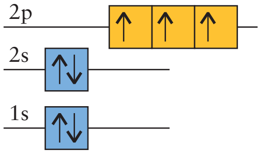
The first rule takes into account the Pauli exclusion principle. The second rule is called **Hund's rule,** for the German spectroscopist Friedrich Hund, who first proposed it. This procedure gives the configuration of the atom that corresponds to the lowest total energy, which maximizes the attraction of the electrons to the nucleus and minimizes their repulsion by one another. An atom with electrons in energy states higher than predicted by the building-up principle is said to be in an **excited state.** For example, the electron configuration $[He]2s^1 2p^3$ represents an excited state of a carbon atom. An excited state is unstable and emits a photon as the electron returns to an orbital that restores the atom to a lower energy.

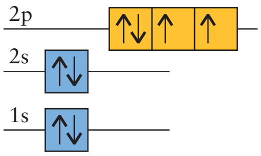
In general, we can think of an atom of any element as having a noble-gas core surrounded by a number of electrons in the valence shell, the outermost occupied shell. The **valence shell** is the occupied shell with the largest value of n.

The underlying organization of the periodic table described in Section B now begins to unfold. All the atoms of the main-group elements in a given period have a valence shell with the same principal quantum number, which is equal to the period number. For example, the valence shell of elements in Period 2 (from lithium to neon) is the shell with $n = 2$. Thus all the atoms in a given *period* have the same type of core and valence electrons with the same principal quantum number. For example, the atoms of Period 2 elements all have a heliumlike $1s^2$ core, and those of Period 3 elements have a neonlike $1s^2 2s^2 2p^6$ core, denoted [Ne]. All the atoms of a given *group* (in the main groups, particularly) have analogous valence electron configurations that differ only in the value of n. For instance, all the members of Group 1 have the valence configuration ns^1; and all the members of Group 14/IV have the valence configuration $ns^2 np^2$. These similar electron configurations give the elements in a group similar chemical properties, as illustrated in Section B.

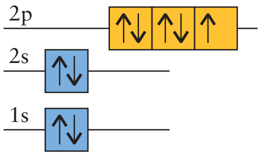
With these points in mind, let's continue building up the electron configurations across Period 2. Nitrogen has $Z = 7$ and one more electron than carbon, giving $[He]2s^2 2p^3$. Each p-electron occupies a different orbital, and the three have parallel spins (7). Oxygen has $Z = 8$ and one more electron than nitrogen; therefore, its configuration is $[He]2s^2 2p^4$ (8) and two of its 2p-electrons are paired. Similarly, fluorine, with $Z = 9$ and one more electron than oxygen, has the configuration $[He]2s^2 2p^5$ (9), with only one unpaired electron. Neon, with $Z = 10$, has one more electron than fluorine. This electron completes the 2p-subshell, giving $[He]2s^2 2p^6$ (10). According to Figs. 1.41 and 1.44, the next electron enters the 3s-orbital, the lowest-energy orbital of the next shell. The configuration of sodium is therefore $[He]2s^2 2p^6 3s^1$, or more briefly, $[Ne]3s^1$, where [Ne] denotes the neonlike core.



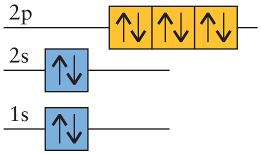
7 N $1s^2 2s^2 2p^3$, $[He]2s^2 2p^3$



8 O $1s^2 2s^2 2p^4$, $[He]2s^2 2p^4$



9 F $1s^2 2s^2 2p^5$, $[He]2s^2 2p^5$



10 Ne $1s^2 2s^2 2p^6$, $[He]2s^2 2p^6$

Self-Test 1.11A Predict the ground-state configuration of a magnesium atom.

[***Answer:*** $1s^2 2s^2 2p^6 3s^2$, or $[Ne]3s^2$]

Self-Test 1.11B Predict the ground-state configuration of an aluminum atom.

The s- and p-orbitals of the shell with $n = 3$ are full by the time we get to argon, $[Ne]3s^2 3p^6$, which is a colorless, odorless, unreactive gas resembling neon. Argon completes the third period. From Fig. 1.41, we see that the energy of the 4s-orbital is slightly lower than that of the 3d-orbitals. As a result, instead of electrons entering the 3d-orbitals, the fourth period now begins by filling the 4s-orbitals (see Fig. 1.41). Hence, the next two electron configurations are $[Ar]4s^1$ for potassium and $[Ar]4s^2$ for calcium, where [Ar] denotes the argonlike core, $1s^2 2s^2 2p^6 3s^2 3p^6$. At this point, however, the 3d-orbitals begin to be occupied, and there is a change in the rhythm of the periodic table.

According to the pattern of increasing energy of the orbitals (see Fig. 1.41), the next 10 electrons (for scandium, with $Z = 21$, through zinc, with $Z = 30$) enter the 3d-orbitals. The ground-state electron configuration of scandium, for example, is $[Ar]3d^1 4s^2$, and that of its neighbor titanium is $[Ar]3d^2 4s^2$. Note that, beginning at scandium, we write the 4s-electrons after the 3d-electrons: once they contain electrons, the 3d-orbitals lie lower in energy than the 4s-orbital (recall Fig. 1.41; the same relation holds true for nd- and $(n + 1)$s-orbitals in subsequent periods). Successive electrons are added to the d-orbitals as Z increases. However, there are two exceptions: the experimental electron configuration of chromium is $[Ar]3d^5 4s^1$ instead of $[Ar]3d^4 4s^2$, and that of copper is

[Ar]$3d^{10}4s^1$ instead of [Ar]$3d^9 4s^2$. This apparent discrepancy occurs because the half-complete subshell configuration d^5 and the complete subshell configuration d^{10} turn out to have a lower energy than simple theory suggests. As a result, a lower total energy may be achieved if an electron enters a 3d-orbital instead of the expected 4s-orbital, if that arrangement completes a half-subshell or a full subshell. Other exceptions to the building-up principle can be found in the complete listing of electron configurations in Appendix 2C and in the periodic table inside the front cover.

As we can anticipate from the structure of the periodic table (see Fig. 1.44), electrons occupy 4p-orbitals once the 3d-orbitals are full. The configuration of germanium, [Ar]$3d^{10}4s^2 4p^2$, for example, is obtained by adding two electrons to the 4p-orbitals outside the completed 3d-subshell. Arsenic has one more electron and the configuration [Ar]$3d^{10}4s^2 4p^3$. The fourth period of the table contains 18 elements, because the 4s- and 4p-orbitals together can accommodate a total of 8 electrons and the 3d-orbitals can accommodate 10. Period 4 is the first **long period** of the periodic table.

Next in line for occupation at the beginning of Period 5 is the 5s-orbital, followed by the 4d-orbitals. As in Period 4, the energy of the 4d-orbitals falls below that of the 5s-orbital after 2 electrons have been accommodated in the 5s-orbital. A similar effect is seen in Period 6, but now another set of inner orbitals, the 4f-orbitals, begins to be occupied. Cerium, for example, has the configuration [Xe]$4f^1 5d^1 6s^2$. Electrons then continue to occupy the seven 4f-orbitals, which are complete after 14 electrons have been added, at ytterbium, [Xe]$4f^{14}6s^2$. Next, the 5d-orbitals are occupied. The 6p-orbitals are occupied only after the 6s-, 4f-, and 5d-orbitals are filled at mercury; thallium, for example, has the configuration [Xe]$4f^{14}5d^{10}6s^2 6p^1$. You may notice in Appendix 2C that there are several apparent disruptions in the order in which the 4f orbitals are filled. The apparent exceptions result because the 4f and 5d orbitals are very close in energy. In fact, closely spaced energy levels account for the fact that about 25% of the elements have electron configurations that deviate in some way from these rules. However, for the majority of elements they are useful guidelines and a good starting point for them all; Toolbox 1.1 outlines a procedure for writing the electron configuration of a heavy element.

TOOLBOX 1.1 HOW TO PREDICT THE GROUND-STATE ELECTRON CONFIGURATION OF AN ATOM

CONCEPTUAL BASIS

Electrons occupy orbitals in such a way as to minimize the total energy of an atom by maximizing attractions and minimizing repulsions in accord with the Pauli exclusion principle and Hund's rule.

PROCEDURE

We use the following rules of the building-up principle to assign a ground-state configuration to a neutral atom of an element with atomic number Z:

1 Add Z electrons, one after the other, to the orbitals in the order shown in Figs. 1.41 and 1.44 but with no more than two electrons in any one orbital (the Pauli exclusion principle).

2 If more than one orbital in a subshell is available, add electrons to different orbitals of the subshell before doubly occupying any of them (Hund's rule).

3 Write the labels of the orbitals in order of increasing energy, with a superscript that gives the number of electrons in that orbital. The configuration of a filled shell is represented by the symbol of the noble gas having that configuration, as in [He] for $1s^2$.

4 When drawing a box diagram, show the electrons in different orbitals of the same subshell with parallel spins; electrons sharing an orbital have paired spins.

In most cases this procedure gives the ground-state electron configuration of an atom, the arrangement with the lowest energy. Any arrangement other than the ground state corresponds to an excited state of the atom. Note that we can use the structure of the periodic table to predict the electron configurations of most elements once we realize which orbitals are being filled in each block of the periodic table (see Fig. 1.44).

A useful shortcut for atoms of elements with large numbers of electrons is to write the valence electron configuration from the group number, which gives the number of valence electrons in the ground state of the atom, and the period number, which gives the value of the principal quantum number of the valence shell. The core consists of the preceding noble-gas configuration together with any completed d- and f-subshells.

Example 1.10 shows how these rules are applied.

EXAMPLE 1.10 **Predicting the ground-state electron configuration of a heavy atom**

Predict the ground-state electron configuration of (a) a vanadium atom and (b) a lead atom.

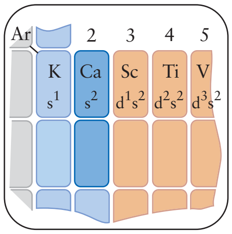
Anticipate Because vanadium is a member of the d-block, we should expect its atoms to have a partially filled set of d-orbitals. Because lead is in the same group as carbon, we should expect the configuration of its valence electrons to be similar to that of carbon (s^2p^2).

PLAN Follow the procedure in Toolbox 1.1.

SOLVE

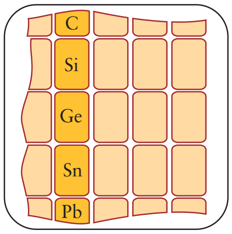
(a) Vanadium is in Period 4, and so it has an argon core. Add two electrons to the 4s-orbital, and the last three electrons to three separate 3d-orbitals.

$[Ar]3d^34s^2$



(b) Lead belongs to Group 14/IV and Period 6. It therefore has four electrons in its valence shell, two in a 6s-orbital and two in different 6p-orbitals. The atom has complete 5d- and 4f-subshells, and the preceding noble gas is xenon.

$[Xe]4f^{14}5d^{10}6s^26p^2$



Evaluate As expected, vanadium has an incomplete set of d-electrons and the valence-shell configuration of lead is analogous to that of carbon.

Self-Test 1.12A Write the ground-state configuration of a bismuth atom.

[***Answer:*** $[Xe]4f^{14}5d^{10}6s^26p^3$]

Self-Test 1.12B Write the ground-state configuration of an arsenic atom.

We account for the ground-state electron configuration of an atom by using the building-up principle in conjunction with Fig. 1.41, the Pauli exclusion principle, and Hund's rule.

1.14 Electronic Structure and the Periodic Table

The periodic table (Section B) was formulated long before the structures of atoms were known, by noting trends in experimental data, but the reason for the periodicity of the elements remained a mystery (Box 1.2). Now, however, we can understand the organization of the periodic table in terms of the electron configurations of the elements. The table is divided into s-, p-, d-, and f-**blocks,** named for the last subshell that is occupied according to the building-up principle (as shown in Fig. 1.44). Two elements are exceptions. Because it has two 1s-electrons, we would place helium in the s block, but it is shown in the p-block because of its properties. It is a gas with properties matching those of the noble gases in Group 18/VIII, rather than the reactive metals in Group 2. Its place in Group 18/VIII is justified because it has a filled valence shell, like all the other Group 18/VIII elements. Hydrogen occupies a unique position in the periodic table. It has one s-electron, and so it belongs in Group 1; but it is also one electron short of a noble-gas configuration, and so it can act like a member of Group 17/VII. Because hydrogen has such a unique character, we do not ascribe it to any group; however, you will often see it placed in Group 1 or Group 17/VII, and sometimes in both.

Thinking point: What are the arguments for and against including He in Group 2, above beryllium?

BOX 1.2 THE DEVELOPMENT OF THE PERIODIC TABLE

The periodic table is one of the most notable achievements in chemistry because it helps to organize what would otherwise be a bewildering array of properties of the elements. However, the fact that its structure corresponds to the electronic structure of atoms was unknown to its discoverers. The periodic table was developed solely from a consideration of physical and chemical properties of the elements.

Dmitri Ivanovich Mendeleev (1834–1907).

In 1860, the Congress of Karlsruhe brought together many prominent chemists in an attempt to resolve issues such as the existence of atoms and the correct atomic masses. One of the new ideas presented was Avogadro's principle—that the numbers of molecules in samples of different gases of equal volume, pressure, and temperature are the same (see Section 4.4). This principle allowed the relative atomic masses of the gases to be determined. Two scientists attending the congress were the German Lothar Meyer and the Russian Dmitri Mendeleev, both of whom left with copies of Avogadro's paper. In 1869, Meyer and Mendeleev discovered independently that the elements fell into families with similar properties when they were arranged in order of increasing atomic mass. Mendeleev called this observation the periodic law.

Mendeleev's chemical insight led him to leave gaps for elements that would be needed to complete the pattern but were unknown at the time. When they were discovered later, he turned out (in most cases) to be strikingly correct. For example, his pattern required an element that he named "eka-silicon" below silicon and between gallium and arsenic. He predicted that the element would have a relative atomic mass of 72 (taking the mass of hydrogen as 1) and properties similar to those of silicon. This prediction spurred the German chemist Clemens Winkler in 1886 to search for eka-silicon, which he eventually discovered and named germanium. It has a relative atomic mass of 72.59 and properties similar to those of silicon, as shown in the accompanying table.

One problem with Mendeleev's table was that some elements seemed to be out of place. For example, when argon was isolated, it did not seem to have the correct mass for its location. Its relative atomic mass of 40 is the same as that of calcium, but argon is an inert gas and calcium a reactive metal. Such anomalies led scientists to question the use of relative atomic mass as the basis for organizing the elements. When Henry Moseley examined x-ray spectra of the elements in the early twentieth century, he realized that he could infer the atomic number itself. It was soon discovered that elements fall into the uniformly repeating pattern of the periodic table if they are organized according to atomic number, rather than atomic mass.

Related Exercises: 1.113 and 1.116.

Mendeleev's Predictions for Eka-Silicon (Germanium)

Property	Eka-silicon, E	Germanium, Ge
molar mass	72 $g \cdot mol^{-1}$	72.59 $g \cdot mol^{-1}$
density	5.5 $g \cdot cm^{-3}$	5.32 $g \cdot cm^{-3}$
melting point	high	937°C
appearance	dark gray	gray-white
oxide	EO_2; white solid; amphoteric; density 4.7 $g \cdot cm^{-3}$	GeO_2; white solid; amphoteric; density 4.23 $g \cdot cm^{-3}$
chloride	ECl_4; boils below 100°C; density 1.9 $g \cdot cm^{-3}$	$GeCl_4$; boils at 84°C; density 1.84 $g \cdot cm^{-3}$

The s- and p-blocks form the **main groups** of the periodic table. The similar valence-shell electron configurations for the elements in the same main group are the reason for the similar properties of these elements. The group number tells us how many valence-shell electrons are present. In the s-block, the group number (1 or 2) is the same as the number of valence electrons. This relation is also true for all main groups when the Roman numerals (I–VIII) are used to label the groups. However, when the group labels 1–18 are used, in the p-block we subtract 10 from the group number to find the number of valence electrons. For example, fluorine in Group 17/VII has seven valence electrons.

Each new period corresponds to the occupation of a shell with a higher principal quantum number. This correspondence explains the different lengths of the periods. Period 1 consists of only two elements, H and He, in which the single 1s-orbital of the $n = 1$ shell is being filled with its two electrons. Period 2 consists of the eight elements Li through Ne, in which the one 2s- and three 2p-orbitals are being filled with eight more electrons. In Period 3 (Na through Ar), the 3s- and 3p-orbitals are being occupied by eight additional electrons. In Period 4, not only are the eight electrons of the 4s- and 4p-orbitals being added, but so are the ten electrons of the 3d-orbitals. Hence there are

eighteen elements in Period 4. Period 5 elements add another 18 electrons as the 5s-, 4d-, and 5p-orbitals are filled. In Period 6, a total of 32 electrons are added, because 14 electrons are also being added to the seven 4f-orbitals. The f-block elements have very similar chemical properties, because their electron configurations differ only in the population of inner f-orbitals, and electrons in these orbitals do not participate much in bond formation.

The blocks of the periodic table are named for the last orbital to be occupied according to the building-up principle. The periods are numbered according to the principal quantum number of the valence shell.

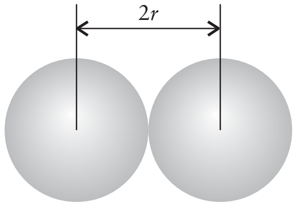
THE PERIODICITY OF ATOMIC PROPERTIES

The periodic table can be used to predict a wide range of properties, many of which are crucial for understanding chemistry. The variation of effective nuclear charge through the periodic table plays an important role in the explanation of periodic trends. Figure 1.45 shows the variation for the first three periods. The effective charge increases from left to right across a period and falls back sharply on going to the next period.

Thinking point: Before reading further, predict how the effective nuclear charge might affect some atomic properties, such as the size of an atom or the ease with which an outer electron can be removed.

1.15 Atomic Radius

Electron clouds do not have sharp boundaries, and so we cannot measure the exact radius of an atom. However, when atoms pack together in solids and bond together to form molecules, their centers are found at definite distances from one another. The **atomic radius** of an element is defined as half the distance between the centers of neighboring atoms (**11**). If the element is a metal, its atomic radius is taken to be half the distance between the centers of neighboring atoms in a solid sample. For instance, because the distance between neighboring nuclei in solid copper is 256 pm, the atomic radius of copper is 128 pm. If the element is a nonmetal or a metalloid, we use half the distance between the nuclei of atoms joined by a chemical bond; this radius is also called the **covalent radius** of the element, for reasons that will become clear in Chapter 2. For instance, the distance between the nuclei in a Cl_2 molecule is 198 pm, and so the covalent radius of chlorine is 99 pm. If the element is a noble gas, we use the **van der Waals radius,** which is half the distance between the centers of neighboring atoms in a sample of the solidified gas. The atomic radii of the noble gases listed in Appendix 2D are all van der Waals radii. Because the atoms in a sample of a noble gas are not chemically bonded together, van der Waals radii are generally much larger than covalent radii and are best not included in the discussion of trends.



11 Atomic radius

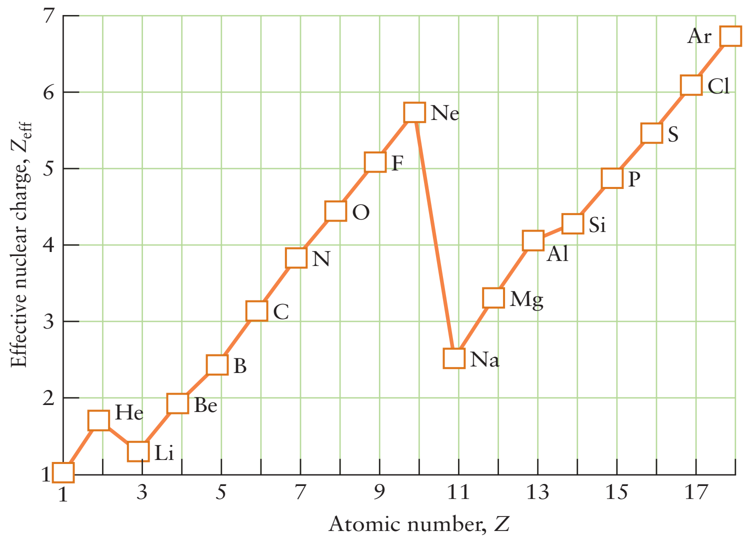


FIGURE 1.45 The variation of the effective nuclear charge for the outermost valence electron with atomic number. Notice that the effective nuclear charge increases from left to right across a period but drops when the outer electrons occupy a new shell. (The effective nuclear charge is actually $Z_{eff}e$, but Z_{eff} itself is commonly referred to as the charge.)

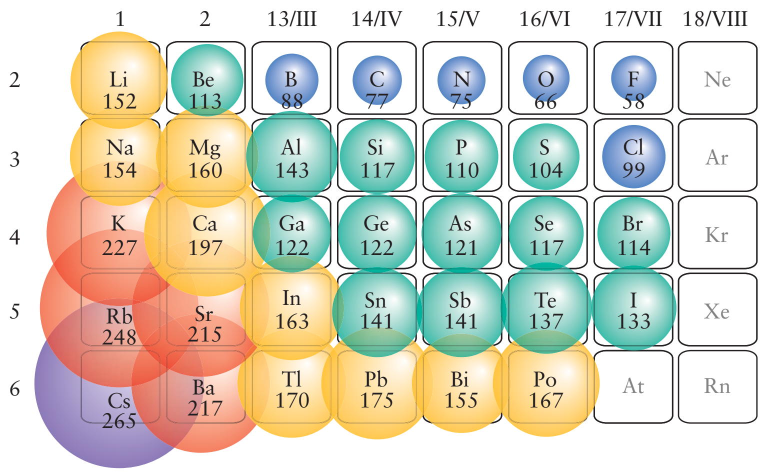

FIGURE 1.46 The atomic radii (in picometers) of the main-group elements. The radii decrease from left to right in a period and increase down a group. The colors used here and in subsequent charts represent the general magnitude of the property. Atomic radii, including those of the d-block elements, are listed in Appendix 2D.

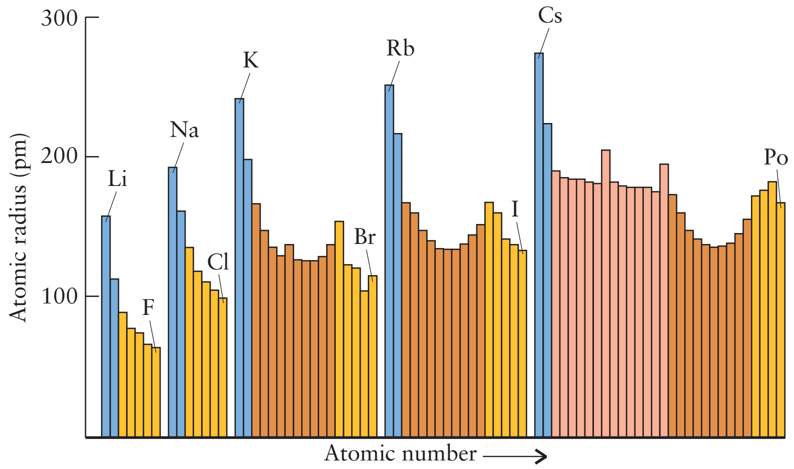

FIGURE 1.47 The periodic variation in the atomic radii of the elements. The decrease across a period can be explained in terms of the effect of increasing effective nuclear charge; the increase down a group by the occupation of shells with increasing principal quantum number.

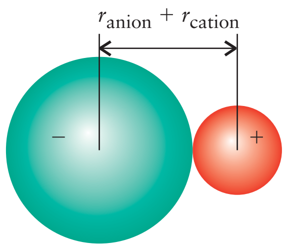
Figure 1.46 shows some atomic radii, and Fig. 1.47 shows the variation in atomic radius with atomic number. Note the periodic, sawtooth pattern in the latter plot. A feature to note is that:

Atomic radius generally decreases from left to right across a period and increases down a group.

The increase down a group, such as that from Li to Cs, makes sense: with each new period, the outermost electrons occupy shells with increasing principal quantum number and therefore lie farther from the nucleus. The decrease across a period, such as that from Li to Ne, is surprising at first, because the number of electrons is increasing along with the number of protons. The explanation is that the new electrons are in the same shell of the atom and about as close to the nucleus as other electrons in the same shell. However, because they are spread out, the electrons do not shield one another well from the nuclear charge; so the effective nuclear charge increases across the period. The increasing effective nuclear charge draws the electrons in, and, as a result, the atom is more compact and we see a diagonal trend for atomic radii to increase from the upper right of the periodic table to the lower left.

Atomic radii generally decrease from left to right across a period as the effective atomic number increases, and they increase down a group as successive shells are occupied.



12 Ionic radius

1.16 Ionic Radius

The radii of ions differ markedly from the radii of their parent atoms. As described in Section C, in an ionic solid each ion is surrounded by ions with the opposite charge. The **ionic radius** of an element is its share of the distance between neighboring ions in an ionic solid (**12**). The distance between the centers of a neighboring cation and anion is

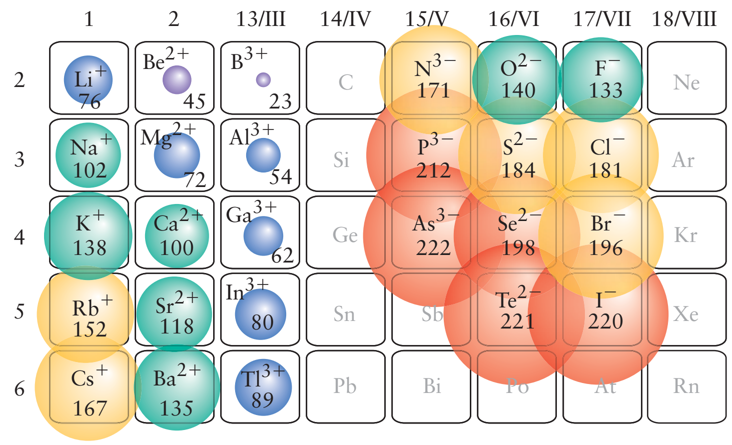


FIGURE 1.48 The ionic radii (in picometers) of the ions of the main-group elements. Note that cations are typically smaller than anions—in some cases, very much smaller.

the sum of the two ionic radii. In practice, we take the radius of the oxide ion to be 140. pm and calculate the radii of other ions on the basis of that value. For example, because the distance between the centers of neighboring Mg^{2+} and O^{2-} ions in magnesium oxide is 212 pm, the radius of the Mg^{2+} ion is reported as 212 pm − 140 pm = 72 pm.

Figure 1.48 illustrates the trends in ionic radii, and Fig. 1.49 shows the relative sizes of some ions and their parent atoms. All cations are smaller than their parent atoms, because the atom loses one or more electrons to form the cation and exposes its core, which is generally much smaller than the parent atom. For example, the atomic radius of Li, with the configuration $1s^22s^1$, is 152 pm, but the ionic radius of Li^+, the bare heliumlike $1s^2$ core of the parent atom, is only 76 pm. This size difference is comparable to that between a cherry and its pit. Atoms in the same main group tend to form ions with the same charge. Like atomic radii, the radii of these ions increase down each group because electrons are occupying shells with higher principal quantum numbers.

Figure 1.49 shows that anions are larger than their parent atoms. The reason can be traced to the increased number of electrons in the valence shell of the anion and the repulsive effects exerted by electrons on one another. The variation in the radii of anions shows the same diagonal trend as that for atoms and cations, with the smallest at the upper right of the periodic table, close to fluorine.

Atoms and ions with the same number of electrons are called **isoelectronic.** For example, Na^+, F^-, and Mg^{2+} are isoelectronic. All three ions have the same electron configuration, $[He]2s^22p^6$, but their radii differ because they have different nuclear charges (see Fig. 1.48). The Mg^{2+} ion has the largest nuclear charge; so it has the strongest attraction for the electrons and therefore the smallest radius. The F^- ion has the lowest nuclear charge of the three isoelectronic ions and, as a result, it has the largest radius.

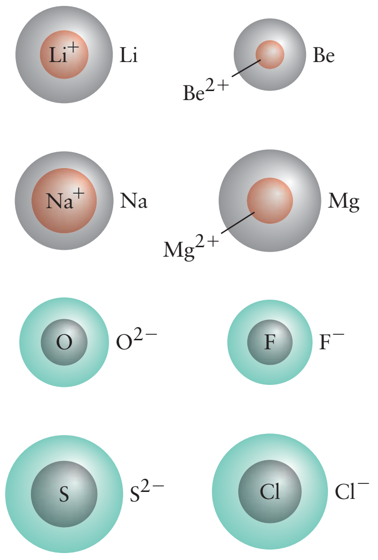

FIGURE 1.49 The relative sizes of some cations and anions compared with their parent atoms. Note that cations (pink) are smaller than their parent atoms (gray), whereas anions (green) are larger.

EXAMPLE 1.11 Deciding the relative sizes of ions

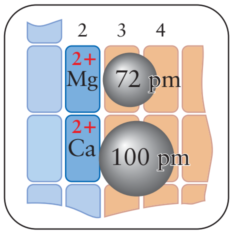
Arrange each of the following pairs of ions in order of increasing ionic radius: (a) Mg^{2+} and Ca^{2+}; (b) O^{2-} and F^-.

PLAN The smaller member of a pair of isoelectronic ions in the same period will be an ion of an element that lies farther to the right in a period, because that ion has the greater effective nuclear charge. If the two ions are in the same group, the smaller ion will be the one that lies higher in the group, because its outermost electrons are closer to the nucleus.

SOLVE

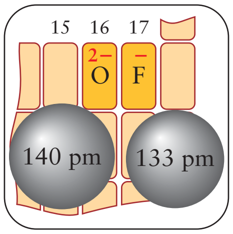
(a) Mg lies above Ca in Group 2.

Mg^{2+} has the smaller ionic radius.



(b) F^- lies to the right of O in Period 2.

F^- has the smaller ionic radius.



Evaluate Appendix 2C shows that the actual values are (a) 72 pm for Mg^{2+} and 100 pm for Ca^{2+}; (b) 133 pm for F^- and 140 pm for O^{2-}.

Self-Test 1.13A Arrange each of the following pairs of ions in order of increasing ionic radius: (a) Mg^{2+} and Al^{3+}; (b) O^{2-} and S^{2-}.

[***Answer:*** (a) $r(Al^{3+}) < r(Mg^{2+})$; (b) $r(O^{2-}) < r(S^{2-})$]

Self-Test 1.13B Arrange each of the following pairs of ions in order of increasing ionic radius: (a) Ca^{2+} and K^+; (b) S^{2-} and Cl^-.

Ionic radii generally increase down a group and decrease from left to right across a period. Cations are smaller than their parent atoms and anions are larger.

1.17 Ionization Energy

We shall see in Chapter 2 that the formation of a bond in an ionic compound depends on the removal of one or more electrons from one atom and their transfer to another atom. The energy needed to remove electrons from atoms is therefore of central importance for understanding their chemical properties. The **ionization energy**, I, is the minimum energy needed to remove an electron from an atom in the gas phase:

By referring to the minimum energy we do not have to worry about the kinetic energy of the electron: it is stationary. Ionization can be achieved by using a higher energy, but then the electron would carry away the excess energy as kinetic energy.

$$X(g) \longrightarrow X^+(g) + e^-(g) \qquad I = E(X^+) - E(X) \qquad (21)^*$$

The ionization energy is normally expressed in electronvolts (eV) for a single atom or in kilojoules per mole of atoms ($kJ\cdot mol^{-1}$). The **first ionization energy,** I_1, is the minimum energy needed to remove an electron from a neutral atom in the gas phase. For example, for copper,

$$Cu(g) \longrightarrow Cu^+(g) + e^-(g) \qquad \text{energy required} = I_1\ (7.73\ \text{eV}, 746\ \text{kJ}\cdot\text{mol}^{-1})$$

The **second ionization energy,** I_2, of an element is the minimum energy needed to remove an electron from a singly charged gas-phase cation. For copper,

$$Cu^+(g) \longrightarrow Cu^{2+}(g) + e^-(g) \qquad \text{energy required} = I_2\ (20.29\ \text{eV}, 1958\ \text{kJ}\cdot\text{mol}^{-1})$$

Because ionization energy is a measure of how difficult it is to remove an electron, elements with low ionization energies can be expected to form cations readily and to conduct electricity (which requires that some electrons be free to move) in their solid forms. Elements with high ionization energies are unlikely to form cations and are unlikely to conduct electricity.

Thinking point: Why is the second ionization energy of an atom always higher than its first ionization energy?

As we can see in Fig. 1.50:

First ionization energies typically decrease down a group.
First ionization energies generally increase across a period.

The decrease down a group can be explained by the finding that, in successive periods, the outermost electron occupies a shell that is farther from the nucleus and is therefore less tightly bound. Therefore, it takes less energy to remove an electron from a cesium atom, for instance, than from a sodium atom.

With few exceptions, the first ionization energy rises from left to right across a period (Fig. 1.51). This trend can be traced to the increase in effective nuclear charge

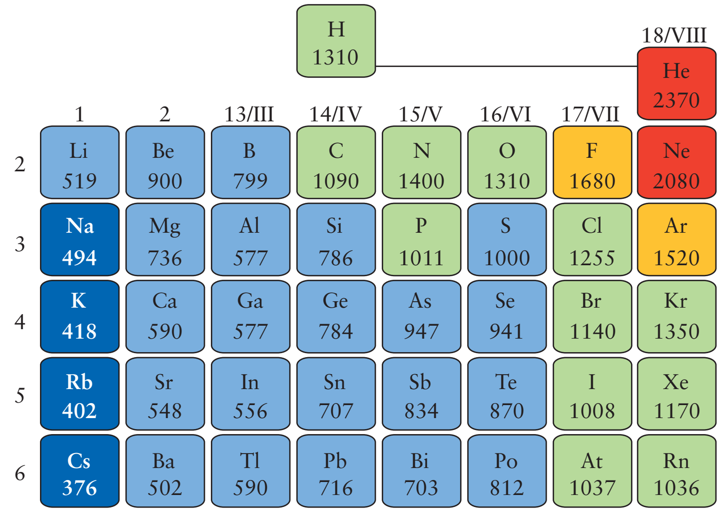


FIGURE 1.50 The first ionization energies of the main-group elements, in kilojoules per mole. In general, low values are found at the lower left of the table and high values are found at the upper right.

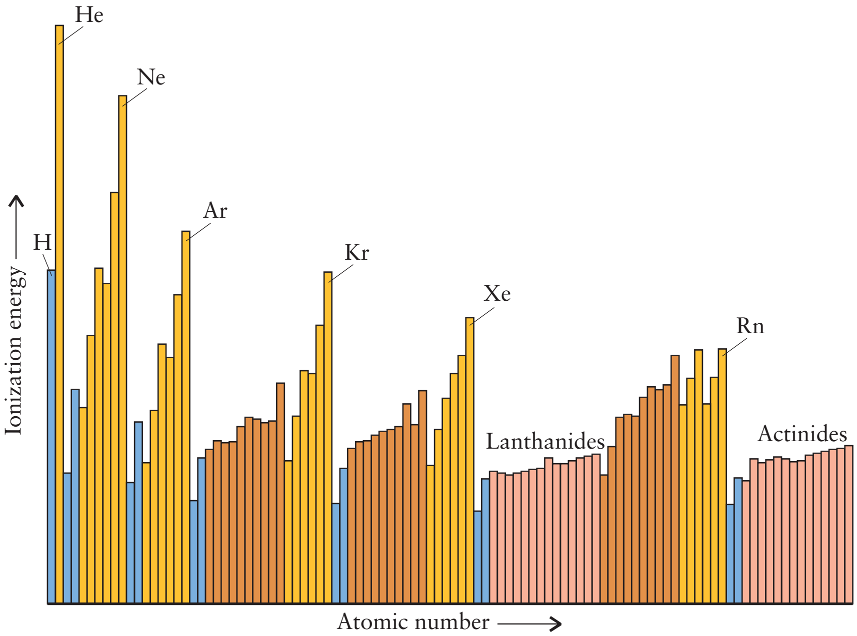

FIGURE 1.51 The periodic variation of the first ionization energies of the elements.

across a period. The small departures from this trend can be traced to repulsions between electrons, particularly electrons occupying the same orbital. For example, the ionization energy of oxygen is slightly lower than that of nitrogen because in a nitrogen atom each p-orbital has one electron, but in oxygen the eighth electron is paired with an electron already occupying an orbital. The repulsion between the two electrons in the same orbital raises their energy and makes one of them easier to remove from the atom than if the two electrons had been in different orbitals.

Figure 1.52 shows that the second ionization energy of an element is always higher than its first ionization energy. It takes more energy to remove an electron from a positively charged ion than from a neutral atom. For the Group 1 elements, the second ionization energy is considerably larger than the first; but, in Group 2, the two ionization energies have similar values. This difference makes sense, because the Group 1 elements have an ns^1 valence-shell electron configuration. Although the removal of the first electron requires only a small energy, the second electron must come from the noble-gas core. The core electrons have lower principal quantum numbers and are much closer to the nucleus. They are strongly attracted to it and a lot of energy is needed to remove them.

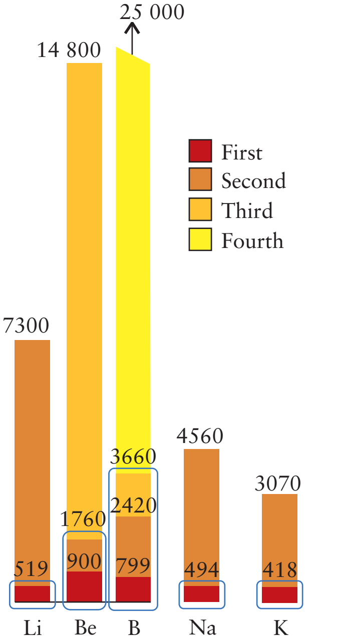

FIGURE 1.52 The successive ionization energies of a selection of main-group elements. Note the great increase in energy required to remove an electron from an inner shell. In each case, the blue outline denotes ionization from the valence shell.

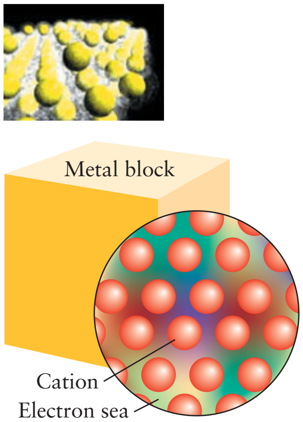

FIGURE 1.53 A block of metal consists of an array of cations (the spheres) surrounded by a sea of electrons. The charge of the electron sea cancels the charges of the cations. The electrons of the sea are mobile and can move past the cations quite easily and hence conduct an electric current.

Animation 1.53

Self-Test 1.14A Account for the slight decrease in first ionization energy between beryllium and boron.

[***Answer:*** Boron loses an electron from a higher-energy subshell than beryllium does.]

Self-Test 1.14B Account for the large decrease in third ionization energy between beryllium and boron.

The low ionization energies of elements at the lower left of the periodic table account for their metallic character. A block of metal consists of a collection of cations of the element surrounded by a sea of valence electrons that the atoms have lost (Fig. 1.53). Only elements with low ionization energies—the members of the s-block, the d-block, the f-block, and the lower left of the p-block—can form metallic solids, because only they can lose electrons easily.

The elements at the upper right of the periodic table have high ionization energies; so they do not readily lose electrons and are therefore not metals. Note that our knowledge of electronic structure has helped us to understand a major feature of the periodic table—in this case, why the metals are found toward the lower left and the nonmetals are found toward the upper right.

The first ionization energy is highest for elements close to helium and is lowest for elements close to cesium. Second ionization energies are higher than first ionization energies (of the same element) and very much higher if the electron is to be removed from a closed shell. Metals are found toward the lower left of the periodic table because these elements have low ionization energies and can readily lose their electrons.

1.18 Electron Affinity

To predict some chemical properties, we need to know how the energy changes when an electron attaches to an atom. The **electron affinity,** E_{ea}, of an element is the energy released when an electron is added to a gas-phase atom. A positive electron affinity means that energy is released when an electron attaches to an atom. A negative electron affinity means that energy must be *supplied* to push an electron onto an atom. This convention matches the everyday meaning of the term "affinity." More formally, the electron affinity of an element X is defined as

$$\mathrm{X(g)} + \mathrm{e^-(g)} \longrightarrow \mathrm{X^-(g)} \qquad E_{ea}(\mathrm{X}) = E(\mathrm{X}) - E(\mathrm{X^-}) \qquad (22)^*$$

where $E(\mathrm{X})$ is the energy of a gas-phase X atom and $E(\mathrm{X^-})$ is the energy of the gas-phase anion. For instance, the electron affinity of chlorine is the energy released in the process

$$\mathrm{Cl(g)} + \mathrm{e^-(g)} \longrightarrow \mathrm{Cl^-(g)} \qquad \text{energy released} = E_{ea}\ (3.62\ \mathrm{eV},\ 349\ \mathrm{kJ \cdot mol^{-1}})$$

In some books, you will see electron affinity defined with an opposite-sign convention. Those values are actually the electron-gain enthalpies (Chapter 7).

Because the electron has a lower energy when it occupies one of the atom's orbitals, the difference $E(\mathrm{Cl}) - E(\mathrm{Cl^-})$ is positive and the electron affinity of chlorine is positive. Like ionization energies, electron affinities are reported either in electronvolts for a single atom or in joules per mole of atoms.

Figure 1.54 shows the variation in electron affinity in the main groups of the periodic table. It is much less periodic than variations in radius and ionization energy. However, one broad trend is clearly visible: with the exception of the noble gases,

Electron affinities are highest toward the right of the periodic table.

This trend is particularly true in the upper right, close to oxygen, sulfur, and the halogens. In these atoms, the incoming electron occupies a p-orbital close to a nucleus with a high effective charge and can experience its attraction quite strongly. The noble gases have negative electron affinities because any electron added to them must occupy an orbital outside a closed shell and far from the nucleus: this process requires energy, and so the electron affinity is negative.

Once an electron has entered the single vacancy in the valence shell of a Group 17/VII atom, the shell is complete and any additional electron would have to begin a new shell. In that shell, it not only would be farther from the nucleus but would also feel the repulsion of the negative charge already present. As a result, the second electron

	1	2	13/III	14/IV	15/V	16/VI	17/VII	18/VIII
1	H +73							He <0
2	Li +60	Be ≤0	B +27	C +122	N −7	O +141, −844	F +328	Ne <0
3	Na +53	Mg ≤0	Al +43	Si +134	P +72	S +200, −532	Cl +349	Ar <0
4	K +48	Ca +2	Ga +29	Ge +116	As +78	Se +195	Br +325	Kr <0
5	Rb +47	Sr +5	In +29	Sn +116	Sb +103	Te +190	I +295	Xe <0
6	Cs +46	Ba +14	Tl +19	Pb +35	Bi +91	Po +174	At +270	Rn <0

FIGURE 1.54 The variation in electron affinity in kilojoules per mole of the main-group elements. Where two values are given, the first refers to the formation of a singly charged anion and the second is the additional energy needed to produce a doubly charged anion. The negative signs of the second values indicate that energy is required to add an electron to a singly charged anion. The variation is less systematic than that for ionization energy, but high values tend to be found close to fluorine (but not for the noble gases).

affinity of fluorine is strongly negative, meaning that a lot of energy has to be expended to form F^{2-} from F^-. Ionic compounds of the halogens are therefore built from singly charged ions such as F^- and never from doubly charged ions such as F^{2-}.

A Group 16/VI atom, such as O or S, has two vacancies in its valence-shell p-orbitals and can accommodate two additional electrons. The first electron affinity is positive because energy is released when an electron attaches to O or S. However, attachment of the second electron *requires* energy because of the repulsion by the negative charge already present in O^- or S^-. Unlike that of a halide ion, however, the valence shell of the O^- anion has only seven electrons and thus can accommodate an additional electron. Therefore, we expect that less energy will be needed to make O^{2-} from O^- than to make F^{2-} from F^-, where no such vacancy exists. In fact, 141 kJ·mol^{-1} is released when the first electron adds to the neutral atom to form O^-, but 844 kJ·mol^{-1} must be supplied to add a second electron to form O^{2-}; so the total energy required to make O^{2-} from O is +703 kJ·mol^{-1}. As we shall see in Chapter 2, this energy can be achieved in chemical reactions, and O^{2-} ions are common in metal oxides.

EXAMPLE 1.12 Predicting trends in electron affinity

The electron affinity of carbon is greater than that of nitrogen; indeed, the latter is negative. Suggest a reason for this observation.

PLAN When a periodic trend is different from what is expected, we examine the electron configurations of all the species to look for clues to the observed behavior.

SOLVE We expect more energy to be released when an electron enters the N atom, because an N atom is smaller than a C atom and its nucleus is more highly charged: the effective nuclear charges for the outermost electrons *of the neutral atoms* are 3.8 for N and 3.1 for C. However, the opposite is observed, and so we must also consider the effective nuclear charges experienced by the valence electrons in the anions (Fig. 1.55). When C^- forms from C, the additional electron occupies an empty 2p-orbital (see **6**). The incoming electron is well separated from the other p-electrons, and so it experiences an effective nuclear charge close to 3.1. When N^- forms from N, the additional electron must occupy a 2p-orbital that is already half full (see **7**). The effective nuclear charge experienced by this electron is therefore much less than 3.8; so energy is required to form N^-, and the electron affinity of nitrogen is lower than that of carbon.

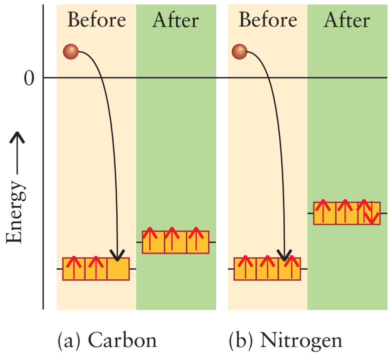

FIGURE 1.55 The energy changes taking place when an electron is added to a carbon atom and a nitrogen atom. (a) A carbon atom can accommodate an additional electron in an empty p-orbital. (b) When an electron is added to a nitrogen atom it must pair with an electron in a p-orbital. The incoming electron experiences so much repulsion from those already present in the nitrogen atom that the electron affinity of nitrogen is less than that of carbon and is in fact negative.

Self-Test 1.15A Account for the large decrease in electron affinity between lithium and beryllium.

[*Answer:* The additional electron enters a 2s-orbital in Li but a 2p-orbital in Be, and a 2s-electron is more tightly bound than a 2p-electron.]

Self-Test 1.15B Account for the large decrease in electron affinity between fluorine and neon.

Elements with the highest electron affinities are those in Groups 16/VI and 17/VII.

FIGURE 1.56 When tin(II) oxide is heated in air, it becomes incandescent as it reacts to form tin(IV) oxide. Even without being heated, it smolders and can ignite.

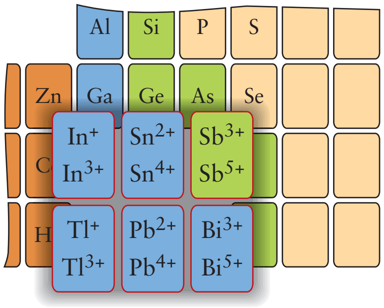

FIGURE 1.57 The typical ions formed by the heavy elements in Groups 13/III through 15/V show the influence of the inert pair—the tendency to form compounds in which the oxidation numbers differ by 2.

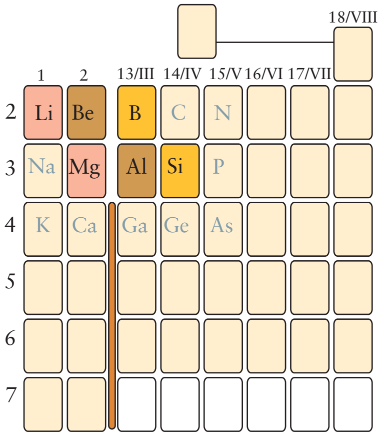

FIGURE 1.58 The pairs of elements represented by similarly colored boxes show a strong diagonal relationship to each other.

1.19 The Inert-Pair Effect

Although both aluminum and indium are in Group 13/III, aluminum forms Al^{3+} ions, whereas indium forms both In^{3+} and In^{+} ions. The tendency to form ions two units lower in charge than expected from the group number is called the **inert-pair effect**. Another example of the inert-pair effect is found in Group 14/IV: tin forms tin(IV) oxide when heated in air, but the heavier lead atom loses only its two p-electrons and forms lead(II) oxide. Tin(II) oxide can be prepared, but it is readily oxidized to tin(IV) oxide (Fig. 1.56). Lead exhibits the inert-pair effect more strongly than tin.

The inert-pair effect is due in part to the relative energies of the valence p- and s-electrons. In the later periods of the periodic table, valence s-electrons are very low in energy because of their good penetration and the low shielding ability of the d-electrons. The valence s-electrons may therefore remain attached to the atom during ion formation. The inert-pair effect is most pronounced among the heaviest members of a group, where the difference in energy between s- and p-electrons is greatest (Fig. 1.57). Even so, the pair of s-electrons can be removed from the atom under sufficiently vigorous conditions. An inert pair would be better called a "lazy pair" of electrons.

The inert-pair effect is the tendency to form ions two units lower in charge than expected from the group number; it is most pronounced for heavy elements in the p-block.

1.20 Diagonal Relationships

A **diagonal relationship** is a similarity in properties between diagonal neighbors in the main groups of the periodic table (Fig. 1.58). A part of the reason for this similarity can be seen in Figs. 1.46 and 1.50 by concentrating on the colors that show the general trends in atomic radius and ionization energy. The colored bands of similar values lie in diagonal stripes across the table. Because these characteristics affect the chemical properties of an element, it is not surprising to find that the elements within a diagonal band show similar chemical properties (Fig. 1.59). Diagonal relationships are helpful for making predictions about the properties of elements and their compounds.

The diagonal band of metalloids dividing the metals from the nonmetals is one example of a diagonal relationship (Section B). So is the chemical similarity of lithium and magnesium and of beryllium and aluminum. For example, both lithium and magnesium react directly with nitrogen to form nitrides. Like aluminum, beryllium reacts with both acids and bases. We shall see many examples of this diagonal similarity when we look at the main-group elements in detail in Chapter 15.

Diagonally related pairs of elements often show similar chemical properties.

1.21 The General Properties of the Elements

We are now at the point where we can begin to predict, in at least a general way, the properties of elements. For example, an s-block element has a low ionization energy, which means that its outermost electrons can easily be lost. An s-block element is therefore likely to be a reactive metal with all the characteristics that the name "metal" implies (Table 1.4, Fig. 1.60). Because ionization energies are lowest at the bottom of each group and the elements there lose their valence electrons most easily, cesium and barium react most vigorously of all s-block elements and have to be stored out of contact with air and water.

Elements on the left of the p-block, especially the heavier elements, have ionization energies that are low enough for these elements to have some of the metallic properties of the members of the s-block. However, the ionization energies of the p-block metals are quite high, and they are less reactive than those in the s-block (Fig. 1.61).

Elements at the right of the p-block (with the exception of the noble gases) have characteristically high electron affinities: they tend to gain electrons to complete closed

TABLE 1.4 Characteristics of Metals and Nonmetals

Metals	Nonmetals
Physical properties	
good conductors of electricity	poor conductors of electricity
malleable	not malleable
ductile	not ductile
lustrous	not lustrous
typically: solid; high melting point; good conductors of heat	typically: solid, liquid, or gas; low melting point; poor conductors of heat
Chemical properties	
react with acids	do not react with acids
form basic oxides (which react with acids)	form acidic oxides (which react with bases)
form cations	form anions
form ionic halides	form covalent halides

FIGURE 1.59 Boron (top) and silicon (bottom) have a diagonal relationship. Both are brittle solids with high melting points. They also show a number of chemical similarities.

shells. Except for the metalloids tellurium and polonium, the members of Groups 16/VI and 17/VII are nonmetals (Fig. 1.62). They typically form molecular compounds with one another.

All d-block elements are metals (Fig. 1.63). Their properties are transitional between the s- and the p-block elements, which (with the exception of the members of Group 12) accounts for their alternative name, the "transition metals." Because transition metals in the same period differ mainly in the number of d-electrons, and these electrons are in inner shells, their properties are very similar.

Variable valence is discussed further in Section 2.1.

When a d-metal atom loses electrons to form a cation, it first loses its outer s-electrons. However, most transition metals form ions with different oxidation states, because the d-electrons have similar energies and a variable number can be lost when they form compounds. Iron, for instance, forms Fe^{2+} and Fe^{3+}; copper forms Cu^{+} and Cu^{2+}. Although copper is like potassium in having a single outermost s-electron, potassium forms only K^{+}. The reason for this difference can be understood by comparing their second ionization energies, which are 1958 kJ·mol^{-1} for copper and 3051 kJ·mol^{-1} for potassium. To form Cu^{2+}, an electron is removed from the d-subshell of [Ar]3d^{10}; but, to form K^{2+}, the electron would have to be removed from potassium's argonlike core.

The availability of d-orbitals and the similarity of the atomic radii of the d-block metals have a significant impact on many areas of our lives. The availability of d-orbitals is in large measure responsible for the action of transition metals and their compounds as catalysts (substances that accelerate reactions but are not themselves consumed) throughout the chemical industry. Thus, iron is used in the manufacture of ammonia, nickel in the conversion of vegetable oils into shortening, platinum in the manufacture of nitric acid, vanadium(V) oxide in the manufacture of sulfuric acid, and titanium compounds in the manufacture of polyethylene. The ability to form ions

FIGURE 1.60 All the alkali metals are soft, reactive, silvery metals. Sodium is kept under mineral oil to protect it from air, and a freshly cut surface soon becomes covered with the oxide.

Lab Video 1.60

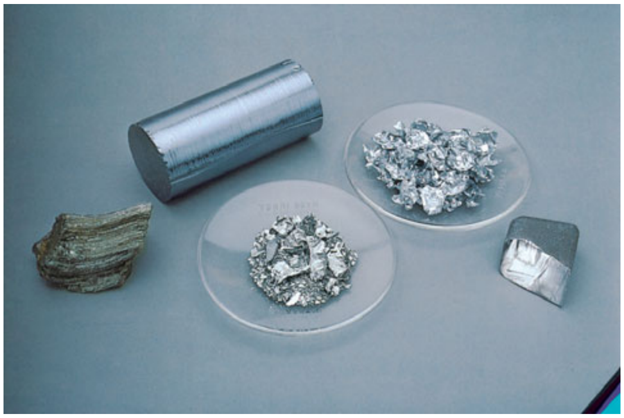

FIGURE 1.61 The Group 14/IV elements. From left to right: carbon (as graphite), silicon, germanium, tin, and lead.

FIGURE 1.62 The Group 16/VI elements. From left to right: oxygen, sulfur, selenium, and tellurium. Note the trend from nonmetal to metalloid.

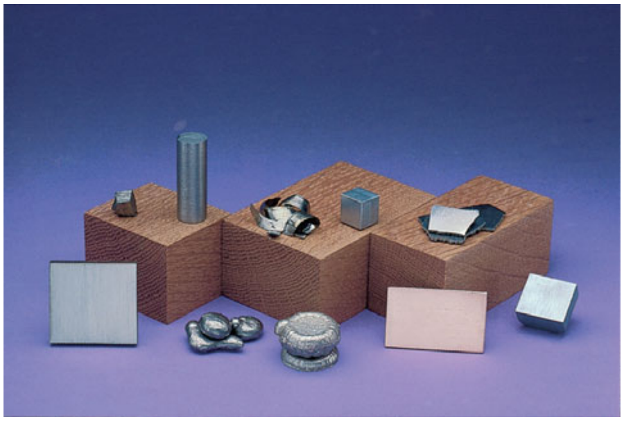

FIGURE 1.63 The elements in the first row of the d-block. Top row (left to right): scandium, titanium, vanadium, chromium, and manganese. Bottom row: iron, cobalt, nickel, copper, and zinc.

with different charges is important for facilitating the very subtle changes that take place in organisms. For instance, iron is present as iron(II) in hemoglobin, the oxygen-transport protein in mammalian blood; copper is present in the proteins responsible for electron transport; and manganese is present in the proteins responsible for photosynthesis. The similarity of their atomic radii is largely responsible for the ability of transition metals to form the mixtures known as *alloys*, especially the wide variety of steels that make modern construction and engineering possible.

Difficulties in separating and isolating the lanthanoids delayed their widespread use in technology. However, today they are studied intensely, because superconducting materials often contain lanthanoids. All the actinoids are radioactive. None of the elements following plutonium occurs naturally on Earth in any significant amount. Because they can be made only in nuclear reactors or particle accelerators, they are available only in small quantities.

All elements in the s-block are reactive metals that form basic oxides. The p-block elements tend to gain electrons to complete closed shells; they range from metals through metalloids to nonmetals. All d-block elements are metals with properties between those of s-block and p-block metals. Many d-block elements form cations in more than one oxidation state.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Describe the experiments that led to the formulation of the nuclear model of the atom (Section 1.1).

❑ 2 Calculate the wavelength or frequency of light from the relation $\lambda\nu = c$ (Example 1.1).

❑ 3 Use Wien's law to estimate a temperature (Example 1.3).

❑ 4 Use the relation $E = h\nu$ to calculate the energy, frequency, or number of photons emitted from a light source (Examples 1.4 and 1.5).

❑ 5 Estimate the wavelength of a particle (Example 1.6).

❑ 6 Estimate the uncertainty in the location or speed of a particle (Example 1.7).

❑ 7 Calculate the energies and describe the wavefunctions of a particle in a box (Example 1.8).

❑ 8 Explain the origin of the lines in the spectrum of an element and correlate them with specific energy transitions (Example 1.2).

❑ 9 Assess the relative probability of finding an electron at a given distance from the nucleus of an atom (Example 1.9).

❑ 10 Name and explain the relation of each of the four quantum numbers to the properties and relative energies of atomic orbitals (Sections 1.8–1.11).

❑ 11 Describe the factors affecting the energy of an electron in a many-electron atom (Section 1.12).

❑ 12 Write the ground-state electron configuration for an element (Toolbox 1.1 and Example 1.10).

❑ 13 Account for periodic trends in atomic radii, ionization energies, and electron affinities (Examples 1.11 and 1.12).

EXERCISES

Exercises labeled C require calculus.

Observing Atoms

1.1 At the time that J. J. Thomson conducted his experiments on cathode rays, the nature of the electron was in doubt. Some considered it to be a form of radiation, like light; others believed the electron to be a particle. Some of the observations made on cathode rays were used to advance one view or the other. Explain how each of the following properties of cathode rays supports either the wave or the particle model of the electron. (a) They pass through metal foils. (b) They travel at speeds slower than that of light. (c) If an object is placed in their path, they cast a shadow. (d) Their path is deflected when they are passed between electrically charged plates.

1.2 J. J. Thomson originally referred to the rays produced in his apparatus (Fig. B.5) as "canal rays." The canal ray is deflected within the region between the poles of a magnet and strikes the phosphor screen. The ratio Q/m (where Q is the charge and m the mass) of the particles making up the canal rays is found to be 2.410×10^7 C·kg^{-1}. The cathode and anode of the apparatus are made of lithium, and the tube contains helium. Use the information inside the back cover to identify the particles (and their charge) that make up the canal rays. Explain your reasoning.

1.3 Arrange the following types of photons of electromagnetic radiation in order of increasing energy: γ-rays, visible light, ultraviolet radiation, microwaves, x-rays.

1.4 Arrange the following types of photons of electromagnetic radiation in order of increasing frequency: visible light, radio waves, ultraviolet radiation, infrared radiation.

1.5 A college student recently had a busy day. Each of the student's activities on that day (reading, having a dental x-ray, making popcorn in a microwave oven, and getting a suntan) involved radiation from a different part of the electromagnetic spectrum. Complete the following table and match each type of radiation to the appropriate event:

Frequency	Wavelength	Energy of photon	Event
8.7×10^{14} Hz			
		3.3×10^{-19} J	
300 MHz			
	2.5 nm		

1.6 A college student used a variety of types of electromagnetic radiation when going to a restaurant for lunch (watching a red traffic light change, listening to the car radio, being struck by a stray gamma ray from outer space while entering the restaurant, and taking food from a serving table heated with an infrared lamp). Complete the following table and match each type of radiation to the appropriate event:

Frequency	Wavelength	Energy of photon	Event
		2.7×10^{-19} J	
	999 nm		
5×10^{19} Hz			
	155 cm		

Atomic Spectra

1.7 Use the Rydberg formula for atomic hydrogen to calculate the wavelength for the transition from $n = 4$ to $n = 2$. (b) What is the name given to the spectroscopic series to which this transition belongs? (c) Use Table 1.1 to determine the region of the spectrum in which the transition takes place. If the change takes place in the visible region of the spectrum, what color will be emitted?

1.8 (a) Use the Rydberg formula for atomic hydrogen to calculate the wavelength for the transition from $n = 5$ to $n = 1$. (b) What is the name given to the spectroscopic series to which this transition belongs? (c) Use Table 1.1 to determine the region of the spectrum in which the transition takes place. If the change takes place in the visible region of the spectrum, what color will be emitted?

1.9 In the spectrum of atomic hydrogen, several lines are generally classified together as belonging to a series (for example, Balmer series, Lyman series, Paschen series), as shown in Fig. 1.28. What is common to the lines within a series that makes grouping them together logical?

1.10 In the spectrum of atomic hydrogen, a violet line is observed at 434 nm. Determine the beginning and ending energy levels of the electron during the emission of energy that leads to this spectral line.

1.11 The energy levels of hydrogenlike one-electron ions of atomic number Z differ from those of hydrogen by a factor of Z^2. Predict the wavelength of the 2s ⟶ 1s transition in He^+.

1.12 Some lasers work by exciting atoms of one element and letting these excited atoms collide with atoms of another element and transfer their excitation energy to those atoms. The transfer is most efficient when the separation of energy levels matches in the two species. Given the information in Exercise 1.11, are there any transitions of He^+ (including transitions from its excited states) that could be excited by collision with an excited hydrogen atom with the configuration $2s^1$?

Quantum Theory

1.13 Consider the following statements about electromagnetic radiation and decide whether they are true or false. If they are false, correct them. (a) The total intensity of radiation emitted from a black body at absolute temperature T is directly proportional to the temperature. (b) As the temperature of a black body increases, the wavelength at which the maximum intensity is found decreases. (c) Photons of radio-frequency radiation are higher in energy than photons of ultraviolet radiation.

1.14 Consider the following statements about electromagnetic radiation and decide whether they are true or false. If they are false, correct them. (a) Photons of ultraviolet radiation have less energy than photons of infrared radiation. (b) The kinetic energy of an electron ejected from a metal surface when the metal is irradiated with ultraviolet radiation is independent of the frequency of the radiation. (c) The energy of a photon is inversely proportional to the wavelength of the radiation.

1.15 The temperature of molten iron can be estimated by using Wien's law. If the melting point of iron is 1540°C, what will be the wavelength (in nanometers) corresponding to maximum intensity when a piece of iron melts?

1.16 An astronomer discovers a new red star and finds that the maximum intensity is at $\lambda = 572$ nm. What is the temperature of the surface of the star?

1.17 The γ-ray photons emitted by the nuclear decay of a technetium-99 atom used in radiopharmaceuticals have an energy of 140.511 keV. Calculate the wavelength of these γ-rays.

1.18 A mixture of argon and mercury vapor used in blue advertising signs emits light of wavelength 470 nm. Calculate the energy change resulting from the emission of 1.00 mol of photons at this wavelength.

1.19 Sodium vapor lamps, used for public lighting, emit yellow light of wavelength 589 nm. How much energy is emitted by (a) an excited sodium atom when it generates a photon; (b) 5.00 mg of sodium atoms emitting light at this wavelength; (c) 1.00 mol of sodium atoms emitting light at this wavelength?

1.20 When an electron beam strikes a block of copper, x-rays with a frequency of 1.2×10^{17} Hz are emitted. How much energy is emitted at this wavelength by (a) an excited copper atom when it generates an x-ray photon; (b) 2.00 mol of excited copper atoms; (c) 2.00 g of copper atoms?

1.21 A lamp rated at 32 W ($1\ \text{W} = 1\ \text{J}\cdot\text{s}^{-1}$) emits violet light of wavelength 420 nm. How many photons of violet light can the lamp generate in 2.0 s?

1.22 A lamp rated at 40 W ($1\ \text{W} = 1\ \text{J}\cdot\text{s}^{-1}$) emits blue light of wavelength 470 nm. How many photons of blue light can the lamp generate in 2.0 s?

1.23 The velocity of an electron that is emitted from a metallic surface by a photon is $3.6 \times 10^3\ \text{km}\cdot\text{s}^{-1}$. (a) What is the wavelength of the ejected electron? (b) No electrons are emitted from the surface of the metal until the frequency of the radiation reaches 2.50×10^{16} Hz. How much energy is required to remove the electron from the metal surface? (c) What is the wavelength of the radiation that caused photoejection of the electron? (d) What kind of electromagnetic radiation was used?

1.24 The work function for chromium metal is 4.37 eV. What wavelength of radiation must be used to eject electrons with a velocity of $1.5 \times 10^3\ \text{km}\cdot\text{s}^{-1}$?

1.25 A baseball must weigh between 5.00 and 5.25 ounces (1 ounce = 28.3 g). What is the wavelength of a 5.15-ounce baseball thrown at 92 mph?

1.26 A certain automobile of mass 1645 kg travels on a German autobahn at $162\ \text{km}\cdot\text{h}^{-1}$. What is the wavelength of the automobile?

1.27 What is the velocity of a neutron of wavelength 100. pm?

1.28 The average speed of a helium atom at 25°C is $1.23 \times 10^3\ \text{m}\cdot\text{s}^{-1}$. What is the average wavelength of a helium atom at this temperature?

1.29 What is the minimum uncertainty in the speed of an electron confined to within the diameter of a lead atom, which has a diameter of 350. pm?

1.30 What is the minimum uncertainty in the position of a hydrogen atom in a particle accelerator given that its speed is known to within $\pm 5.0\ \text{m}\cdot\text{s}^{-1}$?

Wavefunctions

1.31 The energy levels of a particle of mass m in a two-dimensional square box of side L are given by $(n_1^2 + n_2^2)h^2/8mL^2$. Are any of the levels degenerate? If so, find the values of the quantum numbers n_1 and n_2 for which these degeneracies arise for the first three cases.

1.32 Refer to Exercise 1.31. If one side of the box is twice that of the other, the energy levels are given by $(n_1^2/L_1^2 + n_2^2/L_2^2) \times h^2/8m$. Are degeneracies allowed? If so, which are the degenerate states of the lowest level that shows degeneracy?

1.33 (a) Using the particle-in-the-box model for the hydrogen atom and treating the atom as an electron in a one-dimensional box of length 150. pm, predict the wavelength of radiation emitted when the electron falls from the level with $n = 3$ to that with $n = 2$. (b) Repeat the calculation for the transition from $n = 4$ to $n = 2$.

1.34 (a) What is the highest energy photon that can be absorbed by a ground-state hydrogen atom without causing ionization? (b) What is the wavelength of this radiation? (c) To what region of the electromagnetic spectrum does this photon belong?

1.35 (a) Use the Living Graphs on the Web site for this book to plot the particle-in-a-box wavefunction for $n = 2$ and $L = 1$ m. (b) How many nodes does the wavefunction have? Where do these nodes occur? (c) Repeat parts (a) and (b) for $n = 3$. (d) What general conclusion can you draw about the relation between n and the number of nodes present in a wavefunction? (e) Convert the $n = 2$ plot to a probability density distribution: at what values of x is it most likely to find the particle? (f) Repeat part (e) for $n = 3$.

1.36 Verify the conclusion in part (d) of Exercise 1.35 by plotting the wavefunction for $n = 4$ and determining the number of nodes.

1.37 The wavefunction for a particle in a one-dimensional box is given in Eq. 9. (a) Confirm that the probability of finding the particle in the left half of the box is $\frac{1}{2}$ regardless of the value of n. (b) Does the probability of finding the particle in the left-hand one-third of the box depend on n? If so, find the probability. *Hint:* The indefinite integral of $\sin^2 ax$ is $\frac{1}{2}x - (1/4a)\sin(2ax) +$ constant.

1.38 The *Humphreys series* is a set of spectral lines in the emission spectrum of atomic hydrogen that ends in the fifth excited state. If an atom emits a photon of radiation of wavelength 5910 nm, to which spectral line in the Humphreys series does that photon correspond (i.e., the lowest-energy spectral line, the second-lowest-energy spectral line, the third-lowest-energy spectral line, etc.)? Justify your answer with a calculation.

Models of Atoms

1.39 Evaluate the probability of finding an electron in a small region of a hydrogen 1s-orbital at a distance $0.55a_0$ from the nucleus relative to finding it in the same small region located at the nucleus.

1.40 Evaluate the probability of finding an electron in a small region of a hydrogen 1s-orbital at a distance $0.65a_0$ from the nucleus relative to finding it in the same small region located at the nucleus.

1.41 Show that the electron distribution is spherically symmetrical for an atom in which an electron occupies each of the three p-orbitals of a given shell.

1.42 Show that, if the radial distribution function is defined as $P = r^2R^2$, then the expression for P for an s-orbital is $P = 4\pi r^2\psi^2$.

1.43 What is the probability of finding an electron anywhere in a sphere of radius (a) a_0 or (b) $2a_0$ in the ground state of a hydrogen atom?

C **1.44** At what distance from the nucleus is the electron most likely to be found if it occupies (a) a 3d-orbital or (b) a 4s-orbital in a hydrogen atom?

1.45 (a) Sketch the shape of the boundary surfaces corresponding to 1s-, 2p-, and 3d-orbitals. (b) What is meant by a node? (c) How many radial nodes and angular *nodal surfaces* does each orbital have? (d) Predict the number of nodal planes expected for a 4f-orbital.

1.46 Locate the positions of the radial nodes of (a) a 3s-orbital; (b) a 4d-orbital.

1.47 Describe the orientation of the lobes of the p_x-, p_y-, and p_z-orbitals with respect to the reference Cartesian axes.

1.48 Describe the difference in orientation of the d_{xy}- and the $d_{x^2-y^2}$-orbitals with respect to the reference Cartesian axes. You may wish to refer to the animation of the atomic orbitals found on the Web site for this text.

1.49 How many orbitals are in subshells with l equal to (a) 0; (b) 2; (c) 1; (d) 3?

1.50 (a) How many *subshells* are there for principal quantum number $n = 5$? (b) Identify the subshells in the form 5s, etc. (c) How many *orbitals* are there in the shell with $n = 5$?

1.51 (a) How many values of the quantum number l are possible when $n = 7$? (b) How many values of m_l are allowed for an electron in a 6d-subshell? (c) How many values of m_l are allowed for an electron in a 3p-subshell? (d) How many subshells are there in the shell with $n = 4$?

1.52 (a) How many values of the quantum number l are possible when $n = 6$? (b) How many values of m_l are allowed for an electron in a 5f-subshell? (c) How many values of m_l are allowed for an electron in a 2s-subshell? (d) How many subshells are there in the shell with $n = 3$?

1.53 What are the principal and orbital angular momentum quantum numbers for each of the following orbitals: (a) 6p; (b) 3d; (c) 2p; (d) 5f?

1.54 What are the principal and orbital angular momentum quantum numbers for each of the following orbitals: (a) 2s; (b) 6f; (c) 4d; (d) 5p?

1.55 For each orbital listed in Exercise 1.53, give the possible values for the magnetic quantum number.

1.56 For each orbital listed in Exercise 1.54, give the possible values for the magnetic quantum number.

1.57 How many electrons can occupy (a) the 4p-orbitals? (b) the 3d-orbitals? (c) the 1s-orbital? (d) the 4f-orbitals?

1.58 How many electrons can occupy a subshell with $l =$ (a) 0; (b) 1; (c) 2; (d) 3?

1.59 Write the subshell notation (3d, for instance) and the number of orbitals having the following quantum numbers: (a) $n = 5$, $l = 2$; (b) $n = 1$, $l = 0$; (c) $n = 6$, $l = 3$; (d) $n = 2$, $l = 1$.

1.60 Write the subshell notation (3d, for instance) and the number of electrons that can have the following quantum numbers if all the orbitals of that subshell are filled: (a) $n = 4$, $l = 1$; (b) $n = 5$, $l = 0$; (c) $n = 6$, $l = 2$; (d) $n = 7$, $l = 3$.

1.61 How many electrons can have the following quantum numbers in an atom: (a) $n = 2$, $l = 1$; (b) $n = 4$, $l = 2$, $m_l = -2$; (c) $n = 2$; (d) $n = 3$, $l = 2$, $m_l = +1$?

1.62 How many electrons can have the following quantum numbers in an atom: (a) $n = 3$, $l = 1$; (b) $n = 5$, $l = 3$, $m_l = -1$; (c) $n = 2$, $l = 1$, $m_l = 0$; (d) $n = 7$?

1.63 Which of the following subshells cannot exist in an atom: (a) 2d; (b) 4d; (c) 4g; (d) 6f?

1.64 Which of the following subshells cannot exist in an atom: (a) 4f; (b) 3f; (c) 5g; (d) 6h?

The Structures of Many-Electron Atoms

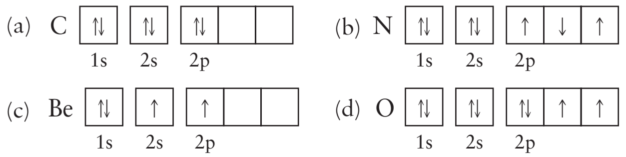
1.65 (a) Write an expression for the total coulombic potential energy for a lithium atom. (b) What does each individual term represent?

1.66 (a) Write an expression for the total coulombic potential energy for a beryllium atom. (b) If Z denotes the number of electrons present in an atom, write a general expression to represent the total number of terms that will be present in the total coulombic potential energy equation.

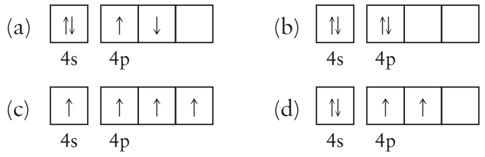
1.67 Which of the following statements are true for many-electron atoms? If false, explain why. (a) The effective nuclear charge Z_{eff} is independent of the number of electrons present in an atom. (b) Electrons in an s-orbital are more effective than those in other orbitals at shielding other electrons from the nuclear charge because an electron in an *s*-orbital can penetrate to the nucleus of the atom. (c) Electrons having $l = 2$ are better at shielding than electrons having $l = 1$. (d) Z_{eff} for an electron in a p-orbital is lower than for an electron in an *s*-orbital in the same shell.

1.68 For the electrons on a carbon atom in the ground state, decide which of the following statements are true. If false, explain why. (a) Z_{eff} for an electron in a 1s-orbital is the same as Z_{eff} for an electron in a 2s-orbital. (b) Z_{eff} for an electron in a 2s-orbital is the same as Z_{eff} for an electron in a 2p-orbital. (c) An electron in the 2s-orbital has the same energy as an electron in the 2p-orbital. (d) The electrons in the 2p-orbitals have spin quantum numbers m_s of opposite sign. (e) The electrons in the 2s-orbital have the same value of the quantum number m_s.

1.69 Determine whether each of the following electron configurations represents the ground state or an excited state of the atom given.



1.70 Each of the following *valence-shell configurations* is possible for a neutral atom of a certain element. What is the element and which configuration represents the ground state?



1.71 Of the following sets of four quantum numbers $\{n, l, m_l, m_s\}$, identify the ones that are forbidden for an electron in an atom and explain why they are invalid:

(a) $\{4, 2, -1, +\frac{1}{2}\}$; (b) $\{5, 0, -1, +\frac{1}{2}\}$; (c) $\{4, 4, -1, +\frac{1}{2}\}$.

1.72 Of the following sets of four quantum numbers $\{n, l, m_l, m_s\}$, identify the ones that are forbidden for an electron in an atom and explain why they are invalid:

(a) $\{2, 2, -1, +\frac{1}{2}\}$; (b) $\{6, 6, 0, +\frac{1}{2}\}$; (c) $\{5, 4, +5, +\frac{1}{2}\}$

1.73 What is the ground-state electron configuration expected for each of the following elements: (a) silver; (b) beryllium; (c) antimony; (d) gallium; (e) tungsten; (f) iodine?

1.74 What is the ground-state electron configuration expected for each of the following elements: (a) arsenic; (b) strontium; (c) tin; (d) platinum; (e) osmium; (f) molybdenum?

1.75 Which elements are predicted to have the following ground-state electron configurations: (a) $[Kr]4d^{10}5s^25p^4$; (b) $[Ar]3d^34s^2$; (c) $[He]2s^22p^2$; (d) $[Rn]7s^26d^2$?

1.76 Which elements are predicted to have the following ground-state electron configurations: (a) $[Ar]3d^{10}4s^24p^1$; (b) $[Ne]3s^1$; (c) $[Kr]5s^2$; (d) $[Xe]4f^76s^2$?

1.77 For each of the following ground-state atoms, predict the type of orbital (1s, 2p, 3d, 4f, etc.) from which an electron will be removed to form the +1 ion: (a) Ge; (b) Mn; (c) Ba; (d) Au.

1.78 For each of the following ground-state atoms, predict the type of orbital (1s, 2p, 3d, 4f, etc.) from which an electron will be removed to form the +1 ion: (a) Zn; (b) Cl; (c) Al; (d) Cu.

1.79 Predict the number of valence electrons present in each of the following atoms (include the outermost d-electrons: (a) N; (b) Ag; (c) Nb; (d) W.

1.80 Predict the number of valence electrons present in each of the following atoms (include the outermost d-electrons): (a) Bi; (b) Ba; (c) Mn; (d) Zn.

1.81 How many *unpaired* electrons are predicted for the ground-state configuration of each of the following atoms: (a) Bi; (b) Si; (c) Ta; (d) Ni?

1.82 How many *unpaired* electrons are predicted for the ground-state configuration of each of the following atoms: (a) Pb; (b) Ir; (c) Y; (d) Cd?

1.83 The elements Ga, Ge, As, Se, and Br lie in the same period in the periodic table. Write the electron configuration expected for the ground-state atoms of these elements and predict how many unpaired electrons, if any, each atom has.

1.84 The elements N, P, As, Sb, and Bi belong to the same group in the periodic table. Write the electron configuration expected for the ground-state atoms of these elements and predict how many unpaired electrons, if any, each atom has.

1.85 Give the notation for the valence-shell configuration (including the outermost d-electrons) of (a) the alkali metals; (b) Group 15/V elements; (c) Group 5 transition metals; (d) "coinage" metals (Cu, Ag, Au).

1.86 Give the notation for the valence-shell configuration (including the outermost d-electrons) of (a) the halogens; (b) the chalcogens (the Group 16/VI elements); (c) the transition metals in Group 5; (d) the Group 14/IV elements.

The Periodicity of Atomic Properties

1.87 Arrange the elements in each of the following sets in order of *decreasing* atomic radius: (a) sulfur, chlorine, silicon; (b) cobalt, titanium, chromium; (c) zinc, mercury, cadmium; (d) antimony, bismuth, phosphorus.

1.88 Arrange the elements in each of the following sets in order of *decreasing* atomic radius: (a) bromine, chlorine, iodine; (b) gallium, selenium, arsenic; (c) calcium, potassium, zinc; (d) barium, calcium, strontium.

1.89 Place the following ions in order of *increasing* ionic radius: S^{2-}, Cl^-, P^{3-}.

1.90 Which ion of each of the following pairs has the *larger* radius: (a) Ca^{2+}, Ba^{2+}; (b) As^{3-}, Se^{2-}; (c) Sn^{2+}, Sn^{4+}?

1.91 Which member of each pair has the *smaller* first ionization energy: (a) Ca or Mg; (b) Mg or Na; (c) Al or Na?

1.92 Which member of each pair is likely to have the *smaller second* ionization energy: (a) Ca or Mg; (b) Mg or Na; (c) Al or Na?

1.93 Place each of the following sets of elements in order of *decreasing* ionization energy. Explain your choices. (a) Selenium, oxygen, tellurium; (b) gold, tantalum, osmium; (c) lead, barium, cesium.

1.94 (a) Generally, the first ionization energies for elements in the same *period* increase on going to higher atomic number. Why? (b) Examine the data for the p-block elements given in Fig. 1.50. Note any exceptions to the rule given in part (a). How are these exceptions explained?

1.95 Which element of each of the following pairs has the *higher* electron affinity: (a) oxygen or fluorine; (b) nitrogen or carbon; (c) chlorine or bromine; (d) lithium or sodium?

1.96 Which element of each of the following pairs has the *higher* electron affinity: (a) aluminum or indium; (b) bismuth or antimony; (c) silicon or lead?

1.97 (a) What is the inert-pair effect? (b) Why is the inert-pair effect observed only for heavy elements?

1.98 Identify which of the following elements experience the inert-pair effect and write the formulas for the ions that they form: (a) Sb; (b) As; (c) Tl; (d) Ba.

1.99 (a) What is a diagonal relationship? (b) How does it arise? (c) Give two examples to illustrate the concept.

1.100 Use Appendix 2D to find the values for the atomic radii of germanium and antimony as well as the ionic radii for Ge^{2+} and Sb^{3+}. What do these values suggest about the chemical properties of these two ions?

1.101 Which of the following pairs of elements exhibit a diagonal relationship: (a) Li and Mg; (b) Ca and Al; (c) F and S?

1.102 Which of the following pairs of elements do not exhibit a diagonal relationship: (a) Be and Al; (b) As and Sn; (c) Ga and Sn?

1.103 Why are s-block metals more reactive than p-block metals?

1.104 Which of the following elements are transition metals: (a) radium; (b) radon; (c) hafnium; (d) niobium?

1.105 Identify the following elements as metals, nonmetals, or metalloids: (a) lead; (b) sulfur; (c) zinc; (d) silicon; (e) antimony; (f) cadmium.

1.106 Identify the following elements as metals, nonmetals, or metalloids: (a) aluminum; (b) carbon; (c) germanium; (d) arsenic; (e) selenium; (f) tellurium.

Integrated Exercises

1.107 Photoelectron spectroscopy (PES, see Section 1.4 and Box 3.3) can be used to determine the energies of atomic orbitals by measuring the energies required to remove electrons from them. The following peaks were observed in the PES spectra for two elements. Identify the elements, write their electron configurations, and explain your reasoning:
(a) 7.30 $MJ{\cdot}mol^{-1}$ and 0.52 $MJ{\cdot}mol^{-1}$
(b) 11.5 $MJ{\cdot}mol^{-1}$ and 0.90 $MJ{\cdot}mol^{-1}$

1.108 The following peaks were observed in the PES spectra for two elements (see Exercise 1.107). Identify the elements, write their electron configurations, and explain your reasoning:
(a) 21 $MJ{\cdot}mol^{-1}$, 2.4 $MJ{\cdot}mol^{-1}$, and 0.80 $MJ{\cdot}mol^{-1}$
(b) 29 $MJ{\cdot}mol^{-1}$, 4.6 $MJ{\cdot}mol^{-1}$, and 1.10 $MJ{\cdot}mol^{-1}$

1.109 Infrared spectroscopy is an important tool for studying vibrations of molecules. Just as an atom can absorb a photon of suitable energy to move an electron from one electronic state to another, a molecule can absorb a photon of electromagnetic radiation in the infrared region to move from one *vibrational* energy level to another. In infrared spectroscopy, it is common to express energy in terms of ν/c, with the units cm^{-1} (read as *reciprocal centimeters*). (a) If an absorption occurs in the infrared spectrum at 3600 cm^{-1}, what is the frequency of radiation that corresponds to that absorption? (b) What is the energy, in joules (J), of that absorption? (c) How much energy would be absorbed by 1.00 mol of molecules absorbing at 3600 cm^{-1}?

1.110 *Diffraction* of electromagnetic radiation by atoms and molecules occurs when the wavelength of the electromagnetic radiation is similar to the size of the particle that causes the diffraction—in this case, atoms or molecules. (a) Using 2.0×10^2 pm as the diameter of an atom, decide what type(s) of electromagnetic radiation would give rise to diffraction when passed through a sample of atoms or molecules. Beams of electrons and neutrons can also be used in diffraction experiments because of their high speeds and the de Broglie relation. Calculate the speed of (b) an electron and (c) a neutron that would be necessary to generate wavelengths comparable to the diameter of an atom.

1.111 Ionization energies usually increase on going from left to right across the periodic table. The ionization energy for oxygen, however, is lower than that of either nitrogen or fluorine. Explain this anomaly.

1.112 Thallium is the heaviest member of Group 13/III. Aluminum is also a member of that group, and its chemical properties are dominated by the +3 oxidation state. Thallium, however, is found most usually in the +1 oxidation state. Examine this difference by plotting the first, second, and third ionization energies for the Group 13/III elements against atomic number (see Appendix 2D or the periodic-table data found on the Web site for this text). Explain the trends you observe.

1.113 The German physicist Lothar Meyer observed a periodicity in the physical properties of the elements at about the same time that Mendeleev was working on their chemical properties. Some of Meyer's observations can be reproduced by examining the molar volume for the solid element as a function of atomic number. Calculate the molar volumes for the elements in Periods 2 and 3 from the densities of the elements found in Appendix 2D and the following solid densities ($g{\cdot}cm^{-3}$): nitrogen, 0.88; fluorine, 1.11; neon, 1.21. Plot your results as a function of atomic number and describe any variations that you observe.

1.114 In the spectroscopic technique known as photoelectron spectroscopy (PES), ultraviolet radiation is directed at an atom or a molecule. Electrons are ejected from the valence shell, and their kinetic energies are measured. Because the energy of the incoming ultraviolet photon is known and the kinetic energy of the outgoing electron is measured, the ionization energy, I, can be deduced from the fact that the total energy is conserved. (a) Show that the speed v of the ejected electron and the frequency ν of the incoming radiation are related by

$$h\nu = I + \tfrac{1}{2} m_e v^2$$

(b) Use this relation to calculate the ionization energy of a rubidium atom, given that radiation of wavelength 58.4 nm produces electrons with a speed of 2450 $km{\cdot}s^{-1}$; recall that $1\ J = 1\ kg{\cdot}m^2{\cdot}s^{-2}$.

1.115 In the heavier transition-metal elements, especially the lanthanoids and actinoids, there are numerous exceptions to the regular order of orbital occupation predicted by the building-up principle. Suggest why more exceptions would be noted for these elements.

1.116 Modern periodic tables sometimes differ in which elements are placed immediately to the right of barium and radium. In some cases, the elements are lanthanum and actinium, whereas others place lutetium and lawrencium there. Why? Justify each selection.

1.117 Wavefunctions corresponding to states of different energy of a particle in a box are mutually "orthogonal" in the sense that, if the two wavefunctions are multiplied together and then integrated over the length of the box, then the outcome is zero. (a) Confirm that the wavefunctions for $n = 1$ and $n = 2$ are orthogonal.
(b) Demonstrate, without doing a calculation, that all wavefunctions with even n are orthogonal to all wavefunctions with odd n. *Hint*: Think about the area under the product of any two such functions.

1.118 Wavefunctions are "normalized" to 1. This term means that the total probability of finding an electron in the system is 1. Verify this statement for a particle-in-the-box wavefunction (Eq. 10).

1.119 The intensity of a transition between the states n and n' of a particle in a box is proportional to the square of the integral I, where

$$I_{nn'} = \int_0^L \psi_n \psi_{n'} \mathrm{d}x$$

(a) Can there be a transition between states with quantum numbers 3 and 1? (b) Consider the transition between states with quantum numbers 2 and 1. Does the intensity decrease or increase as the box lengthens?

1.120 Millikan measured the charge of the electron in *electrostatic units*, esu. The data that he collected included the following series of charges found on oil drops: 9.60×10^{-10} esu, 1.92×10^{-9} esu, 2.40×10^{-9} esu, 2.88×10^{-9} esu, and 4.80×10^{-9} esu. (a) From this series find the likely charge on the electron in electrostatic units. (b) Predict the number of electrons on an oil drop with the charge 6.72×10^{-9} esu.

1.121 Atomic orbitals may be combined to form molecular orbitals. In such orbitals, there is a nonzero probability of finding

an electron on any of the atoms that contribute to that molecular orbital. Consider an electron that is confined in a molecular orbital that extends over two adjacent carbon atoms. The electron can move freely between the two atoms. The C–C distance is 139 pm. (a) Using the one-dimensional particle-in-the-box model, calculate the energy required to promote an electron from the $n = 1$ to the $n = 2$ level, assuming that the length of the box is determined by the distance between two carbon atoms. (b) To what wavelength of radiation does this correspond? (c) Repeat the calculation for a linear chain of 1000 carbon atoms. (d) What can you conclude about the energy separation between energy levels as the size of the atom chain increases?

1.122 The energy required to break a C–C bond in a molecule is 348 $kJ\cdot mol^{-1}$. Will visible light be able to break this bond? If yes, what is the color of that light? If not, what type of electromagnetic radiation will be suitable?

1.123 Apparent anomalies in the filling of electron orbitals in atoms occur in chromium and copper. In these elements an electron expected to occupy an s-orbital occupies a d-orbital instead. (a) Explain why these anomalies occur. (b) Similar anomalies are known to occur in seven other elements. Using Appendix 2C, identify those elements and indicate for which ones the explanation used to rationalize the chromium and copper electron configurations is valid. (c) Explain why there are no elements in which electrons fill $(n + 1)$s-orbitals instead of np-orbitals.

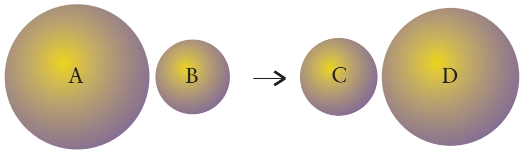
1.124 The electron in a hydrogen atom is excited to a 4d-orbital. Calculate the energy of the photon released if the electron were then to move to each of the following orbitals: (a) 1s; (b) 2p; (c) 2s; (d) 4s. (e) If the outermost electron in a potassium atom were excited to a 4d-orbital and then fell to the same orbitals, describe qualitatively how the emission spectrum would differ from that of hydrogen (do not do any calculations). Explain your answer.

1.125 The following properties are observed for an unknown element. Identify the element from its properties. (a) The neutral atom has two unpaired electrons. (b) One of the valence electrons in the ground state atom has $m_l = +1$. (c) The most common oxidation state is +4. (d) If an electron in a hydrogen atom were excited to the same principal quantum level, n, as the valence electrons in an atom of this element, and fell to the $n - 1$ quantum level, the photon emitted would have an energy of 4.9×10^{-20} J.

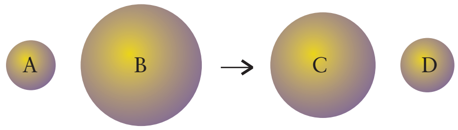
1.126 The electron affinity of thulium has been measured by laser photodetachment electron spectroscopy. In this technique a gaseous beam of the anions of an element is bombarded with photons from a laser. The photons eject electrons from some of the anions and the energies of the ejected electrons are detected. The photons had a wavelength of 1064 nm and the ejected electrons had an energy of 0.137 eV. Although the analysis is somewhat more complicated, we can obtain a rough estimate of the electron affinity as the difference in energy between the photons and the energy of the ejected electrons. What is the electron affinity of thulium in $kJ\cdot mol^{-1}$?

1.127 Francium is thought to be the most reactive of the alkali metals. Because it is radioactive and available in only very small amounts it is difficult to study. However, we can predict its properties based on its location in Group 1 of the periodic table. Estimate the following properties of francium: (a) atomic radius; (b) ionic radius of the +1 cation; (c) ionization energy.

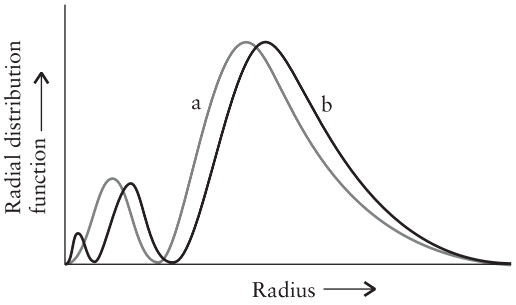
1.128 Below is pictured the reaction between an atom of magnesium and an atom of oxygen. Identify each element and the ions formed and explain your reasoning.



1.129 Below is pictured the reaction between an atom of sodium and an atom of chlorine. Identify each element and the ions formed and explain your reasoning.



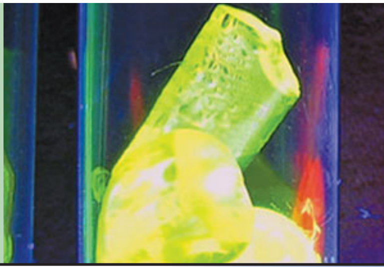
1.130 This plot shows the radial distribution function of the 3s- and 3p-orbitals of a hydrogen atom. Identify each curve and explain how you made your decision.



Chemistry Connections

1.131 Green chemistry methods, which use nontoxic chemicals, are replacing elemental chlorine for the bleaching of paper pulp. Chlorine causes problems because it is a strong oxidizing agent that reacts with organic compounds to form toxic by-products such as furan and dioxins.
(a) Write the electron configuration of a chlorine atom in its ground state. How many unpaired electrons are present in the atom? Write the electron configuration you expect a chloride ion to have. The electron configuration of the chloride ion is identical to that of a neutral atom of what other element?
(b) When a chlorine atom is excited by heat or light, one of its valence electrons may be promoted to a higher energy level. Predict the most likely electron configuration for the lowest possible excited state for an excited chlorine atom.
(c) Estimate the wavelength (in nm) of the energy that needs to be absorbed for the electron to reach the excited state in part (b). To make this estimate, use Eq. 20 and take the effective nuclear charge from Fig. 1.45.
(d) What is the value of the energy required in part (c) in kilojoules per mole and electronvolts?
(e) The proportion of ^{37}Cl in a typical sample is 75.77%, with the remainder being ^{35}Cl. What would the molar mass of a sample of chlorine atoms be if the proportion of ^{37}Cl were reduced to half its current value? The mass of an atom of ^{35}Cl is 5.807×10^{-23} g and that of an atom of ^{37}Cl is 6.139×10^{-23} g.
(f) What are the oxidation numbers of chlorine in the bleaching agents ClO_2 and NaClO?
(g) What are the oxidation numbers of chlorine in the oxidizing agents $KClO_3$ and $NaClO_4$?
(h) Write the names of the compounds in parts (f) and (g).

CHEMICAL BONDS



What Are the Key Ideas? Bond formation is accompanied by a lowering of energy. The energy lowering is due to the attractions between oppositely charged ions or between nuclei and shared electron pairs. The electron configurations of individual atoms control how the atoms combine with one another.

Why Do We Need to Know This Material? The existence of compounds is central to the science of chemistry; and by seeing how bonds form between atoms, we come to see how chemists design new materials. Research into artificial blood, new pharmaceuticals, agricultural chemicals, and the polymers used in materials such as compact discs, cell phones, and synthetic fibers is based on an understanding of how atoms link together.

What Do We Need to Know Already? This chapter assumes that we know about atomic structure and electron configurations (Chapter 1), the basic features of energy, and the nature of the Coulomb interaction between charges (Section A). It is also helpful to be familiar with the nomenclature of compounds (Section D) and oxidation numbers (Section K).

A **chemical bond** is the link between atoms. When a chemical bond forms between two atoms the resulting arrangement of the two nuclei and their electrons has a lower energy than the total energy of the separate atoms. If the lowest energy can be achieved by the *complete transfer* of one or more electrons from each atom of one element to those of another, then ions form and the compound is held together by the electrostatic attraction between them. This attraction is called an **ionic bond.** Sodium and chlorine atoms, for example, bond together as ions because solid sodium chloride, which consists of Na^+ and Cl^- ions, has a lower energy than a collection of widely separated sodium and chlorine atoms. If the lowest energy can be achieved by *sharing* electrons, then the atoms link through a **covalent bond** and discrete molecules are formed. Hydrogen and nitrogen atoms bond together as molecules of ammonia, NH_3, for example, because a gas consisting of NH_3 molecules has a lower energy than a gas consisting of the same number of widely separated nitrogen and hydrogen atoms. A third type of bond is the **metallic bond,** in which large numbers of cations are held together by a sea of electrons. For example, a piece of copper consists of a stack of copper ions held together by a sea of electrons, each of which comes from one of the atoms in the sample (recall Fig. 1.53). We consider the metallic bond in more detail in Chapters 5 and 6. In this chapter we examine ionic and covalent bonds.

The changes in energy responsible for the formation of bonds occur when the **valence electrons** of atoms, the electrons in the outermost shells, move to new locations. Therefore, bond formation depends on the electronic structures of atoms discussed in Chapter 1.

IONIC BONDS

The **ionic model,** the description of bonding in terms of ions, is particularly appropriate for describing binary compounds formed from a metallic element, especially an s-block metal, and a nonmetallic element. An **ionic solid** is an assembly of cations and anions stacked together in a regular array. In sodium chloride, sodium ions alternate with chloride ions, and large numbers of oppositely charged ions are lined up in all three dimensions (Fig. 2.1). Ionic solids are examples of **crystalline solids,** or solids that consist of atoms, molecules, or ions stacked together in a regular pattern. We explore these patterns in Chapter 5; here we concentrate on the changes in the valence electrons that accompany the formation of ions and the energetics of the formation of ionic solids.

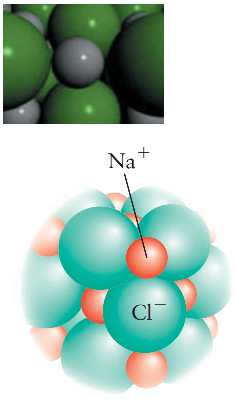

FIGURE 2.1 This tiny fragment of sodium chloride is an example of an ionic solid. The sodium ions are represented by pale red spheres and the chloride ions by green spheres. An ionic solid consists of an array of enormous numbers of cations and anions stacked together to give the lowest energy arrangement. The pattern shown here is repeated throughout the crystal.

Animation 2.1

2.1 The Ions That Elements Form

When an atom of a metallic element in the s-block forms a cation, it loses electrons down to its noble-gas core (Fig. 2.2). In general, that core has an ns^2np^6 outer electron configuration, which is called an **octet** of electrons. For example, sodium ([Ne]$3s^1$) loses its 3s-electron to form Na^+, which has the same electron configuration as neon, [Ne] or $1s^22s^22p^6$. The Na^+ ions cannot lose more electrons in a chemical reaction, because the ionization energies of core electrons are too high. Hydrogen loses an electron to form a bare proton. Lithium ([He]$2s^1$) and beryllium ([He]$2s^2$) lose their s-electrons, leaving a heliumlike **duplet,** a pair of electrons with the configuration $1s^2$, when they become Li^+ and Be^{2+}. Some typical electron configurations of atoms and the ions they form are shown in Table 2.1.

When the atoms of metals on the left of the p-block in Periods 2 and 3 lose their valence electrons, they form ions with the electron configuration of the preceding noble gas. Aluminum, [Ne]$3s^23p^1$, for instance, forms Al^{3+} with the same configuration as neon. However, when the metallic p-block elements in Period 4 and later periods lose their s- and p-electrons, they leave a noble-gas core surrounded by an additional, complete subshell of d-electrons. For instance, gallium forms the ion Ga^{3+} with the configuration [Ar]$3d^{10}$. The d-electrons of the p-block atoms are gripped tightly by the nucleus and, in most cases, cannot be lost.

In the d-block, when occupied by electrons, the $(n - 1)$d-orbitals lie below the ns-orbitals in energy. Therefore, the ns-electrons are lost first, followed by a variable number of $(n - 1)$d-electrons. For example, to obtain the configuration of the Fe^{3+} ion, we start from the configuration of the Fe atom, which is [Ar]$3d^64s^2$, and remove three electrons from it. The first two electrons removed are 4s-electrons. The third electron comes from the 3d-subshell, giving [Ar]$3d^5$.

Many metallic elements, such as those in the p- and d-blocks, have atoms that can lose a variable number of electrons. As we saw in Section 1.18, the inert-pair effect implies that the elements listed in Fig. 1.52 can lose either their valence p-electrons alone or all their valence p- and s-electrons. These elements and the d-block metals can form different compounds, such as tin(II) oxide, SnO, and tin(IV) oxide, SnO_2, for tin. The ability of an element to form ions with different charges is called **variable valence.**

Formulas of some common cations are shown in Fig. C.6.

EXAMPLE 2.1 Writing the electron configurations of cations

Write the electron configurations of (a) In^+ and (b) In^{3+}.

Anticipate Because In is in Group 13, with the "generic" electron configuration [core]s^2p^1, we can expect successive loss of the p-electron and then the two s-electrons to give the configurations [core]s^2 and [core], respectively.

PLAN Determine the configuration of the neutral atom from its position in the periodic table. Remove electrons from the valence-shell p-orbitals first, then from the s-orbitals, and finally, if necessary, from the d-orbitals in the next-lower shell, until the number of electrons removed equals the charge on the ion.

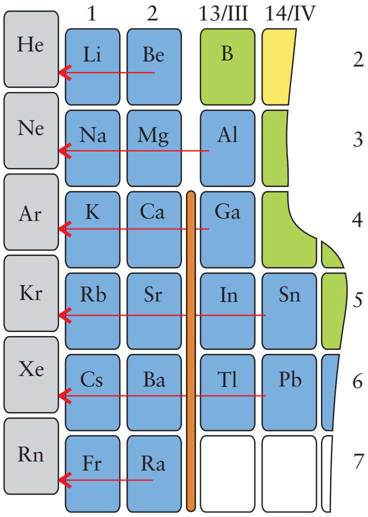

FIGURE 2.2 When a main-group metal atom forms a cation, it loses its valence s- and p-electrons and acquires the electron configuration of the preceding noble-gas atom. The heavier atoms in Groups 13/III and 14/IV retain their complete subshells of d-electrons.

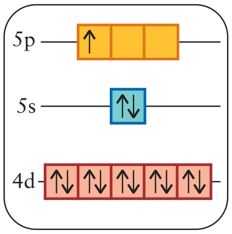
TABLE 2.1 Some Typical Electron Configurations of Atoms and the Ions They Form

Atom	Configuration	Ion	Configuration
Li	[He]$2s^1$	Li^+	[He] ($1s^2$)
Be	[He]$2s^2$	Be^{2+}	[He]
Na	[Ne]$3s^1$	Na^+	[Ne] ([He]$2s^22p^6$)
Mg	[Ne]$3s^2$	Mg^{2+}	[Ne]
Al	[Ne]$3s^23p^1$	Al^{3+}	[Ne]
N	[He]$2s^22p^3$	N^{3-}	[Ne] ([He]$2s^22p^6$)
O	[He]$2s^22p^4$	O^{2-}	[Ne]
F	[He]$2s^22p^5$	F^-	[Ne]
S	[Ne]$3s^23p^4$	S^{2-}	[Ar] ([Ne]$3s^23p^6$)
Cl	[Ne]$3s^23p^5$	Cl^-	[Ar]

SOLVE

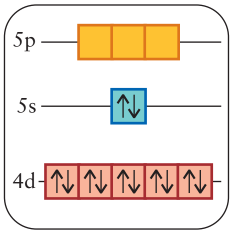
Determine the configuration of the neutral atom.

Indium is in Group 13/III, Period 5. Its ground-state configuration is therefore $[Kr]4d^{10}5s^25p^1$.



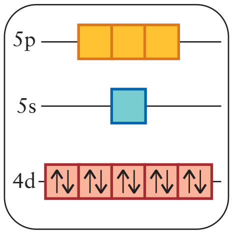
(a) Remove the outermost electron.

In^+ is $[Kr]4d^{10}5s^2$



(b) Remove the next two electrons.

In^{3+} is $[Kr]4d^{10}$



Evaluate As we anticipated from the location of the element in the periodic table, the two configurations have the form $[core]s^2$ (as in $[Kr]4d^{10}5s^2$) and [core] (as in $[Kr]4d^{10}$).

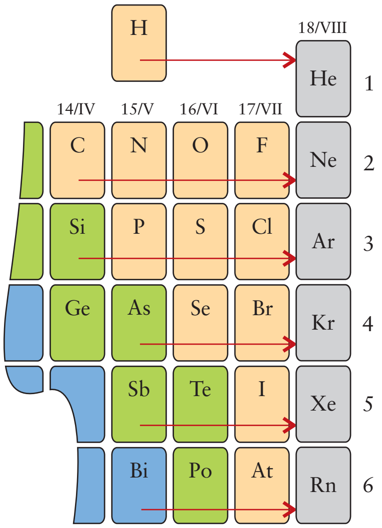


FIGURE 2.3 When nonmetal atoms acquire electrons and form anions, they do so until they have reached the electron configuration of the next noble gas.

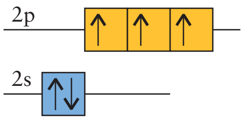
Self-Test 2.1A Write the electron configurations of (a) the copper(I) ion and (b) the copper(II) ion.

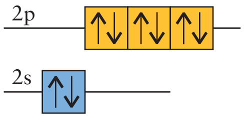
[*Answer:* (a) $[Ar]3d^{10}$, $[Ar]3d^9$]

Self-Test 2.1B Write the electron configurations of (a) the manganese(II) ion and (b) the lead(IV) ion.

Nonmetals rarely lose electrons in chemical reactions because their ionization energies are too high. However, a nonmetal atom can acquire enough electrons to complete its valence shell and form an anion with an octet corresponding to the configuration of the next noble gas ($1s^2$ in the case of the hydride ion, H^-), Fig. 2.3. It does not gain more electrons, because any additional electrons would have to be accommodated in a higher-energy shell. To form a monatomic anion, we add enough electrons to complete the valence shell. For example, nitrogen has five valence electrons (**1**); so three more electrons are needed to reach a noble-gas configuration, that of neon. Therefore, the nitride ion will be N^{3-} (**2**). Notice that in each case the ion has the electron configuration of the next noble gas.



1 N $[He]2s^22p^3$



2 N^{3-} $[He]2s^22p^6$

Self-Test 2.2A Predict the chemical formula and electron configuration of the phosphide ion.

[*Answer:* P^{3-}, $[Ne]3s^23p^6$]

Self-Test 2.2B Predict the chemical formula and electron configuration of the iodide ion.

The formulas of some common anions are shown in Fig. C.7.

To predict the electron configuration of a monatomic cation, remove outermost electrons in the order np, ns, and (n − 1)d; for a monatomic anion, add electrons until the next noble-gas configuration has been reached. The transfer of electrons results in the formation of an octet (or duplet) of electrons in the valence shell on each of the atoms: metals achieve an octet (or duplet) by electron loss and nonmetals achieve it by electron gain.

2.2 Lewis Symbols

Many of our basic ideas about the chemical bond were proposed by G. N. Lewis in the early years of the twentieth century. Lewis devised a simple way to keep track of valence electrons when atoms form ionic bonds. He represented each valence electron as a dot and arranged the dots around the symbol of the element. A single dot represents an electron alone in an orbital; a pair of dots represents two paired electrons sharing an orbital. Examples of the **Lewis symbols** of atoms are

H· He: :Ṅ· ·Ö· :C̈l· K· Mg:

The Lewis symbol for nitrogen, for example, represents the valence electron configuration $2s^2 2p_x^{\,1} 2p_y^{\,1} 2p_z^{\,1}$ (see **1**), with two electrons paired in a 2s-orbital and three unpaired electrons in different 2p-orbitals. The Lewis symbol is a visual summary of the valence-shell electron configuration of an atom and allows us to see what happens to the electrons when an ion forms.

To work out the formula of an ionic compound by using Lewis symbols:

- Represent the cation by removing the dots from the symbol for the metal atom.
- Represent the anion by transferring those dots to the Lewis symbol for the nonmetal atom to complete its valence shell.
- It might then be necessary to adjust the numbers of atoms of each kind so that all the dots removed from the metal atom symbols are accommodated by the nonmetal atom symbols.
- Write the charge of each ion as a superscript in the normal way, using brackets to indicate that the charge is the overall charge of the ion.

A simple example is the formula of calcium chloride. The calcium atom loses its two valence electrons when it forms the Ca^{2+} ion. Because each chlorine atom has one vacancy, two are required to accommodate the two electrons lost:

:C̈l· + Ca: + :C̈l· ⟶ :C̈l:$^-$ Ca^{2+} :C̈l:$^-$

The ratio of two chloride ions for each calcium ion results in the formula $CaCl_2$. However, note that this is an empirical formula (Section E). There are no $CaCl_2$ molecules. Crystals of $CaCl_2$ contain huge numbers of these ions in three-dimensional arrays.

Formulas of compounds consisting of the monatomic ions of main-group elements can be predicted by assuming that cations have lost all their valence electrons and anions have gained electrons in their valence shells until each ion has an octet of electrons, or a duplet in the case of H, Li, and Be.

2.3 The Energetics of Ionic Bond Formation

To understand why a crystal of sodium chloride, an ionic compound, has a lower energy than widely separated sodium and chlorine atoms, we picture the formation of the solid as taking place in three steps: sodium atoms release electrons, these electrons attach to chlorine atoms, and then the resulting cations and anions clump together as a crystal. Chemists often analyze complex processes by breaking them down into simpler steps, which can be hypothetical steps such as these.

Sodium is in Group 1 of the periodic table and can be expected to form a +1 ion. However, the valence electron is tightly held by the effective nuclear charge—it does not just fall off. In fact, the ionization energy of sodium is 494 $kJ \cdot mol^{-1}$ (see Fig. 1.51), and so we must supply that much energy to form the cations:

$$Na(g) \longrightarrow Na^+(g) + e^-(g) \qquad \text{energy required} = 494\ kJ \cdot mol^{-1}$$

The electron affinity of chlorine atoms is $+349\ \text{kJ·mol}^{-1}$ (see Fig. 1.54), and so we know that $349\ \text{kJ·mol}^{-1}$ of energy is *released* when electrons attach to chlorine atoms to form anions:

$$\text{Cl(g)} + \text{e}^-\text{(g)} \longrightarrow \text{Cl}^-\text{(g)} \qquad \text{energy released} = 349\ \text{kJ·mol}^{-1}$$

A positive electron affinity signifies a release of energy when an electron attaches to a gas-phase atom or ion (Section 1.18).

At this stage, the net change in energy (energy required − energy released) is $494 - 349\ \text{kJ·mol}^{-1} = +145\ \text{kJ·mol}^{-1}$, an *increase* in energy. A gas of widely separated Na^+ and Cl^- ions has a higher energy than a gas of neutral Na and Cl atoms.

Now consider what happens when gaseous Na^+ and Cl^- ions come together to form a crystalline solid. Their mutual attraction releases a lot of energy, and experimentally it is found that

$$\text{Na}^+\text{(g)} + \text{Cl}^-\text{(g)} \longrightarrow \text{NaCl(s)} \qquad \text{energy released} = 787\ \text{kJ·mol}^{-1}$$

Therefore, the net change in energy for the overall process

$$\text{Na(g)} + \text{Cl}^-\text{(g)} \longrightarrow \text{NaCl(s)}$$

is $145 - 787\ \text{kJ·mol}^{-1} = -642\ \text{kJ·mol}^{-1}$ (Fig. 2.4), a huge *decrease* in energy. We conclude that a solid composed of Na^+ and Cl^- ions has a lower energy than does a collection of widely separated Na and Cl atoms.

We can now begin to understand the formation of ionic bonds and learn when to expect them. There is a net lowering of energy below that of the individual atoms, provided the net attraction between ions is greater than the energy needed to make them. The major contribution to the energy requirement is normally the ionization energy of the element that forms the cation. Although some of this energy may be recovered from the electron affinity of the nonmetal when the anion is formed, in some cases energy is also needed to make the anion. For instance, we saw in Section 1.17 that the formation of an O^{2-} ion from an O atom *requires* $703\ \text{kJ·mol}^{-1}$ and adds to the energy that must be recovered from the interactions between ions. Typically, *only metallic elements have ionization energies that are low enough for the formation of ionic bonds to be energetically feasible.*

The energy required for the formation of ionic bonds is supplied largely by the attraction between oppositely charged ions.

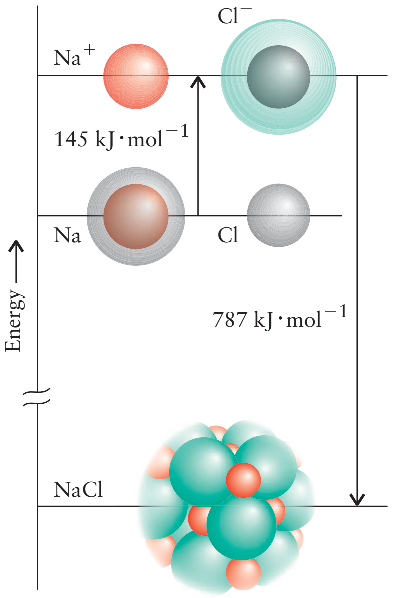


FIGURE 2.4 Considerable energy is needed to produce cations and anions from neutral atoms: the ionization energy of the metal atoms is only partly recovered from the electron affinity of the nonmetal atoms. The overall lowering of energy that drags the ionic solid into existence arises from the strong attraction between cations and anions that occurs in the solid. In Chapter 7, we discuss the actual chemical reaction between Na(s) and Cl_2(g): this illustration is for the energies of Na(g) and Cl(g) relative to the energy of NaCl(s).

2.4 Interactions Between Ions

We have seen that a key contribution to the formation of ionic bonds is the strength of the interaction between ions in a solid: it must be strong enough to overcome the energy investment needed to make the ions. However, a very important point to note is that an ionic solid is not held together by bonds between specific pairs of ions: *all* the cations interact to a greater or lesser extent with *all* the anions, *all* the cations repel each other, and *all* the anions repel each other. An ionic bond is a "global" characteristic of the entire crystal, a net lowering of energy of the entire crystal. By assessing this interaction quantitatively we can see what determines the **lattice energy** of the solid, the difference in energy between the ions packed together in a solid and the ions widely separated as a gas. High lattice energy indicates that the ions interact strongly with one another to give a tightly bonded solid.

The strong electrostatic interactions between charged ions account for the typical properties of ionic solids, such as their high melting points and their brittleness. A high temperature is required before the ions are able to move past one another to form a liquid. Ionic solids are brittle because of the same strong attractions and repulsions. We cannot just push a block of ions in one region of the crystal past the ions in a neighboring region: when we strike an ionic solid, ions with like charges come into contact and repel one another. The resulting repulsions cause it to shatter into fragments (Fig. 2.5).

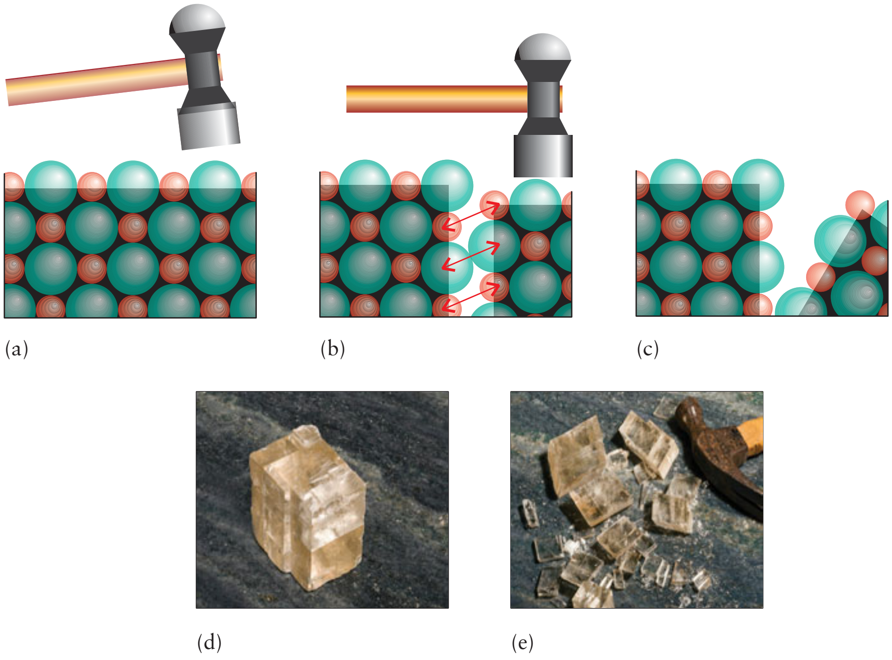

FIGURE 2.5 This sequence of images illustrates why ionic solids are brittle. (a) The original solid consists of an orderly array of cations and anions. (b) A hammer blow can push ions with like charges into adjacent positions; this proximity of like charges raises strong repulsive forces (as depicted by the double-headed arrows). (c) As the result of these repulsive forces, the solid breaks apart into fragments. (d) The smooth faces of this calcite crystal result from the regular arrangement of the calcium and carbonate ions. (e) The blow of a hammer has shattered the crystal, leaving flat, regular surfaces consisting of planes of ions. Compare this image with the result of striking a metallic crystal (Fig. 6.2).

Our starting point for understanding the interaction between ions in a solid is the expression for the Coulomb potential energy of the interaction of two individual ions (Section B):

$$E_{p,12} = \frac{(z_1 e) \times (z_2 e)}{4\pi\varepsilon_0 r_{12}} = \frac{z_1 z_2 e^2}{4\pi\varepsilon_0 r_{12}} \qquad \textbf{(1)*}$$

In this expression, e is the fundamental charge (the absolute value of the charge of an electron), z_1 and z_2 are the charge numbers of the two ions, r_{12} is the distance between the centers of the ions, and ε_0 ("epsilon zero") is the vacuum permittivity (see inside the back cover for the value of this fundamental constant).

A note on good practice: The charge number, z, is positive for cations and negative for anions and the charge of an ion is ze. However, chemists almost always refer to z itself as the charge, and speak of a charge of +1, −1, and so on.

Each ion in a solid experiences attractions from all the other oppositely charged ions and repulsions from all the other like-charged ions. The total potential energy is the sum of all these contributions. Each cation is surrounded by anions, and there is a large negative (energy-lowering) contribution from the attraction of the opposite charges. Beyond those nearest neighbors, there are cations that contribute a positive (repulsive, energy-raising) term to the total potential energy of the central cation. There is also a negative contribution from the anions beyond those cations, a positive contribution from the cations beyond them, and so on, to the edge of the solid. These repulsions and attractions become progressively weaker as the distance from the central ion increases, but because the nearest neighbors of an ion give rise to a strong attraction, the net outcome of all these contributions is a lowering of energy. Our task is to assess how far the energy is lowered by using the Coulomb potential energy expression in Eq. 1.

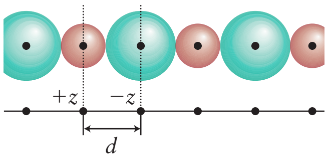

FIGURE 2.6 The arrangement used to calculate the potential energy of an ion in a line of alternating cations (red spheres) and anions (green spheres). We concentrate on one ion, the "central" ion denoted by the vertical dotted line.

HOW DO WE DO THAT?

To calculate the electrostatic potential energy of an ionic solid we start with a simple model: a single line of uniformly spaced alternating cations and anions, with d the distance between their centers, the sum of the ionic radii (Fig. 2.6). If the charge numbers of the ions have the same absolute value (+1 and −1, or +2 and −2, for instance), then $z_1 = +z$,

$z_2 = -z$, and $z_1 z_2 = -z^2$. The potential energy of the central ion is calculated by summing all the Coulomb potential energy terms, with negative terms representing attractions to oppositely charged ions and positive terms representing repulsions from like-charged ions. For the interaction arising from ions extending in a line to the right of the central ion, the total potential energy of the central ion is

$$\begin{aligned} E_p &= \frac{e^2}{4\pi\varepsilon_0} \times \left(-\frac{z^2}{d} + \frac{z^2}{2d} - \frac{z^2}{3d} + \cdots\right) \\ &= -\frac{z^2e^2}{4\pi\varepsilon_0 d}\left(1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \cdots\right) = -\frac{z^2e^2}{4\pi\varepsilon_0 d} \times \ln 2 \end{aligned}$$

In the last step, we have used the relation $1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \ldots = \ln 2$. Next, we multiply E_p by 2 to obtain the total energy arising from interactions with ions on each side of the ion. We then multiply by Avogadro's constant, N_A, to obtain the potential energy per mole of ions. At this point, we know the total potential energy per mole of ions of one kind (cations, for instance) is

$$E_p(\text{cations}) = -2\ln 2 \times \frac{N_A z^2 e^2}{4\pi\varepsilon_0 d}$$

The same expression applies to the energy per mole of the anions present:

$$E_p(\text{anions}) = -2\ln 2 \times \frac{N_A z^2 e^2}{4\pi\varepsilon_0 d}$$

However, we cannot simply add the two expressions together to get the total potential energy, for in doing so we would count each interaction (Jack with Jill, Jill with Jack) twice. Therefore, the total energy per mole of pairs of ions is half this sum, which is

$$E_p = \frac{1}{2}\{E_p(\text{cations}) + E_p(\text{anions})\} = -2\ln 2 \times \frac{N_A z^2 e^2}{4\pi\varepsilon_0 d}$$

with $d = r_{\text{cation}} + r_{\text{anion}}$ the distance between the centers of neighboring ions.

We have found that the molar potential energy of a one-dimensional crystal in which cations and anions alternate along a line has the form

$$E_p = -A \times \frac{N_A z^2 e^2}{4\pi\varepsilon_0 d} \qquad (2)$$

with $A = 2\ln 2$ (or 1.386) for this model system.

What does this equation tell us? Because the potential energy is negative, there is a net lowering of energy, which means that the attraction between opposite charges overcomes the repulsion between like charges. The potential energy is strongly negative when the ions are highly charged (large values of z) and the separation between them is small (small values of d), which is the case when the ions themselves are small.

The calculation that led to Eq. 2 can be extended to more realistic three-dimensional arrays of ions with different charges. The result has the same form but with different values of A and $|z_1 z_2|$ (that is, the absolute value of $z_1 z_2$, its value without the negative sign) in place of z^2. The factor A is a numerical coefficient called the **Madelung constant**; its value depends on how the ions are arranged about one another (Table 2.2). In all cases, the energy lowering that occurs when an ionic solid forms is greatest for small, highly charged ions. For example, there is a strong interaction between the Mg^{2+} and the O^{2-} ions in magnesium oxide, MgO, because the ions have high charges and small radii. This strong interaction is one reason why magnesium oxide survives at such high temperatures that it can be used for furnace linings. It is an example of a "refractory" material, a substance that can withstand high temperatures.

TABLE 2.2 Madelung Constants

Structural type*	A
cesium chloride	1.763
fluorite	2.519
rock salt	1.748
rutile	2.408

*For information about these structures, see Chapter 5.

EXAMPLE 2.2 **Estimating the relative lattice energies of solids**

The ionic solids NaCl and KCl form the same type of crystal structure. In which solid are the ions bound together more strongly by coulombic interactions?

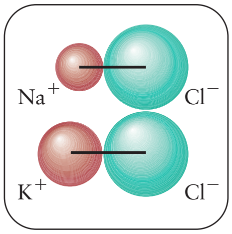
Anticipate Because sodium lies above potassium in the same group, we anticipate that the ionic radius of sodium is less than that of potassium and, therefore, that NaCl is more strongly bonded than KCl.

PLAN Compare the radii of the ions (Fig. 1.48), for they determine the size of the separation *d*.

SOLVE

We compare the radii:

The radius of Na^+ is 102 pm and that of K^+ is 138 pm; the radius of Cl^- is 181 pm.



Evaluate As we anticipated, the ions in NaCl should be bound together more strongly than those in KCl because the Na^+ ion has a smaller radius than the K^+ ion and so *d* is smaller in NaCl than in KCl.

Self-Test 2.3A The ionic solids CaO and KCl crystallize to form structures of the same type. In which compound are the interactions between the ions stronger?

[***Answer:*** CaO, higher charges and smaller radii]

Self-Test 2.3B The ionic solids KBr and KCl crystallize to form structures of the same type. In which compound are the interactions between ions stronger?

The potential energy in Eq. 2 becomes more and more negative as the separation *d* decreases. However, a collection of ions does not collapse to a point because repulsive effects between neighbors become important as soon as they come into contact, and the energy quickly rises again. To take the repulsion effects between close neighbors in an ionic solid into account it is commonly supposed that the repulsive contribution to the potential energy rises exponentially with decreasing separation and therefore has the form

$$E_p^* \propto e^{-d/d^*}$$

with d^* a constant (it is commonly taken to be 34.5 pm). The total potential energy is the sum of E_p and E_p^* and passes through a minimum as the ion separation decreases and then rises sharply again (Fig. 2.7). The energy at the minimum is given by the **Born–Mayer equation** (which we do not derive here):

$$E_{p,min} = -A \times \frac{N_A|z_1z_2|e^2}{4\pi\varepsilon_0 d}\left(1 - \frac{d^*}{d}\right) \qquad (3)^*$$

What does this equation tell us? As before, the negative sign of this potential energy tells us that the ions have a lower potential energy when they are present as a solid rather than widely separated as a gas. The greatest stabilization is expected when the ions are highly charged (so $|z_1z_2|$ is large) and small (so *d* is small, but not smaller than d^*).

We can now see why nature has adopted an ionic solid, calcium phosphate, for our skeletons: the doubly charged small Ca^{2+} ions and the triply charged PO_4^{3-} ions attract one another very strongly and clump together tightly to form a rigid, insoluble solid (Fig. 2.8).

Ionic solids typically have high melting points and are brittle. The coulombic interaction between ions in a solid is large when the ions are small and highly charged.

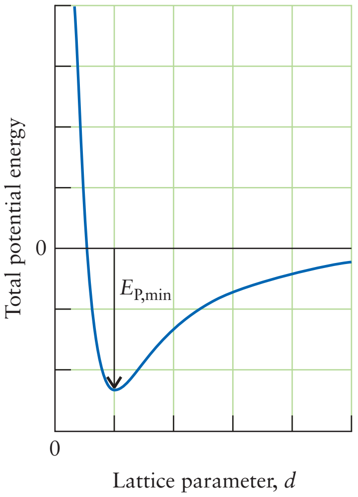


FIGURE 2.7 The potential energy of an ionic solid, taking into account the coulombic interaction of the ions and the exponential increase in their repulsion when they are in contact. The minimum potential energy is given by the Born–Mayer equation, Eq. 3.

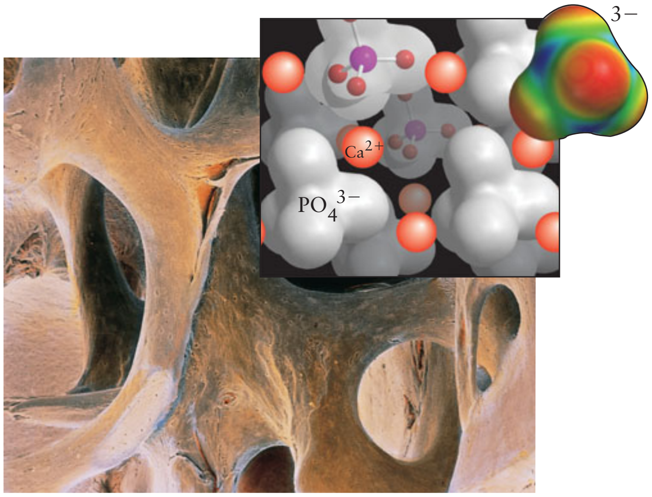

FIGURE 2.8 A micrograph of bone, which owes its rigidity to calcium phosphate. The overlay shows part of the crystal structure of calcium phosphate. Phosphate ions are polyatomic ions; however, as shown in the inset, they are nearly spherical and fit into crystal structures in much the same way as monatomic ions of charge −3.

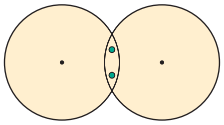
COVALENT BONDS

Because nonmetals do not form monatomic cations, the nature of bonds between atoms of nonmetals puzzled scientists until 1916, when Lewis published his explanation. With brilliant insight, and before anyone knew about quantum mechanics or orbitals, Lewis proposed that a **covalent bond** is a pair of electrons shared between two atoms (**3**). The rest of this chapter and the next develop Lewis's vision of the covalent bond. In this chapter, we consider the types, numbers, and properties of bonds that can be formed by sharing pairs of electrons. In Chapter 3, we see how to understand Lewis's concept in terms of orbitals.



3 Shared electron pair

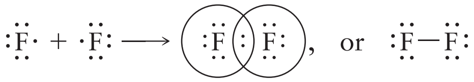
2.5 Lewis Structures

When ionic bonds form, the atoms of one element lose electrons and the atoms of the second element gain them until both types of atoms have reached a noble-gas configuration. The same idea can be extended to covalent bonds. However, when a covalent bond forms, atoms *share* electrons until they reach a noble-gas configuration. Lewis called this principle the **octet rule:**

> ***In covalent bond formation, atoms go as far as possible toward completing their octets by sharing electron pairs.***

For example, nitrogen (:Ṅ·) has five valence electrons and needs three more electrons to complete its octet. Chlorine (:C̈l·) has seven valence electrons and needs one more electron to complete its octet. Argon (:Är:) already has a complete octet and has no tendency to share any more electrons. Hydrogen (H·) needs one more electron to reach its helium-like duplet. Because hydrogen completes its duplet by sharing one pair of electrons, we say that it has "a valence of 1" in all its compounds. In general, the **valence** of an element is the number of bonds that its atoms can form.

We can extend the Lewis symbols introduced in Section 2.2 to describe covalent bonding by using a line (—) to represent a shared pair of electrons. For example, the hydrogen molecule formed when two H· atoms share an electron pair (H:H) is represented by the symbol H—H. A fluorine atom has seven valence electrons and needs one more to complete its octet. It can achieve an octet by accepting a share in an electron supplied by another atom, such as another fluorine atom:



The circles drawn around each F atom show how each one gets an octet by sharing one electron pair. The valence of fluorine is therefore 1, the same as that of hydrogen.

As well as a bonding pair of electrons, a fluorine molecule also possesses **lone pairs** of electrons; that is, pairs of valence electrons that do not take part in bonding. The lone pairs on one F atom repel the lone pairs on the other F atom, and this repulsion is

almost enough to overcome the favorable attractions of the bonding pair that holds the atoms together. This repulsion is one of the reasons why fluorine gas is so reactive: the atoms are bound together as F_2 molecules only very weakly. Among the common diatomic molecules, only H_2 has no lone pairs.

It is sometimes necessary to write a Lewis structure at the end of a sentence or clause: be careful to distinguish electron dots from periods and colons!

The **Lewis structure** of a molecule shows atoms by their chemical symbols, covalent bonds by lines, and lone pairs by pairs of dots. For example, the Lewis structure of HF is H—F̤̈: .We shall see that Lewis structures are a great help in understanding the properties of molecules, including their shapes and the reactions that they can undergo.

Self-Test 2.4A Write the Lewis structure for the "interhalogen" compound chlorine monofluoride, ClF, and state how many lone pairs each atom possesses in the compound.

[*Answer*: :C̤̈l—F̤̈: ; three on each atom]

Self-Test 2.4B Write the Lewis structure for the compound HBr and state how many lone pairs each atom in the compound possesses.

Nonmetal atoms share electrons until each has completed its octet (or duplet); a Lewis structure shows the arrangement of electrons as lines (bonding pairs) and dots (lone pairs).

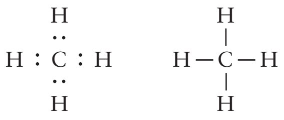
2.6 Lewis Structures of Polyatomic Species

Each atom in a polyatomic molecule completes its octet (or duplet for hydrogen) by sharing pairs of electrons with its immediate neighbors. Each shared pair counts as one covalent bond and is represented by a line between the two atoms. A Lewis structure does not in general portray the three-dimensional shape of a polyatomic molecule; it simply displays which atoms are bonded together and which atoms have lone pairs.

Let's construct the Lewis structure for the simplest organic molecule, the hydrocarbon methane, CH_4. First, we count the valence electrons available from all the atoms in the molecule. For methane, the Lewis symbols of the atoms are

:Ċ̣ H· H· H· H·

and so there are eight valence electrons. The next step is to arrange the dots representing the electrons so that the C atom has an octet and each H atom has a duplet. We draw the arrangement shown on the left in (4); the Lewis structure of methane is then drawn as shown on the right in (4). Because the carbon atom is linked by four bonds to other atoms, we say that carbon is *tetravalent*: it has a valence of 4. We emphasize once again that a Lewis structure does not in general show the shape of the molecule, just the pattern of bonds, its "connectivity." In Chapter 3, we shall see that the three-dimensional arrangement of bonds in a methane molecule is in fact tetrahedral.



4 Methane, CH_4

The general procedure for constructing the Lewis structure of any molecule or ion is set out in Toolbox 2.1 at the end of this section, but the following information is essential for applying those rules.

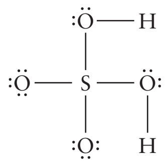
A single shared pair of electrons is called a **single bond.** Two electron pairs shared between two atoms constitute a **double bond**, and three shared electron pairs constitute a **triple bond**. A double bond, such as C::O, is written C═O in a Lewis structure. Similarly, a triple bond, such as C:::C, is written C≡C. Double and triple bonds are collectively called **multiple bonds.** The **bond order** is the number of bonds that link a specific pair of atoms. The bond order in H_2 is 1; in the group C═O, it is 2; and for C≡C in a molecule such as ethyne, C_2H_2, the bond order is 3.

To write a Lewis structure, we need to know which atoms are linked together in a molecule. A "terminal" atom is bonded to only one other atom; an H atom in methane is an example. Except in the strange compounds called the boranes (Section 15.11), an H atom is always a terminal atom. A "central" atom is bonded to at least two other atoms. Two examples are the O atom in a water molecule, HOH, and the C atom in methane. The arrangement of atoms in a molecule and the identity of the central atom are often known in advance (for instance, it is easy to remember the arrangements of

atoms in CH_4, NH_3, and H_2O). If there is doubt, a good rule of thumb for molecules other than compounds of hydrogen is to *choose as the central atom the element with the lowest ionization energy*. This arrangement often results in the lowest energy because an atom in the central position shares more of its electrons than does a terminal atom. Atoms with higher ionization energies are more reluctant to share and are more likely to hold on to their electrons as lone pairs.

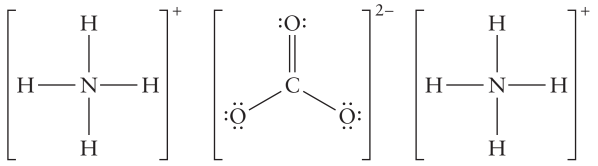
Another rule of thumb for predicting the structure of a molecule is to *arrange the atoms symmetrically around the central atom*. For instance, SO_2 is OSO, not SOO. One common exception to this rule is dinitrogen monoxide, N_2O (nitrous oxide), which has atoms in the asymmetrical arrangement NNO. Another clue for writing the correct arrangement of atoms is that, in simple chemical formulas, the central atom is often written first, followed by the atoms attached to it. For example, in the compound with the chemical formula OF_2, the arrangement of the atoms is actually FOF, not OFF; and, in SF_6, the S atom is surrounded by six F atoms. Acids are exceptions to this rule, because the H atoms are written first, as in H_2S, which has the arrangement HSH. If the compound is an oxoacid, then the acidic hydrogen atoms are attached to oxygen atoms, which in turn are attached to the central atom. For example, the arrangement of atoms in sulfuric acid, H_2SO_4, is $(HO)_2SO_2$ (**5**), and that in hypochlorous acid, with the formula HClO, is actually HOCl.

In Section 2.12, when we have met the concept of electronegativity, we shall see that another and more common way to express this rule is to say that the central atom is usually the element with lowest electronegativity.



5

Finally, the same general procedure is used to determine the Lewis structures of polyatomic ions, except that we add or subtract electrons to account for the charge on the ion. We count the electrons available for bonds and lone pairs, arrange the atoms in the appropriate order, and then construct the Lewis structure. As for neutral molecules, it is essential to know the general arrangement of atoms in the ion. For oxoanions, it is usually the case that (except for H) the atom written first in the chemical formula is the central atom. In CO_3^{2-}, for instance, the C atom is surrounded by three O atoms. Each atom provides the number of dots (electrons) equal to the number of electrons in its valence shell, but we have to adjust the total number of dots to represent the overall charge. For a cation, we subtract one dot for each positive charge. For an anion, we add one dot for each negative charge. The cation and the anion must be treated separately: they are individual ions and are not linked by shared pairs. The Lewis structure of ammonium carbonate, $(NH_4)_2CO_3$, for instance, is written as three bracketed ions (**6**).



6

TOOLBOX 2.1 HOW TO WRITE THE LEWIS STRUCTURE OF A POLYATOMIC SPECIES

CONCEPTUAL BASIS

We look for ways of using all the valence electrons to complete the octets (or duplets).

PROCEDURE

Step 1 Count the number of valence electrons on each atom; for ions adjust the number of electrons to account for the charge. Divide the total number of valence electrons in the molecule by 2 to obtain the number of electron pairs.

Step 2 Write down the most likely arrangements of atoms by using common patterns and the clues indicated in the text.

Step 3 Place one electron pair between each pair of bonded atoms.

Step 4 Complete the octet (or duplet, in the case of H) of each atom by placing any remaining electron pairs around the atoms. If there are not enough electron pairs, form multiple bonds.

Step 5 Represent each bonded electron pair by a line.

To check on the validity of a Lewis structure, verify that each atom has an octet or a duplet. As we shall see in Section 2.10, a common exception to this rule arises when the central atom is an atom of an element in Period 3 or higher. Such an atom can accommodate more than eight electrons in its valence shell. Consequently, the most stable Lewis structure may be one in which the central atom has more than eight electrons.

This procedure is illustrated in Examples 2.3 and 2.4.

EXAMPLE 2.3 **Writing the Lewis structure of a molecule or an ion**

Write the Lewis structures of (a) water, H_2O; (b) methanal, H_2CO; and (c) the chlorite ion, ClO_2^-. Use the rules in Toolbox 2.1; note that we must add one electron for the negative charge of ClO_2^-.

Anticipate It is hard to anticipate Lewis structures when you are starting out in your studies, but as you gain experience, you will be able to write them down without going through the systematic procedure used here.

PLAN Go through the steps set out in the Toolbox.

SOLVE

	(a) H_2O	(b) H_2CO	(c) ClO_2^-
Step 1 Count the valence electrons and adjust the number for charges on ions.	1 + 1 + 6 = 8	1 + 1 + 4 + 6 = 12	7 + 6 + 6 + 1 = 20
Count the electron pairs.	4	6	10
Step 2 Arrange the atoms.	H O H	H C O H	O Cl O
Step 3 Connect the atoms with bonding electron pairs.	H : O : H	H : C : O : H	O:Cl:O
Count electron pairs not yet located.	: : (2)	: : : (3)	: : : : : : : : (8)
Step 4 Complete the octets.	H : $\ddot{O}$: H (with lone pairs on O)	H : C : : $\ddot{O}$ (with lone pairs on O) : H	$[:\ddot{O}:\ddot{Cl}:\ddot{O}:]^-$
Step 5 Represent the bonds.	H—$\ddot{O}$—H (with lone pairs on O)	H | C=$\ddot{O}$ (with lone pairs on O) | H	$[:\ddot{O}—\ddot{Cl}—\ddot{O}:]^-$

Self-Test 2.5A Write a Lewis structure for the cyanate ion, CNO^- (the C atom is in the center).

[*Answer:* $[\ddot{N}{=}C{=}\ddot{O}]^-$]

Self-Test 2.5B Write a Lewis structure for NH_3.

EXAMPLE 2.4 **Writing Lewis structures for molecules with more than one "central" atom**

Write the Lewis structure for acetic acid, CH_3COOH, the carboxylic acid in vinegar that forms when the ethanol in wine is oxidized. In the —COOH group, both O atoms are attached to the same C atom, and one of them is bonded to the final H atom. The two C atoms are bonded to each other.

Anticipate The formula of acetic acid suggests that the molecule consists of a CH_3— group and a —COOH group. We can anticipate that the CH_3— group, by analogy with methane, will consist of a C atom joined to three H atoms by single bonds.

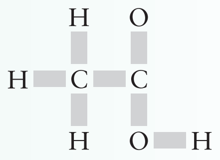
PLAN Apply the procedure in Toolbox 2.1.

SOLVE

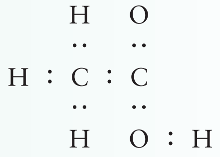
	CH_3COOH
Step 1 Count the valence electrons to determine the number of electron pairs:	: : : : : : : : : : : :

4 + (3 × 1) + 4 + 6 + 6 + 1 = 24, 12 pairs

Step 2 Arrange atoms (linked atoms are indicated by the rectangles).

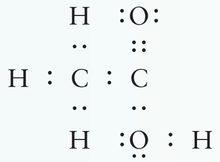


Step 3 Connect the atoms with bonding electron pairs.

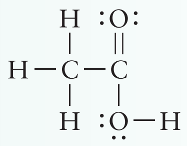


Count electron pairs not yet located. : : : : : (5 pairs)

Step 4 Complete the octets.

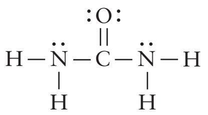


Step 5 Represent the bonds.



Self-Test 2.6A Write a Lewis structure for the urea molecule, $(NH_2)_2CO$.

[*Answer:* See (7).]



7 Urea, $(NH_2)_2CO$

Self-Test 2.6B Write a Lewis structure for hydrazine, H_2NNH_2.

The Lewis structure of a polyatomic species is obtained when all the valence electrons are used to complete the octets (or duplets) of the atoms present by forming single or multiple bonds and leaving some electrons as lone pairs.

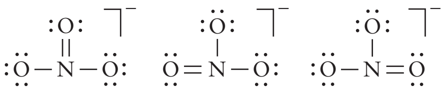
2.7 Resonance

Some molecules are not represented adequately by a single Lewis structure. For example, consider the nitrate ion, NO_3^-, which, as potassium nitrate, is used in fireworks and fertilizers. The three Lewis structures shown in (8) differ only in the position of the double bond. All are valid structures and have exactly the same energy. If one of the pictured structures were correct, we would expect the nitrate ion to have two long single bonds and one short double bond because a double bond between two atoms is shorter than a single bond between the same types of atoms. However, detailed measurements have shown that the bond lengths in a nitrate ion are all the same. At 124 pm, they are longer than a typical N=O double bond (120 pm) but shorter than a typical N—O single bond (140 pm). The bond order in the nitrate ion lies between 1 (a single bond) and 2 (a double bond).

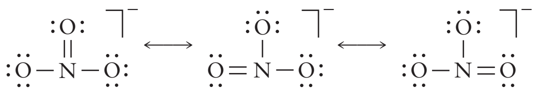
Bond length, the distance between the centers of bonded atoms, is discussed in more detail in Section 2.16.

Thinking point: How do you think lengths as short as 120 pm could be measured? (For an answer, see Box 2.2.)

Because all three bonds are identical, a better model of the nitrate ion is a *blend* of all three Lewis structures with each bond intermediate in properties between a single and a double bond. This blending of structures, which is called **resonance**, is depicted in (9) by double-headed arrows. The blended structure is a **resonance hybrid** of the



8



9 Nitrate ion, NO_3^-

contributing Lewis structures. A molecule does not flicker between different structures: a resonance hybrid is a blend of structures, just as a mule is a blend of a horse and a donkey, not a creature that flickers between the two.

Electrons that are shown in different positions in a set of resonance structures are said to be **delocalized.** Delocalization means that a shared electron pair is distributed over several pairs of atoms and cannot be identified with just one pair of atoms. As well as delocalizing electrons over the atoms, resonance also lowers the energy below that of any single contributing structure and helps to stabilize the molecule. This lowering of energy occurs for quantum mechanical reasons. Broadly speaking, the wavefunction that describes the resonance structure is a more accurate description of the electronic structure of the molecule than the wavefunction for any single structure alone, and the more accurate the wavefunction, the lower the corresponding energy.

The following points will help you to write appropriate resonance structures and to predict which are more important:

- In each contributing structure, the nuclei are in the same positions; only the locations of lone pairs and bonding pairs are changed.
- Structures with the same energy (so called "equivalent structures") contribute equally to the resonance.
- Low-energy structures contribute more to the resonance mixture than high-energy structures.

For example, although we might be able to write the two hypothetical structures NNO and NON for the dinitrogen oxide (nitrous oxide) molecule, there is no resonance between them, because the atoms lie in different locations.

EXAMPLE 2.5 Writing a resonance structure

Stratospheric ozone, O_3, protects life on Earth from harmful ultraviolet radiation from the Sun. Suggest two Lewis structures that contribute equally to the resonance structure for the O_3 molecule. Experimental data show that the two bond lengths are the same.

PLAN Write a Lewis structure for the molecule by using the method outlined in Toolbox 2.1. Decide whether there is another equivalent structure that results from the interchange of a single bond and a double or triple bond. Write the actual structure as a resonance hybrid of these Lewis structures.

SOLVE

Count the valence electrons.	
Oxygen is a member of Group 16/VI; so each atom has six valence electrons: 6 + 6 + 6 = 18 electrons.	
Draw a Lewis structure for the molecule.	Draw a second Lewis structure by exchanging the bonds.	Draw the resonance hybrid as the two resonance structures connected with a double-headed arrow.	

10 Acetate ion, $CH_3CO_2^-$

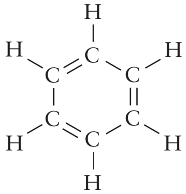
Self-Test 2.7A Write Lewis structures contributing to the resonance hybrid for the acetate ion, $CH_3CO_2^-$. The structure of CH_3COOH is described in Example 2.4; the acetate ion has a similar structure, except that it has lost the final H atom while keeping both electrons from the OH bond.

[*Answer:* See (**10**).]

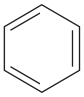
FIGURE 2.9 When bromine dissolved in a solvent (the brown liquid) is mixed with an alkene (the colorless liquid), the bromine atoms add to the alkene molecule at the double bond, resulting in colorless products.

Self-Test 2.7B Write Lewis structures contributing to the resonance hybrid for the nitrite ion, NO_2^-.

Benzene, C_6H_6, is another molecule best described as a resonance hybrid. It consists of a planar hexagonal ring of six carbon atoms, each one having a hydrogen atom attached to it. One Lewis structure that contributes to the resonance hybrid is shown in (**11**); it is called a **Kekulé structure.** The structure is normally written as a line structure (see Section C), a simple hexagon with alternating single and double lines (**12**).



11 Kekulé structure



12 Kekulé structure, stick form

The difficulty with a single Kekulé structure is that it does not fit all the experimental evidence:

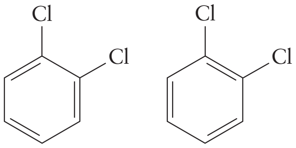
- *Reactivity* Benzene does not undergo reactions typical of compounds with double bonds.

The German chemist Friedrich Kekulé first proposed (in 1865) that benzene has a cyclic structure with alternating single and double bonds.

For example, when a solution of red-brown bromine is mixed with an alkene such as 1-hexene, $CH_2{=}CHCH_2CH_2CH_2CH_3$, the color due to bromine is lost as the Br_2 molecule reacts with the molecule at the double bond to produce $CH_2Br{-}CHBrCH_2CH_2CH_2CH_3$ (Fig. 2.9). However, benzene does not react with liquid bromine.

- *Bond lengths* All the carbon–carbon bonds in benzene are the same length.

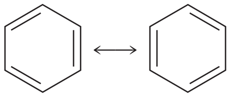
A Kekulé structure suggests that benzene should have two different bond lengths: three longer single bonds (154 pm) and three shorter double bonds (134 pm). Instead, all the bonds are found experimentally to have the same intermediate length (139 pm).



13 Dichlorobenzene, $C_6H_4Cl_2$

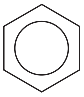
- *Structural evidence* Only one 1,2-dichlorobenzene (in which the chlorine atoms are attached to two adjacent carbon atoms) exists.

If the Kekulé structure were correct, there would be two distinct 1,2-dichlorobenzenes (**13**), one in which the carbon atoms are joined by a single bond and one with a double bond. In fact, only one 1,2-dichlorobenzene is known.



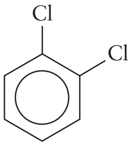
14 Benzene resonance structure

We can use the concept of resonance to explain these characteristics of the benzene molecule. There are two Kekulé structures with exactly the same energy: they differ only in the positions of the double bonds. As a result of resonance between these two equivalent structures (**14**), the electrons shared in the C=C double bonds are delocalized over the whole molecule, thereby giving each bond a length intermediate between that of a single and that of a double bond. Resonance makes all six C—C bonds identical; this equivalence is implied by representing the double bonds in the resonance hybrid with a circle (**15**). We can see from (**16**) why there can be only one 1,2-dichlorobenzene. Finally, as we have remarked, an important consequence of resonance is that it stabilizes a molecule by lowering its total energy. This stabilization makes benzene less reactive than expected for a molecule with three carbon–carbon double bonds.



15 Benzene, C_6H_6

Other arrangements may be drawn, but they differ from the one shown only by a rotation of the molecule.



16 1,2-Dichlorobenzene, $C_6H_4Cl_2$

Resonance is a blending of structures with the same arrangement of atoms but different arrangements of electrons. It spreads multiple bond character over a molecule and results in a lower energy.

2.8 Formal Charge

Nonequivalent Lewis structures—Lewis structures that do not correspond to the same energy—do not in general make the same contribution to a resonance structure. One way to decide which structures are likely to make the major contribution is to compare the number of valence electrons distributed around each atom in a structure with the

number of valence electrons on the free atoms. The smaller these differences for a structure, the lower is its energy and the greater is its contribution to a resonance hybrid.

A measure of the redistribution of electrons is the **formal charge** on an atom in a given Lewis structure, the charge it would have if the bonding were perfectly covalent in the sense that the atom had exactly a half-share in the bonding electrons. That is, the formal charge takes into account the number of electrons that an atom can be regarded as "owning" in a molecule. It "owns" all its lone pairs and half of each shared bonding pair. The difference between this number and the number of valence electrons in the free atom is the formal charge:

$$\text{Formal charge} = V - (L + \tfrac{1}{2}B) \qquad \textbf{(4)*}$$

where V is the number of valence electrons in the free atom, L is the number of electrons present on the bonded atom as lone pairs, and B is the number of bonding electrons on the atom. If the atom has more electrons in the molecule than when it is a free, neutral atom, then the atom has a negative formal charge, like a monatomic anion. If the assignment of electrons leaves the atom with fewer electrons than when it is free, then the atom has a positive formal charge, as if it were a monatomic cation.

Formal charge can be used to predict the most favorable arrangement of atoms in a molecule and the most likely Lewis structure for that arrangement:

A Lewis structure in which the formal charges of the individual atoms are closest to zero typically represents the lowest energy arrangement of the atoms and electrons.

17

18

A low formal charge indicates that an atom has undergone the least redistribution of electrons relative to the free atom. The structure with formal charges closest to zero typically has the lowest energy of all possible structures. For example, the formal charge rule suggests that the structure OCO is more likely for carbon dioxide than COO, as shown in (**17**). Similarly, it also suggests that the structure NNO is more likely than NON for dinitrogen monoxide, as shown in (**18**).

TOOLBOX 2.2 HOW TO USE FORMAL CHARGE TO DETERMINE THE MOST LIKELY LEWIS STRUCTURE

CONCEPTUAL BASIS

To assign a formal charge, we establish the "ownership" of the valence electrons of an atom in a molecule and compare that ownership with the free atom. An atom owns one electron of each bonding pair attached to it and owns its lone pairs completely. The most plausible Lewis structure will be the one in which the formal charges of the atoms are lowest.

PROCEDURE

Step 1 Decide on the number of valence electrons (V) possessed by each free atom by noting the number of its group in the periodic table.

Step 2 Draw the Lewis structures.

Step 3 For each bonded atom, count each electron in its lone pairs (L), plus one electron from each of its bonding pairs (B).

Step 4 For each bonded atom, subtract the total number of electrons it "owns" from V, as in Eq. 4.

Each equivalent atom (the same element, the same number of bonds and lone pairs) has the same formal charge. A check on the calculated formal charges is that their sum is equal to the overall charge of the molecule or ion. For an electrically neutral molecule, the sum of the formal charges is zero. Compare the formal charges of each possible structure. The structure with the lowest formal charges represents the least disturbance of the electronic structures of the atoms and is the most plausible (lowest energy) structure.

This procedure is illustrated in Example 2.6.

EXAMPLE 2.6 Selecting the most likely atom arrangement

One test for the presence of iron(III) ions in solution is to add a solution of potassium thiocyanate, KSCN; a blood-red color indicates that a compound of iron and the thiocyanate ion has formed. Write three Lewis structures with different atomic arrangements for the thiocyanate ion and select the most likely structure by identifying the structure with formal charges closest to zero. For simplicity, consider only structures with double bonds between neighboring atoms.

Anticipate The element with the lowest ionization energy (after you have read Section 2.12, you will find it is more appropriate to think "lowest electronegativity") of the three is carbon, so we should expect it to be the central atom and for the structure to be NCS^-.

PLAN We proceed as set out in Toolbox 2.2.

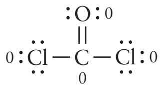
SOLVE

	NCS^-	CNS^-	CSN^-
Step 1 Count the valence electrons *V* and, for ions, adjust for the charge.	C: 4, N: 5, S: 6 Charge: 1 Total: 16 electrons	C: 4, N: 5, S: 6 Charge: 1 Total: 16 electrons	C: 4, N: 5, S: 6 Charge: 1 Total: 16 electrons
Step 2 Draw Lewis structures.	N=C=S	C=N=S	C=S=N
Step 3 Assign electron ownership, $L + \frac{1}{2}B$.	6 4 6 N=C=S	6 4 6 C=N=S	6 4 6 C=S=N
Step 4 Find formal charge, $V - (L + \frac{1}{2}B)$.	−1 0 0 N=C=S	−2 +1 0 C=N=S	−2 +2 −1 C=S=N

Evaluate The individual formal charges are closest to zero in the first column; the atom arrangement NCS^- is therefore the most likely one, as we anticipated.

Self-Test 2.8A Suggest a likely structure for the poisonous gas phosgene, $COCl_2$. Write its Lewis structure and formal charges.

[***Answer:*** See (**19**).]



19 Phosgene, $COCl_2$

Self-Test 2.8B Suggest a likely structure for the oxygen difluoride molecule. Write its Lewis structure and formal charges.

Although formal charge and oxidation number (Section K of *Fundamentals*) both give us information about the number of electrons around an atom in a compound, they are determined by different methods and often have different values:

- Formal charge exaggerates the covalent character of bonds by assuming that the electrons are shared equally.
- Oxidation number exaggerates the ionic character of bonds. It represents the atoms as ions, and *all* the electrons in a bond are assigned to the atom with the lower ionization energy (in Section 2.12, we shall see that this is the more *electronegative* atom).

Thus, although the formal charge of C in structure **17** for CO_2 is 0, its oxidation number is +4 because all the bonding electrons are assigned to the oxygen atoms to give a structure that could be represented $O^{2-}C^{4+}O^{2-}$. Formal charges depend on the particular Lewis structure we write; oxidation numbers do not.

The formal charge gives an indication of the extent to which atoms have gained or lost electrons in the process of covalent bond formation; atom arrangements and Lewis structures with the lowest formal charges are likely to have the lowest energy.

EXCEPTIONS TO THE OCTET RULE

The octet rule accounts for the valences of many of the elements and the structures of many compounds. Carbon, nitrogen, oxygen, and fluorine obey the octet rule rigorously, provided there are enough electrons to go around. However, some compounds have an odd number of electrons. In addition, an atom of phosphorus, sulfur, chlorine, or another nonmetal in Period 3 and subsequent periods can accommodate more than eight electrons in its valence shell. The following two sections show how to recognize exceptions to the octet rule.

2.9 Radicals and Biradicals

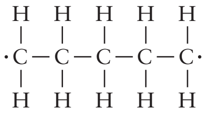
The older, still widely used term for radicals is *free radicals*.

Some species have an odd number of valence electrons, and so at least one of their atoms cannot have an octet. Species having electrons with unpaired spins are called **radicals.** They are generally highly reactive. One example is the methyl radical, $\cdot CH_3$, which is so reactive that it cannot be stored. It occurs in the flames of burning hydrocarbon fuels. The single unpaired electron is indicated by the dot on the C atom in $\cdot CH_3$.

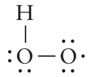
The role of radicals in the depletion of stratospheric ozone is developed further in Box 14.3.

Radicals are of crucial importance for the chemical reactions that take place in the upper atmosphere, where they contribute to the formation and decomposition of ozone. Radicals also play a role in our daily lives, sometimes a destructive one. They are responsible for the rancidity of foods and the degradation of plastics in sunlight. Damage from radicals can be delayed by an additive called an **antioxidant,** which reacts rapidly with radicals before the radicals have a chance to do their damage. Human aging is believed to be partly due to the action of radicals, and antioxidants such as vitamins C and E may delay the process (see Box 2.1). The nitric oxide molecule, NO, has an unpaired electron and plays an important role as a neurotransmitter. Because it is a radical, NO is very reactive and can be eliminated within a few seconds. Because it is small, the NO molecule can move easily throughout the body. These properties allow NO to play several roles, including controlling the supply of blood to various organs.

A **biradical** is a molecule with two unpaired electrons. The unpaired electrons are usually on different atoms, as depicted in (**20**). In that biradical, one unpaired electron is on one carbon atom of the chain and the second is on another carbon atom several bonds away. In some cases, though, both electrons are on the same atom. One of the most important examples is the oxygen atom itself. Its electron configuration is $[He]2s^2 2p_x^2 2p_y^1 2p_z^1$ and its Lewis symbol is $\cdot\ddot{\underset{\cdot\cdot}{\text{O}}}\cdot$. The O atom has two unpaired electrons, and so it can be regarded as a special type of biradical. However, there is a difference: whereas in a normal biradical the relative orientations of the two electron spins are random, in an O atom they are locked together in a parallel arrangement.



20 A biradical



21 Hydrogenperoxyl, $HO_2\cdot$

Self-Test 2.9A Write a Lewis structure for the hydrogenperoxyl radical, HOO·, which plays an important role in atmospheric chemistry and which, in the body, has been implicated in the degeneration of neurons.

[*Answer:* See (**21**).]

Self-Test 2.9B Write a Lewis structure for NO_2.

A radical is a species with an unpaired electron; a biradical has two unpaired electrons on either the same or different atoms.

2.10 Expanded Valence Shells

The octet rule tells us that eight electrons fill the outer shell of an atom to give a noble-gas ns^2np^6 valence-shell configuration. However, when the central atom in a molecule has empty d-orbitals, it may be able to accommodate 10, 12, or even more electrons. The electrons in such an **expanded valence shell** may be present as lone pairs or may be used by the central atom to form additional bonds.

A note on good practice: Although "expanded valence shell" is the logically precise term, most chemists still use the term *expanded octet*.

Because the additional electrons must be accommodated in valence orbitals, only nonmetal atoms in Period 3 or later periods can expand their valence shells. Atoms of these elements have empty d-orbitals in the valence shell. Another factor—possibly the main factor—in determining whether more atoms than allowed by the octet rule can bond to a central atom is the size of that atom. A P atom is big enough for as many as six Cl atoms to fit comfortably around it, and PCl_5 (which in the solid is $PCl_4^+PCl_6^-$) is a common laboratory chemical. An N atom, though, is too small, and NCl_5 is unknown. A compound that contains an atom with more atoms attached to it than is permitted by the octet rule is called a **hypervalent compound.**

BOX 2.1 WHAT HAS THIS TO DO WITH . . . STAYING ALIVE?

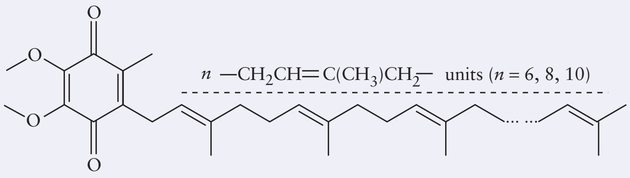
Chemical Self-Preservation

In nearly every pharmacy, supermarket, and health food store, you can find bottles of antioxidants and antioxidant-rich natural products, such as fish oils, *Gingko biloba* leaves, and wheat grass. These dietary supplements are intended to help the body control its population of radicals and, as a result, slow aging and degenerative diseases such as heart failure and cancer.

Radicals occur naturally in the body, partly as a by-product of metabolism. They serve many useful functions but can cause trouble if they are not eliminated when they are no longer needed. They often contain oxygen atoms and oxidize the *lipid* (fat) molecules that make up cell membranes and other vital tissues. This oxidation changes the structures of the lipid molecules and hence affects the function of the membranes. Cell membranes damaged in this way may not be able to protect cells against disease, and heart and nerve cells may lose their function. Recent evidence suggests that radical damage to living cells is the main factor in the aging process. When the nucleic acids such as DNA and RNA are attacked by radicals, they cannot replicate properly. These alterations result in defective cells with diminished function and a lessened ability to protect themselves against diseases such as cancer.

Leaves of the *Gingko biloba* tree, which originated in China. Extracts of these leaves are thought to have antioxidant properties. Some also believe that the extracts improve thinking ability by increasing oxygen flow to the brain.

The body maintains an antioxidant network consisting of vitamins A, C, and E, antioxidant enzymes, and a group of related compounds called coenzyme Q, for which the general formula is shown below. The *n* represents the number of times that a particular group is repeated; it can be 6, 8, or 10. *Antioxidants* are molecules that are easily oxidized, so they react readily with radicals before the radicals can react with other compounds in the body. Many common foods, such as green leafy vegetables, orange juice, and chocolate, contain antioxidants, as do coffee and tea.



Molecular structure of coenzyme Q, an antioxidant used by the body to control the level of radicals.

Harmful environmental conditions, such as ultraviolet radiation, ozone in the air we breathe, poor nutrition, and tobacco smoke can cause *oxidative stress*, a condition in which the concentration of radicals has become so high that the body's natural antioxidant network cannot cope. Premature aging of skin that has been overexposed to sunlight and lung cancer in smokers are two possible results. Herbal medicines containing certain *phytochemicals*, chemicals derived from plant sources and fish oils, are being investigated as antioxidants that can supplement the diet to protect against damage from free radicals. These same chemicals are also being studied for their ability to prolong life beyond the currently expected lifespan.

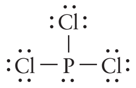
Elements that can expand their valence shells commonly show **variable covalence,** the ability to form different numbers of covalent bonds. Elements that have variable covalence can form one number of bonds in some compounds and a different number in others. Phosphorus is an example. It reacts directly with a limited supply of chlorine to form the toxic, colorless liquid phosphorus trichloride:

$$P_4(s) + 6\,Cl_2(g) \longrightarrow 4\,PCl_3(l)$$

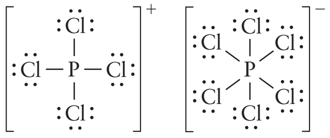
The Lewis structure of the PCl_3 molecule is shown in (**22**), and we see that it obeys the octet rule. However, when phosphorus trichloride reacts with more chlorine (Fig. 2.10), phosphorus pentachloride, a pale yellow crystalline solid, is produced:

$$PCl_3(l) + Cl_2(g) \longrightarrow PCl_5(s)$$



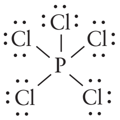
22 Phosphorus trichloride, PCl_3

FIGURE 2.10 Phosphorus trichloride is a colorless liquid. When it reacts with chlorine (the pale yellow-green gas in the flask), it forms the very pale yellow solid phosphorus pentachloride (at the bottom of the flask).

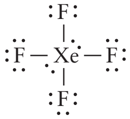


(a) PCl_4^+ (b) PCl_6^-

23 Phosphorus pentachloride, $PCl_5(s)$



24 Phosphorus pentachloride, PCl_5



25 Xenon tetrafluoride, XeF_4

Phosphorus pentachloride is an ionic solid consisting of PCl_4^+ cations and PCl_6^- anions; but at 160°C, it vaporizes to a gas of PCl_5 molecules. The Lewis structures of the polyatomic ions and the molecule are shown in (**23**) and (**24**). In the anion, the P atom has expanded its valence shell to 12 electrons, by making use of two of its 3d-orbitals. In PCl_5, the P atom has expanded its valence shell to 10 electrons by using one 3d-orbital. Phosphorus pentachloride is therefore an example of a hypervalent compound in both its solid and its gaseous forms.

EXAMPLE 2.7 Writing a Lewis structure with an expanded valence shell

The fluoride SF_4 forms when a mixture of fluorine and nitrogen gases is passed over a film of sulfur at 275°C in the absence of oxygen and moisture. Write the Lewis structure of sulfur tetrafluoride and give the number of electrons in the expanded valence shell.

Anticipate Sulfur, in Group 16/VI, has six valence electrons; if each fluorine atom provides one electron for the bond it forms, we can expect there to be 4 + 6 = 10 electrons around the S atom.

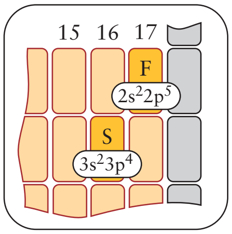
PLAN Elements in Period 3 and higher have empty 3d-orbitals available, and so can expand their valence shells to accept additional electrons. After assigning all the valence electrons to bonds and lone pairs to give each atom an octet, assign any remaining electrons to the central atom.

SOLVE

Count the number of valence electrons.

6 from sulfur (·S̈·)

7 from each fluorine atom (:F̈·)



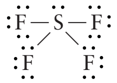
Find the number of electron pairs.

There are $6 + (4 \times 7) = 34$ electrons, or 17 electron pairs.

: : : : : : : : : : : : : : : : :

Construct the Lewis structure.

Give each F atom 3 lone pairs and 1 bonding pair shared with the central S atom; place the 2 extra electrons on the S atom.



Evaluate As expected, in this structure sulfur has 10 electrons in its expanded valence shell.

Self-Test 2.10A Write the Lewis structure for xenon tetrafluoride, XeF_4, and give the number of electrons in the expanded valence shell.

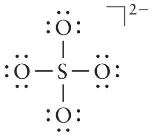
[***Answer:*** See (**25**); 12 electrons.]

Self-Test 2.10B Write the Lewis structure for the I_3^- ion and give the number of electrons in the expanded valence shell.

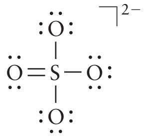
When different resonance structures are possible, some giving the central atom in a compound an octet and some an expanded valence shell, the dominant resonance structure is likely to be the one with the lowest formal charges. However, there are many exceptions and the selection of the best structure often depends on a careful analysis of experimental data.

EXAMPLE 2.8 Selecting the dominant resonance structure for a molecule

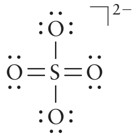
The sulfate ion, SO_4^{2-}, is present in a number of important minerals, including gypsum ($CaSO_4{\cdot}2H_2O$), which is used in cement, and Epsom salts ($MgSO_4{\cdot}7H_2O$), which is used as a purgative. Determine the dominant resonance structure of a sulfate ion from the three shown in (**26a–26c**) by calculating the formal charges on the atoms in each structure.



26a



26b



26c

Anticipate As you gain experience, you will be able to recognize the most favorable structure from the patterns of bonds and lone pairs, but until then the only way forward is to calculate the formal charges.

PLAN Follow the procedure in Toolbox 2.2. We need do only one calculation for equivalent atoms, such as the oxygen atoms in the first diagram, because they all have the same arrangement of electrons and hence the same formal charge.

SOLVE Draw up the following table, in accord with Toolbox 2.2.

	26a	**26b**	**26c**
Step 1 Count the valence electrons (V).	O: 6 S: 6 Total: 30 electrons plus two electrons from the charge of −2, for a total of 16 pairs of electrons.		
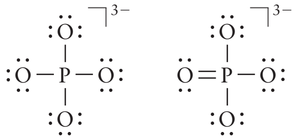
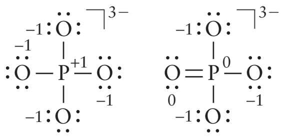
Step 2 Draw the Lewis structure.			Step 3 Assign electron ownership, $(L + \frac{1}{2}B)$.			Step 4 Find the formal charge, $V - (L + \frac{1}{2}B)$.			
Evaluate The individual formal charges are closest to zero in structure (**26c**); so the structure with two double bonds is likely to make the biggest contribution to the resonance hybrid, even though the valence shell on the S atom has expanded to hold 12 electrons. Note this pattern for future reference. Also note that the formal charges of the atoms add up to the overall charge of the ion in each case.



27

Self-Test 2.11A Calculate the formal charges for the two Lewis structures of the phosphate ion shown in (**27**).

[***Answer:*** See (**28**).]

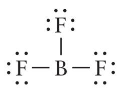


28

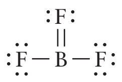
Self-Test 2.11B Calculate the formal charges for the three oxygen atoms in one of the Lewis structures of the ozone resonance structure (Example 2.5).

2.11 The Unusual Structures of Some Group 13/III Compounds

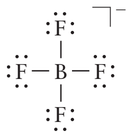
An unusual feature of the Lewis structure of the colorless gas boron trifluoride, BF_3 (**29**), is that the boron atom has an **incomplete octet:** its valence shell consists of only six electrons. We might expect the boron atom to complete its octet by sharing more



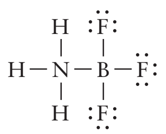
29 Boron trifluoride, BF_3



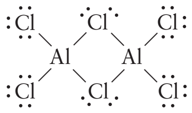
30 Boron trifluoride, BF_3



31 Tetrafluoroborate, BF_4^-



32 NH_3BF_3



33 Aluminum chloride, Al_2Cl_6

electrons with fluorine, as depicted in (**30**), but fluorine has such a high ionization energy that it is unlikely to exist with a positive formal charge. Experimental evidence, such as the short B—F bond lengths, suggests that the true structure of BF_3 is a resonance hybrid of both types of Lewis structures, with the singly bonded structure making the major contribution.

The boron atom in BF_3 can complete its octet if an additional atom or ion with a lone pair of electrons forms a bond by providing *both* electrons. A bond in which both electrons come from one of the atoms is called a **coordinate covalent bond.** For example, the tetrafluoroborate anion, BF_4^- (**31**), forms when boron trifluoride is passed over a metal fluoride. In this anion, the formation of a coordinate covalent bond with a fluoride ion gives the B atom an octet. Another example of a coordinate covalent bond is that formed when boron trifluoride reacts with ammonia:

$$BF_3(g) + NH_3(g) \longrightarrow NH_3BF_3(s)$$

The Lewis structure of the product, a white molecular solid, is shown in (**32**). In this reaction, the lone pair on the nitrogen atom of ammonia, H_3N:, can be regarded as completing boron's octet in BF_3 by forming a coordinate covalent bond.

Boron trichloride, a colorless, reactive gas of BCl_3 molecules, behaves chemically like BF_3. However, the trichloride of aluminum, which is in the same group as boron, forms *dimers*, linked pairs of molecules. Aluminum chloride is a volatile white solid that vaporizes at 180°C to a gas of Al_2Cl_6 molecules. These molecules survive in the gas up to about 200°C and only then fall apart into $AlCl_3$ molecules. The Al_2Cl_6 molecule exists because a Cl atom in one $AlCl_3$ molecule uses one of its lone pairs to form a coordinate covalent bond to the Al atom in a neighboring $AlCl_3$ molecule (**33**). This arrangement can occur in aluminum chloride but not boron trichloride because the atomic radius of Al is bigger than that of B.

Compounds of boron and aluminum may have unusual Lewis structures in which boron and aluminum have incomplete octets or halogen atoms act as bridges.

IONIC VERSUS COVALENT BONDS

Ionic and covalent bonding are two extreme models of the chemical bond. Most actual bonds lie somewhere between purely ionic and purely covalent. When we describe bonds between nonmetals, covalent bonding is a good model. When a metal and nonmetal are present in a simple compound, ionic bonding is a good model. However, the bonds in many compounds seem to have properties between the two extreme models of bonding. Can we describe these bonds more accurately by improving the two basic models?

2.12 Correcting the Covalent Model: Electronegativity

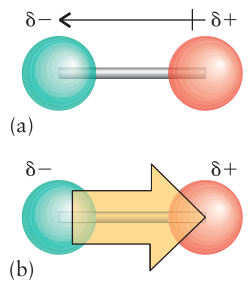
All bonds can be viewed as resonance hybrids of purely covalent and purely ionic structures. For example, the structure of a Cl_2 molecule can be described as

In this case, the ionic structures make only a small contribution to the resonance hybrid, and we regard the bond as almost purely covalent. Moreover, the two ionic structures have the same energy and make equal contributions to the hybrid; so the average charge on each atom is zero. However, in a molecule composed of different elements, such as HCl, the resonance

has unequal contributions from the two ionic structures. The lower-energy ionic structure is $H^+ :\ddot{Cl}:^-$. Because the chlorine atom has a greater attraction for electrons than does the hydrogen atom, the structure with the negative charge on the Cl atom makes

a bigger contribution than $\mathrm{H}{:}^{-}\ \ddot{\underset{\cdot\cdot}{\mathrm{Cl}}}{:}^{+}$. As a result, there is a small net negative charge on the Cl atom and a small net positive charge on the H atom. Here we see the limitations of using formal charge alone to determine the distribution of electrons in a structure. The formal charge on each atom in HCl is zero.

The charges on the atoms in HCl are called **partial charges**. We show the partial charges on the atoms by writing $^{\delta+}\mathrm{H{-}Cl}^{\delta-}$. A bond in which ionic contributions to the resonance result in partial charges is called a **polar covalent bond**. All bonds between atoms of different elements are polar to some extent. The bonds in homonuclear (same element) diatomic molecules and ions are nonpolar.



34

The two atoms in a polar covalent bond form an **electric dipole,** a partial positive charge next to an equal but opposite partial negative charge. In the original convention, a dipole was represented by an arrow that points toward the negative partial charge (**34a**); in the modern convention, the arrow points toward the positive partial charge (**34b**). Clearly, it is important to know which convention is being used! In this text, we use the modern convention. The size of an electric dipole—which is a measure of the magnitude of the partial charges and their separation—is reported as the **electric dipole moment**, μ (the Greek letter mu), in units called **debye** (D). The debye is defined so that a single negative charge (an electron) separated by 100. pm from a single positive charge (a proton) has a dipole moment of 4.80 D. The dipole moment associated with a Cl—H bond is about 1.1 D. We can think of this dipole as arising from a partial charge of about 23% of an electron's charge on the Cl atom and an equivalent positive charge on the H atom.

The debye is named for the Dutch chemist Peter Debye, who carried out important studies of dipole moments.

The SI unit of dipole moment is 1 C·m (1 coulomb meter). It is the dipole moment of a charge of 1 C separated from a charge of −1 C by a distance of 1 m; 1 D = 3.336×10^{-30} C·m.

A covalent bond is polar if one atom has a greater attraction for electrons than the other atom, because then the electron pair is more likely to be drawn closer to the former atom. In 1932, the American chemist Linus Pauling proposed a quantitative measure of electron distribution in bonds. The electron-pulling power of an atom when it is part of a molecule is called its **electronegativity**. Electronegativities are denoted χ (the Greek letter chi, pronounced "kye"). An atom of the element with the higher electronegativity has a stronger pulling power on electrons and tends to pull them away from the atom of the element with lower electronegativity (Fig. 2.11). Pauling based his scale on the dissociation energies, D, of the A—A, B—B, and A—B bonds, measured in electronvolts. He defined the difference in electronegativity of the two elements A and B as

Dissociation energies, a measure of the strengths of bonds, are discussed in Section 2.14.

$$|\chi_A - \chi_B| = \{D(A - B) - \tfrac{1}{2}[D(A - A) + D(B - B)]\}^{1/2} \quad (5)$$

He then assigned individual values of electronegativities that were consistent with this expression.

A simpler way of setting up a scale of electronegativities was devised by another American chemist, Robert Mulliken. In his approach, the electronegativity is the average of the ionization energy and electron affinity of the element (both expressed in electronvolts):

$$\chi = \tfrac{1}{2}(I + E_a) \quad (6)$$

An atom gives up an electron reluctantly if the ionization energy is high. If the electron affinity is high, attaching electrons to an atom is energetically favorable. Elements with both these properties are reluctant to lose their electrons and tend to gain them; hence, they are classified as highly electronegative. Conversely, if the ionization energy and the electron affinity are both low, then it takes very little energy for the element to give up its electrons and it has little tendency to gain more; hence, the electronegativity is low.

Figure 2.12 shows the variation in electronegativity for the main-group elements of the periodic table. Because ionization energies and electron affinities are highest at the top right of the periodic table (close to fluorine, with the exception of the noble gases), it is not surprising to find that nitrogen, oxygen, bromine, chlorine, and fluorine are the elements with the highest electronegativities.

When the two atoms in a bond have only a small electronegativity difference, the partial charges are very small. As the difference in electronegativities increases, so do the partial charges. If the electronegativities are very different, then one atom can

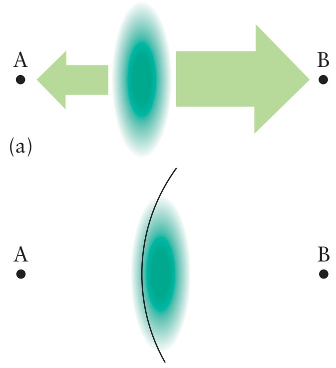


FIGURE 2.11 The electronegativity of an element is its electron-pulling power when it is part of a compound. (a) An atom with a high electronegativity (B) has a strong pulling power on the electrons (as represented by the larger arrow) that it shares with its neighbor, A. (b) The outcome of the tug-of-war is that the more electronegative atom has a greater share in the electron pair of the covalent bond. Electron density is symbolized by the green cloud in each image.

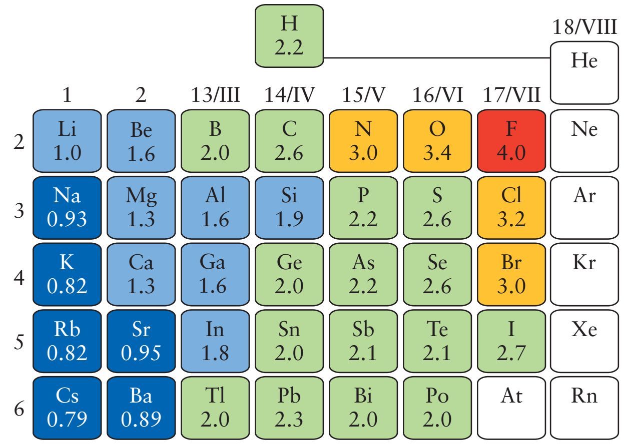

FIGURE 2.12 Variation in the electronegativity of the main-group elements (with the exception of the noble gases). Electronegativity tends to be high toward the upper-right corner of the periodic table and low on the lower left. Elements with low electronegativities (such as the s-block metals) are often called electropositive. These Pauling values are used throughout the text.

acquire the lion's share of the electron pair, and the corresponding ionic structure makes a large contribution to the resonance. Because it has largely robbed the other atom of its share of the electrons, the highly electronegative element resembles an anion and the other atom resembles a cation. We say that such a bond has considerable **ionic character**. If the difference in electronegativity is large, as in NaCl or KF, the ionic contribution dominates the covalent contribution, and it is better to regard the bond as ionic.

There is no sharp dividing line between ionic and covalent bonding. However, a good rule of thumb is that an electronegativity difference of about 2 means that there is so much ionic character present that the bond is best regarded as ionic (Fig. 2.13). For electronegativity differences smaller than about 1.5, a covalent description of the bond is probably reasonable. For example, the electronegativities of carbon and oxygen are 2.6 and 3.4, an electronegativity difference of 0.8, and C—O bonds are best regarded as polar covalent. However, the electronegativity of calcium is 1.3, and Ca—O bonds, with an electronegativity difference of 2.1, are considered ionic.

Self-Test 2.12A In which of the following compounds do the bonds have greater ionic character: (a) P_4O_{10} or (b) PCl_3?

[*Answer:* (**a**)]

Self-Test 2.12B In which of the following compounds do the bonds have greater ionic character: (a) CO_2 or (b) NO_2?

Electronegativity is a measure of the pulling power of an atom on the electrons in a bond. A polar covalent bond is a bond between two atoms with partial electric charges arising from their difference in electronegativity. The presence of partial charges gives rise to an electric dipole moment.

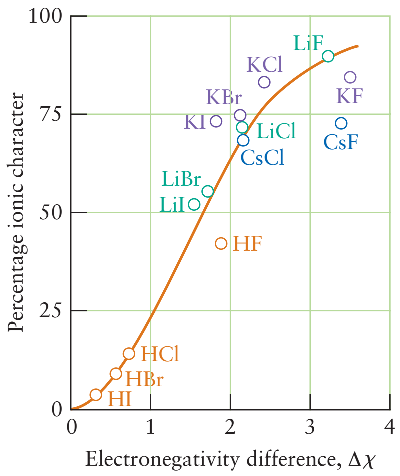

FIGURE 2.13 The dependence of the percentage ionic character of the bond on the difference in electronegativity, $\Delta\chi$, between two bonded atoms for a number of halides.

2.13 Correcting the Ionic Model: Polarizability

All ionic bonds have some covalent character. To see how covalent character can arise, consider a monatomic anion (such as Cl^-) next to a cation (such as Na^+). As the cation's positive charge pulls on the anion's electrons, the spherical electron cloud of the anion becomes distorted in the direction of the cation. We can think of this distortion as the tendency of an electron pair to move into the region between the two nuclei and to form a covalent bond (Fig. 2.14). Ionic bonds acquire more covalent character as the distortion of the electron cloud on the anion increases.

Atoms and ions that readily undergo a large distortion are said to be highly **polarizable.** An anion can be expected to be highly polarizable if it is large, such as an iodide ion, I^-. In such a large, highly polarizable ion, the ion's nucleus exerts only weak control over its outermost electrons because they are so far away. As a result, the electron cloud of the large anion is easily distorted. Cations, which have fewer electrons than their parent atoms, are not significantly polarizable because the remaining electrons are held so tightly.

Atoms and ions that can cause large distortions are said to have a high **polarizing power.** A cation can be expected to have a strong polarizing power if it is small and highly charged, such as an Al^{3+} cation. A small radius means that the center of charge of a highly charged cation can get very close to the anion, where it can exert a strong pull on the anion's electrons. Compounds composed of a small, highly charged cation and a large, polarizable anion tend to have bonds with considerable covalent character.

Cations become smaller, more highly charged, and hence more strongly polarizing, from left to right across a period. Thus, Be^{2+} is more strongly polarizing than Li^+, and Mg^{2+} is more strongly polarizing than Na^+. On the other hand, cations become larger and hence less strongly polarizing down a group. Thus, Na^+ is less strongly polarizing than Li^+, and Mg^{2+} is less strongly polarizing than Be^{2+}. Now we can see that, because polarizing power increases from Li^+ to Be^{2+} but decreases from Be^{2+} to Mg^{2+}, it follows that the polarizing power of the diagonal neighbors Li^+ and Mg^{2+} should be similar. We can expect such similarities in the properties of other diagonally related neighbors. These diagonal similarities underlie the diagonal relationships in the periodic table introduced in Section 1.20 and illustrated in Fig. 1.58.

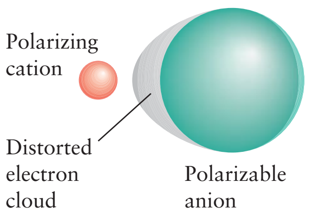

FIGURE 2.14 When a small, highly charged cation is close to a large anion, the electron cloud of the anion is distorted in the process we call polarization. The green sphere represents the shape of anion in the absence of a cation. The gray shadow shows how the shape of the sphere is distorted by the positive charge of the cation.

Self-Test 2.13A In which of the compounds NaBr and $MgBr_2$ do the bonds have greater covalent character?

[*Answer:* $MgBr_2$]

Self-Test 2.13B In which of the compounds CaS and CaO do the bonds have greater covalent character?

Compounds composed of highly polarizing cations and highly polarizable anions have significant covalent character in their bonding.

THE STRENGTHS AND LENGTHS OF COVALENT BONDS

The characteristics of a covalent bond between two atoms are due mainly to the properties of the atoms themselves and vary only a little with the identities of the other atoms present in a molecule. Consequently, we can predict some characteristics of a bond with reasonable certainty once we know the identities of the two bonded atoms. For instance, provided the bond order is the same, the length and strength of an A—B bond are approximately the same regardless of the molecule in which it is found. Thus, to understand the properties of a large molecule, such as how DNA replicates in our cells and transmits genetic information, we can study the character of C═O and N—H bonds in much simpler compounds, such as formaldehyde, $H_2C{=}O$, and ammonia, NH_3.

2.14 Bond Strengths

The strength of a chemical bond is measured by its **dissociation energy**, D, the energy required to separate the bonded atoms. On a plot of the potential energy of a diatomic molecule as a function of the internuclear distance, the dissociation energy is the distance between the bottom of the energy well and the energy of the separated atoms (Fig. 2.15). The bond breaking is **homolytic**, which means that each atom retains one of the electrons from the bond. An example is

$$H{-}Cl(g) \longrightarrow \cdot H(g) + \cdot Cl(g)$$

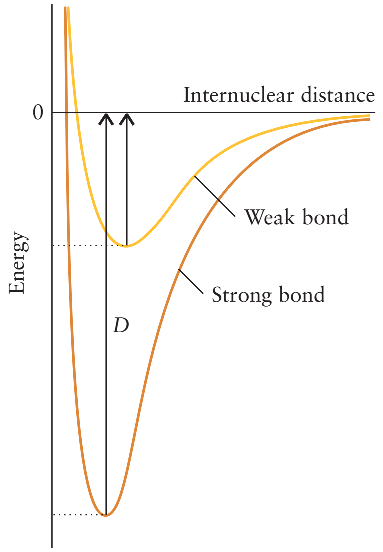

FIGURE 2.15 The variation of the energy of a diatomic molecule with internuclear separation for weak and strong bonds. The dissociation energy is a measure of the depth of the well. (In practice, we have to take into account the small zero-point energy of the vibrating molecule, and so the dissociation energy is slightly less than the depth of the well.)

A high dissociation energy indicates a deep potential energy well and therefore a strong bond that requires a lot of energy to break. The strongest known bond between two nonmetal atoms is the triple bond in carbon monoxide, for which the dissociation energy is 1062 $kJ \cdot mol^{-1}$. One of the weakest bonds is that between the iodine atoms in molecular iodine, for which the dissociation energy is only 139 $kJ \cdot mol^{-1}$.

The strength of a bond between two atoms is measured by its dissociation energy: the greater the dissociation energy, the stronger the bond.

TABLE 2.3 Bond Dissociation Energies of Diatomic Molecules ($kJ \cdot mol^{-1}$)

Molecule	Bond dissociation energy
H_2	424
N_2	932
O_2	484
CO	1062
F_2	146
Cl_2	230
Br_2	181
I_2	139
HF	543
HCl	419
HBr	354
HI	287

TABLE 2.4 Average Bond Dissociation Energies ($kJ \cdot mol^{-1}$)

Bond	Average bond dissociation energy	Bond	Average bond dissociation energy
C—H	412	C—I	238
C—C	348	N—H	388
C=C	612	N—N	163
C⋯C*	518	N=N	409
C≡C	837	N—O	210

C—F	484	O—H	463
C—Cl	338	O—O	157
C—Br	276		

*In benzene.

We shall not distinguish between the average dissociation energy and the average dissociation enthalpy, a concept to be introduced in Section 7.20. The two quantities differ by only a few kilojoules per mole.

2.15 Variation in Bond Strength

Tables 2.3 and 2.4 list a selection of typical dissociation energies. The values given in Table 2.4 are average dissociation energies for a number of different molecules. For instance, the strength quoted for a C—O single bond is the average strength of such bonds in a selection of organic molecules, such as methanol (CH_3—OH), ethanol (CH_3CH_2—OH), and dimethyl ether (CH_3—O—CH_3). The values should therefore be regarded as typical rather than as accurate values for a particular molecule.

The trends in bond strengths shown in Table 2.3 are explained in part by the Lewis structures for the molecules. Consider, for example, the diatomic molecules of nitrogen, oxygen, and fluorine (Fig. 2.16). Note the decline in bond strength as the bond order decreases—from 3 in N_2 to 1 in F_2. The triple bond in nitrogen is the origin of the inertness mentioned at the beginning of the chapter. A multiple bond is almost always stronger than a single bond because more electrons bind the multiply bonded atoms. A triple bond between two atoms is always stronger than a double bond between the same two atoms, and a double bond is always stronger than a single bond between the same two atoms. However, a double bond between two carbon atoms is not twice as strong as a single bond, and a triple bond is a lot less than three times as strong. For example, we see that the average dissociation energy of a C=C double bond is 612 $kJ \cdot mol^{-1}$, whereas it takes 696 $kJ \cdot mol^{-1}$ to break two C—C single bonds; similarly, the average dissociation energy of a C≡C triple bond is 837 $kJ \cdot mol^{-1}$, but it takes 1044 $kJ \cdot mol^{-1}$ to break three C—C single bonds (Fig. 2.17). The origin of these differences is in part the repulsions between the electron pairs in a multiple bond, so each pair is not quite as effective at bonding as a pair of electrons in a single bond. Another contributing factor is that, as will be described in Section 3.4, the electrons in double and triple bonds are not as concentrated between the two atoms as they are in a single bond.

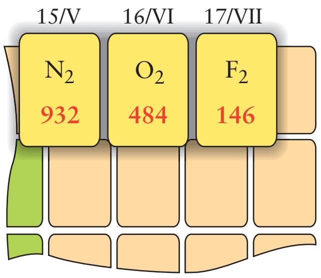

FIGURE 2.16 The bond dissociation energies, in kilojoules per mole of N_2, O_2, and F_2 molecules. Note how the bonds weaken in the change from a triple bond in N_2 to a single bond in F_2.

The values in Table 2.4 show how resonance affects the strengths of bonds. For example, the strength of a carbon–carbon bond in benzene is intermediate between that of a single and that of a double bond. Resonance spreads multiple bond character over the bonds between atoms: as a result, what were single bonds are strengthened and what were double bonds are weakened. The net effect overall is a stabilization of the molecule.

The presence of lone pairs may influence the strengths of bonds. Lone pairs repel each other; and, if they are on neighboring atoms, that repulsion can weaken the bond. This repulsion between lone pairs helps to explain why the bond in F_2 is weaker than the bond in H_2, because the latter molecule has no lone pairs.

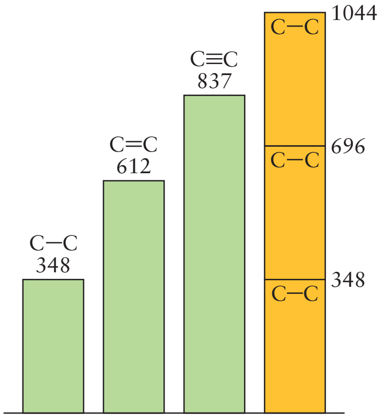

FIGURE 2.17 The strengths (in kilojoules per mole) of single and multiple bonds between two carbon atoms. Note that, for bonds between carbon atoms, a double bond is less than twice as strong as a single bond and a triple bond is less than three times as strong as a single bond, as shown by the fourth column.

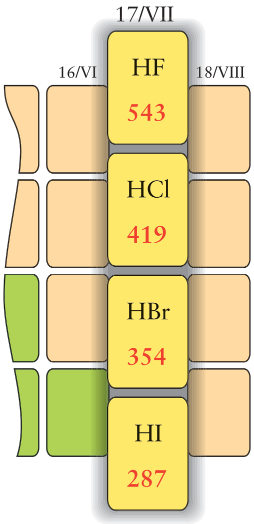

FIGURE 2.18 The bond dissociation energies of the hydrogen halide molecules in kilojoules per mole of molecules. Note how the bond weakens as the halogen atom becomes larger.

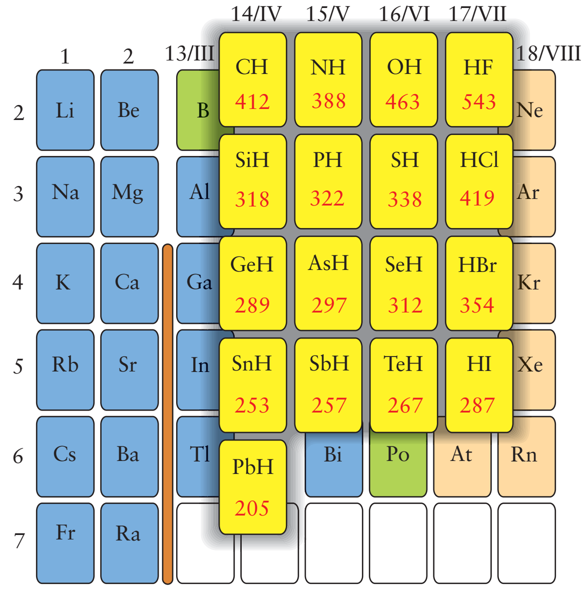

FIGURE 2.19 The dissociation energies for bonds between hydrogen and the p-block elements. The bond strength decreases down each group as the atoms increase in size.

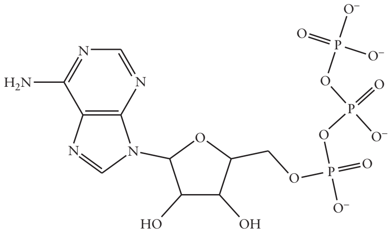
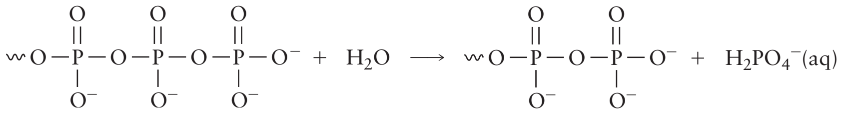
Trends in bond strengths correlate with trends in atomic radii. If the nuclei of the bonded atoms cannot get very close to the electron pair lying between them, the two atoms will be only weakly bonded together. For example, the bond strengths of the hydrogen halides decrease from HF to HI, as shown in Fig. 2.18. The strength of the bond between hydrogen and a Group 14/IV element also decreases down the group (Fig. 2.19). This weakening of the bond correlates with a decrease in the stability of the hydrides down the group. Methane, CH_4, can be kept indefinitely in air at room temperature. Silane, SiH_4, bursts into flame on contact with air. Stannane, SnH_4, decomposes into tin and hydrogen. Plumbane, PbH_4, has never been prepared, except perhaps in trace amounts.

The relative strengths of bonds are important for understanding the way that energy is used in bodies to power our brains and muscles. For instance, adenosine triphosphate, ATP (**35**), is found in every living cell. The triphosphate part of this molecule is a chain of three phosphate groups. One of the phosphate groups is removed in a reaction with water. The P—O bond in ATP requires only 276 kJ·mol^{-1} to break and the new P—O bond formed in $H_2PO_4^-$ releases 350 kJ·mol^{-1} when it forms. As a result, the conversion of ATP to adenosine diphosphate, ADP, in the reaction



35



(where the wiggly line indicates the rest of the molecule) can release energy that is used to power energy-demanding processes in cells.

Closely related to the strength of a bond is its stiffness (its resistance to stretching and compressing), with strong bonds typically being stiffer than weak bonds. The stiffness of bonds is studied by infrared (IR) spectroscopy, as described in Major Technique 1, which follows this chapter, and is used to identify compounds.

The bond strength increases as the multiplicity of a bond increases, decreases as the number of lone pairs on neighboring atoms increases, and decreases as the atomic radii increase. Bonds are strengthened by resonance.

2.16 Bond Lengths

A **bond length** is the distance between the centers of two atoms joined by a covalent bond. It corresponds to the internuclear distance at the potential energy minimum for the two atoms (see Fig. 2.15). Bond lengths affect the overall size and shape of a molecule.

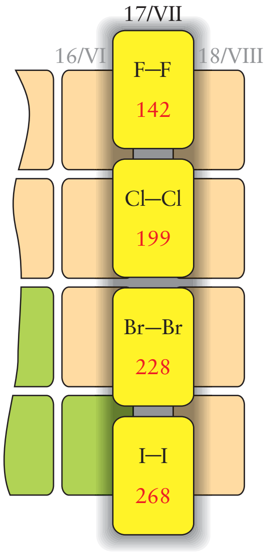


FIGURE 2.20 Bond lengths (in picometers) of the diatomic halogen molecules. Notice how the bond length increases down the group as the atomic radii become larger.

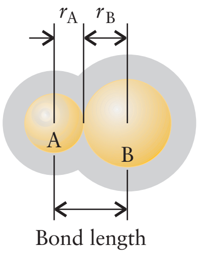
TABLE 2.5 Average and Actual Bond Lengths

Bond	Average bond length (pm)	Molecule	Bond length (pm)
C—H	109	H_2	74
C—C	154	N_2	110
C=C	134	O_2	121
C⋯C*	139	F_2	142
C≡C	120	Cl_2	199
C—O	143	Br_2	228
C=O	112	I_2	268
O—H	96		
N—H	101		
N—O	140		
N=O	120		

*In benzene.

The transmission of hereditary information in DNA, for instance, depends on bond lengths because the two strands of the double helix must fit together like pieces of a jigsaw puzzle (Section 19.15). Bond lengths are also crucial to the action of enzymes because only a molecule of the right size and shape will fit into the active site of the enzyme molecule (Section 14.16). As we see from Table 2.5, the lengths of bonds between Period 2 elements typically lie in the range from 100 pm to 150 pm. Bond lengths are determined experimentally by using either spectroscopy or x-ray diffraction (Box 2.2).

Bonds between heavy atoms tend to be longer than those between light atoms because heavier atoms have larger radii than lighter ones (Fig. 2.20). *Multiple bonds are shorter than single bonds between the same two elements* because the additional bonding electrons attract the nuclei more strongly and pull the atoms closer together: compare the lengths of the various carbon–carbon bonds in Table 2.5. We can also see the averaging effect of resonance: the length of the carbon–carbon bond in benzene is intermediate between the lengths of the single and double bonds of a Kekulé structure (but closer to that of a double bond). For bonds between atoms of the same two elements, *the stronger the bond, the shorter it is*. Thus, a C≡C triple bond is both stronger and shorter than a C=C double bond. Similarly, a C=O double bond is both stronger and shorter than a C—O single bond.



36 Covalent radii

Each atom makes a characteristic contribution, called its **covalent radius**, to the length of a bond (Fig. 2.21). A bond length is approximately the sum of the covalent radii of the two atoms (**36**). The O—H bond length in ethanol, for example, is the sum of the covalent radii of H and O, 37 + 74 pm = 111 pm. We also see from Fig. 2.21 that the covalent radius of an atom taking part in a multiple bond is smaller than that for a single bond of the same atom.

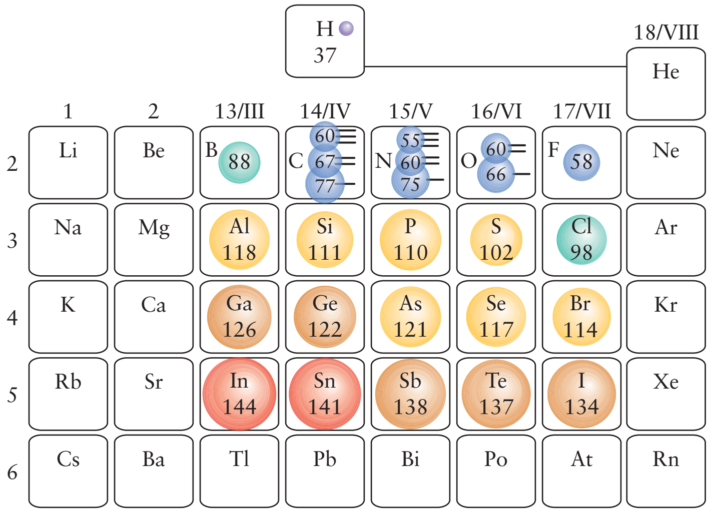


FIGURE 2.21 Covalent radii of hydrogen and the p-block elements (in picometers). Where more than one value is given, the values refer to single, double, and triple bonds. Covalent radii tend to become smaller toward fluorine. A bond length is approximately the sum of the covalent radii of the two participating atoms.

BOX 2.2 HOW DO WE KNOW . . . THE LENGTH OF A CHEMICAL BOND?

Because a chemical bond is only about 10^{-10} m long, special techniques have to be used to measure its length. There are two principal techniques: one for solids and the other for gases. The technique used for solids, x-ray diffraction, is described in Major Technique 3, following Chapter 5. *Microwave spectroscopy,* discussed here, is used to determine bond lengths in gas-phase molecules. This branch of spectroscopy makes use of the ability of rotating molecules to absorb microwave radiation, which has a wavelength close to 1 cm.

According to classical physics, a solid body such as a ball can rotate with any energy. According to quantum mechanics, however, rotational energy is quantized, and a body can rotate only with certain energies—that is, only at certain speeds. Let's see what that means for a diatomic molecule AB, with atomic masses m_A and m_B and bond length R. The molecule can rotate only with the following energies:

$$E_J = \frac{h^2}{8\pi^2 \mu R^2} \times J(J+1) \qquad J = 0,1,2,\ldots$$

where $\mu = m_A m_B/(m_A + m_B)$, h is Planck's constant, and J is a quantum number. These energy levels are shown in the illustration for two kinds of molecules, one with heavy atoms and a long bond (such as ICl) and the other with light atoms and a short bond (such as HF). We see that the energy levels are much closer together for the heavier molecule than for the lighter molecule. The minimum energy needed to excite a molecule into rotation from rest (corresponding to $J = 0$ and $E = 0$) is

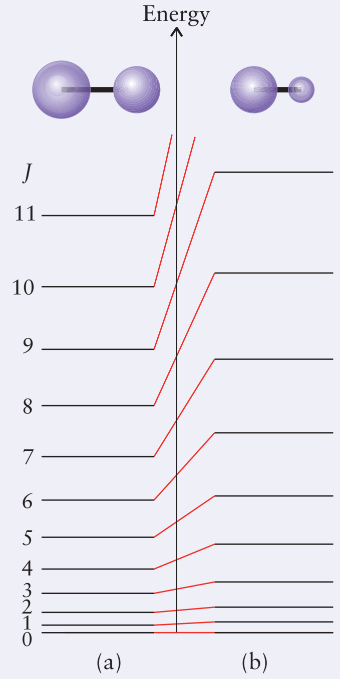
$$\Delta E = E_1 - E_0 = \frac{h^2}{4\pi^2 \mu R^2}$$

Perhaps surprisingly, less energy is needed to excite a large heavy molecule than a small light molecule. The energy needed to excite a molecule from the general state J to the next higher level, $J + 1$, is

$$\Delta E = E_{J+1} - E_J = \frac{h^2}{4\pi^2 \mu R^2} \times (J+1)$$

Because the energy needed to change the rotational state of a molecule depends on the masses of its atoms and the bond length, we can calculate the bond length if we can measure that energy. Photons corresponding to microwave radiation can supply the energy needed to excite the molecule to higher rotational energies. Therefore, to determine a bond length, a beam of microwave radiation is passed through a gaseous sample, its frequency is varied, and the frequencies, ν (nu), that result in a strong absorption are determined. The energy of the photons corresponding to this frequency is $h\nu$, and this value can be set equal to the expression for the energy difference given above. The resulting expression is then solved for the value of R, the bond length.

The technique as we have described it works only for polar molecules, because only they can interact with microwave radiation. However, modifications of this spectroscopic method can be used to investigate nonpolar molecules, too. A major limitation of the technique is that only the spectra of simple molecules can be interpreted. For complex molecules, solid samples are used in conjunction with x-ray diffraction (see Major Technique 3).



The rotational energy levels of (a) a heavy diatomic molecule and (b) a light diatomic molecule. Note that the energy levels are closer together for the heavy diatomic molecule. Microwaves are absorbed when transitions take place between neighboring energy levels.

Covalent radii typically decrease from left to right across a period. The reason is the same as for atomic radii (Section 1.15): the increasing effective nuclear charge draws in the electrons and makes the atom more compact. Like atomic radii, covalent radii increase down a group because, in successive periods, the valence electrons occupy shells that are more distant from the nucleus and are better shielded by the inner core of electrons.

The covalent radius of an atom is the contribution it makes to the length of a covalent bond; covalent radii are added together to estimate the lengths of bonds in molecules.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Write the electron configuration for an ion (Example 2.1 and Self-Test 2.2).

❑ 2 Compare the relative lattice energies of two ionic compounds (Example 2.2).

❑ 3 Draw the Lewis structures of molecules and ions (Toolbox 2.1 and Examples 2.3, 2.4, and 2.7).

❑ 4 Write the resonance structures for a molecule (Example 2.5).

❑ 5 Use formal charge calculations to evaluate alternative Lewis structures (Toolbox 2.2 and Examples 2.6 and 2.8).

❑ 6 Predict which of two bonds has greater ionic or covalent character (Self-Tests 2.12 and 2.13).

❑ 7 Predict and explain periodic trends in the polarizability of anions and the polarizing power of cations (Section 2.13).

❑ 8 Predict and explain relative bond strengths and lengths (Sections 2.14–2.16).

EXERCISES

Electron Configurations of Ions

2.1 Give the number of valence electrons for each of the following elements: (a) Sb; (b) Si; (c) Mn; (d) B.

2.2 Give the number of valence electrons for each of the following elements: (a) Br; (b) Rh; (c) Nb; (d) Te.

2.3 Give the ground-state electron configuration expected for each of the following ions: (a) S^{2-}; (b) As^{3+}; (c) Ru^{3+}; (d) Ge^{2+}.

2.4 Give the ground-state electron configuration expected for each of the following ions: (a) Br^-; (b) Rh^{3+}; (c) Nb^{3+}; (d) Te^{2-}.

2.5 Give the ground-state electron configuration expected for each of the following ions: (a) Cu^+; (b) Bi^{3+}; (c) Ga^{3+}; (d) Tl^{3+}.

2.6 Give the ground-state electron configuration expected for each of the following ions: (a) Al^{3+}; (b) Tc^{4+}; (c) Ra^{2+}; (d) I^-.

2.7 The following species have the same number of electrons: Cd, In^+, and Sn^{2+}. (a) Write the electron configurations for each species. Are they the same or different? Explain. (b) How many unpaired electrons, if any, are present in each species? (c) What neutral atom, if any, has the same electron configuration as that of In^{3+}?

2.8 The following species have the same number of electrons: Ca, Ti^{2+}, and V^{3+}. (a) Write the electron configurations for each ion. Are they the same or different? Explain. (b) How many unpaired electrons, if any, are present in each species? (c) What neutral atom, if any, has the same electron configuration as that of Ti^{3+}?

2.9 Which M^{2+} ions (where M is a metal) are predicted to have the following ground-state electron configurations: (a) $[Ar]3d^7$; (b) $[Ar]3d^6$; (c) $[Kr]4d^4$; (d) $[Kr]4d^3$?

2.10 Which E^{3+} (where E is an element) ions are predicted to have the following ground-state electron configurations: (a) $[Xe]4f^{14}5d^8$; (b) $[Xe]4f^{14}5d^5$; (c) $[Kr]4d^{10}5s^25p^2$; (d) $[Ar]3d^{10}4s^2$?

2.11 Which M^{3+} ions (where M is a metal) are predicted to have the following ground-state electron configurations: (a) $[Ar]3d^6$; (b) $[Ar]3d^5$; (c) $[Kr]4d^5$; (d) $[Kr]4d^3$?

2.12 Which M^{2+} ions (where M is a metal) are predicted to have the following ground-state electron configurations: (a) $[Ar]3d^7$; (b) $[Kr]4d^7$; (c) $[Kr]4d^{10}5s^2$; (d) $[Xe]4f^{14}5d^{10}$?

2.13 For each of the following ground-state atoms, predict the type of orbital (1s, 2p, 3d, 4f, etc.) from which an electron will need to be removed to form the +1 ions: (a) Zn; (b) Cl; (c) Al; (d) Cu.

2.14 For each of the following ground-state ions, predict the type of orbital (1s, 2p, 3d, 4f, etc.) from which an electron will need to be removed to form the ions of one greater positive charge: (a) Ti^{3+}; (b) In^+; (c) Te^{2-}; (d) Ag^+.

2.15 Write the most likely charge for the ions formed by each of the following elements: (a) S; (b) Te; (c) Rb; (d) Ga; (e) Cd.

2.16 Write the most likely charge for the ions formed by each of the following elements: (a) Ba; (b) Bi; (c) Br; (d) Zn; (e) Al.

2.17 Predict the number of valence electrons present for each of the following ions: (a) Mn^{4+}; (b) Rh^{3+}; (c) Co^{3+}; (d) P^{3+}.

2.18 Predict the number of valence electrons present for each of the following ions: (a) In^+; (b) Tc^{2+}; (c) Ta^{2+}; (d) Re^+.

2.19 Give the ground-state electron configuration and number of unpaired electrons expected for each of the following ions: (a) Sb^{3+}; (b) Sn^{4+}; (c) W^{2+}; (d) Br^-; (e) Ni^{2+}.

2.20 Give the ground-state electron configuration and number of unpaired electrons expected for each of the following ions: (a) Sn^{2+}; (b) Cr^{3+}; (c) Ba^{2+}; (d) P^{3-}.

2.21 Give the ground-state electron configuration and number of unpaired electrons expected for each of the following ions: (a) Ca^{2+}; (b) In^+; (c) Te^{2-}; (d) Ag^+.

2.22 Give the ground-state electron configuration and number of unpaired electrons expected for each of the following ions: (a) Fe^{3+}; (b) Bi^{3+}; (c) Si^{4+}; (d) I^-.

2.23 Chlorine can exist in both positive and negative oxidation states. What is the maximum (a) positive and (b) negative oxidation number that chlorine can have? (c) Write the electron configuration for each of these states. (d) Explain how you arrived at these values.

2.24 Sulfur can exist in both positive and negative oxidation states. What is the maximum (a) positive and (b) negative oxidation number that sulfur can have? (c) Write the electron configuration for each of these states. (d) Explain how you arrived at these values.

2.25 On the basis of the expected charges on the monatomic ions, give the chemical formula of each of the following compounds: (a) magnesium arsenide; (b) indium(III) sulfide; (c) aluminum hydride; (d) hydrogen telluride; (e) bismuth(III) fluoride.

2.26 On the basis of the expected charges on the monatomic ions, give the chemical formula of each of the following compounds: (a) manganese(II) telluride; (b) barium arsenide; (c) silicon nitride; (d) lithium bismuthide; (e) zirconium(IV) chloride.

2.27 On the basis of the expected charges of the monatomic ions, give the chemical formula of each of the following compounds: (a) thallium(III) chloride; (b) aluminum sulfide; (c) manganese(IV) oxide.

2.28 On the basis of the expected charges of the monatomic ions, give the chemical formula of each of the following compounds: (a) chromium(III) oxide; (b) manganese(II) chloride; (c) lithium nitride.

Ionic Bonds

2.29 Use data in Appendix 2D to predict which of the following pairs of ions would have the greatest coulombic attraction in a solid compound: (a) K^+, O^{2-}; (b) Ga^{3+}, O^{2-}; (c) Ca^{2+}, O^{2-}.

2.30 Use data from Appendix 2D to predict which of the following pairs of ions would have the greatest coulombic attraction in a solid compound: (a) Mg^{2+}, S^{2-}; (b) Mg^{2+}, Se^{2-}; (c) Mg^{2+}, O^{2-}.

2.31 Explain why the lattice energy of lithium chloride ($861\ kJ\cdot mol^{-1}$) is greater than that of rubidium chloride ($695\ kJ\cdot mol^{-1}$), given that they have similar arrangements of ions in the crystal lattice. See Appendix 2D.

2.32 Explain why the lattice energy of silver bromide ($903\ kJ\cdot mol^{-1}$) is greater than that of silver iodide ($887\ kJ\cdot mol^{-1}$), given that they have similar arrangements of ions in the crystal lattice. See Appendix 2D.

Covalent Bonds

2.33 Write the Lewis structure of (a) CCl_4; (b) $COCl_2$; (c) ONF; (d) NF_3.

2.34 Write the Lewis structure of (a) OCl_2; (b) PBr_3; (c) GeH_4; (d) $GaCl_3$.

2.35 Write the Lewis structure of (a) tetrahydridoborate ion, BH_4^-; (b) hypobromite ion, BrO^-; (c) amide ion, NH_2^-.

2.36 Write the Lewis structure of (a) nitronium ion, ONO^+; (b) chlorite ion, ClO_2^-; (c) peroxide ion, O_2^{2-}; (d) formate ion, HCO_2^-.

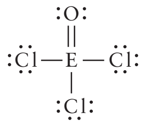
2.37 Write the complete Lewis structure for each of the following compounds: (a) formaldehyde, HCHO, which as its aqueous solution "formalin" is used to preserve biological specimens; (b) methanol, CH_3OH, the toxic compound also called wood alcohol; (c) glycine, $H_2C(NH_2)COOH$, the simplest of the amino acids, the building blocks of proteins.

2.38 Write the Lewis structure of each of the following organic compounds: (a) ethanol, CH_3CH_2OH, which is also called ethyl alcohol or grain alcohol; (b) methylamine, CH_3NH_2, a putrid-smelling substance formed when flesh decays; (c) formic acid, HCOOH, a component of the venom injected by ants.

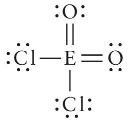
2.39 Write the Lewis structure for each of the following compounds: (a) methanethiol, CH_3SH, one of the compounds found in bad breath and some cheeses; (b) carbon disulfide, CS_2, which is used to make rayon; (c) dichloromethane, CH_2Cl_2, a common solvent.

2.40 Write the Lewis structure for each of the following compounds: (a) urea, $OC(NH_2)_2$, a compound formed in the body when proteins are metabolized; (b) phosgene, Cl_2CO, a deadly gas once used in warfare; (c) nitrosyl fluoride, FNO, an oxidizing agent used in rocket fuel (the atoms are attached in the order shown).

2.41 The following Lewis structure was drawn for a Period 3 element. Identify the element.



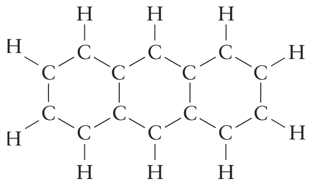
2.42 The following Lewis structure was drawn for a Period 3 element. Identify the element.



2.43 Write the complete Lewis structure for each of the following compounds: (a) ammonium chloride; (b) potassium phosphide; (c) sodium hypochlorite.

2.44 Write the complete Lewis structure for each of the following compounds: (a) calcium cyanide; (b) potassium sulfate; (c) ammonium iodate.

2.45 Anthracene has the formula $C_{14}H_{10}$. It is similar to benzene but has 3 six-membered rings that share common C—C bonds, as shown below. Complete the structure by drawing in multiple bonds to satisfy the octet rule at each carbon atom. Resonance structures are possible. Draw as many as you can find.



2.46 Write the Lewis structures that contribute to the resonance hybrid of the guanadinium ion, $C(NH_2)_3^+$.

2.47 Draw the Lewis structures that contribute to the resonance hybrid of nitryl chloride, $ClNO_2$ (N is the central atom).

2.48 Do H—C≡N and H—N≡C form a pair of resonance structures? Explain your answer.

2.49 Draw the Lewis structure and determine the formal charge on each atom in (a) NO^+; (b) N_2; (c) CO; (d) C_2^{2-}; (e) CN^-.

2.50 Using only Lewis structures that obey the octet rule, draw the Lewis structures and determine the formal charge on each atom in (a) CH_3^-; (b) BrO_2^-; (c) PO_3^{3-}.

2.51 Determine the formal charge on each atom in the following molecules. Identify the structure of lower energy in each pair.

(a) 
(b)

(c) 
2.52 Determine the formal charge on each atom in the following ions. Identify the structure of lowest energy in each case.

(a) 
(b) 
(c) 
Exceptions to the Octet Rule

2.53 Which of the following species are radicals? (a) NO_2^-; (b) CH_3; (c) OH; (d) CH_2O.

2.54 Which of the following species are radicals? (a) ClO_2; (b) Cl_2O; (c) BF_4^-; (d) BrO.

2.55 Write the Lewis structure, including typical contributions to the resonance structure (where appropriate, allow for the possibility of octet expansion, including double bonds in different positions), for (a) sulfite ion; (b) hydrogen sulfite ion; (c) perchlorate ion; (d) nitrite ion.

2.56 Write the Lewis structure, including typical contributions to the resonance structure (where appropriate, allow for the possibility of octet expansion), for (a) hydrogen phosphate ion; (b) bromite ion; (c) perchlorate ion; (d) arsenate ion.

2.57 Write the Lewis structure of each of the following reactive species, all of which are found to contribute to the destruction of the ozone layer, and indicate which are radicals: (a) chlorine monoxide, ClO; (b) dichloroperoxide, Cl—O—O—Cl; (c) chlorine nitrate, $ClONO_2$ (the central O atom is attached to the Cl atom and to the N atom of the NO_2 group).

2.58 Write the Lewis structure of each of the following species and indicate which are radicals: (a) the superoxide ion, O_2^-; (b) the methoxy group, CH_3O; (c) XeO_4; (d) $HXeO_4^-$.

2.59 Determine the numbers of electron pairs (both bonding and lone pairs) on the iodine atom in (a) ICl_2^+; (b) ICl_4^-; (c) ICl_3; (d) ICl_5.

2.60 Determine the numbers of electron pairs (both bonding and lone pairs) on the phosphorus atom in (a) PCl_3; (b) PCl_5; (c) PCl_4^+; (d) PCl_6^-.

2.61 Write the Lewis structure for each of the following molecules or ions and give the number of electrons about the central atom: (a) SF_6; (b) XeF_2; (c) AsF_6^-; (d) $TeCl_4$.

2.62 Write the Lewis structure for each of the following molecules or ions and give the number of electrons about the central atom: (a) SiF_6^{2-}; (b) IF_7; (c) ClF_3; (d) BrF_2^+.

2.63 Write the Lewis structure and state the number of lone pairs on xenon, the central atom of each of the following compounds: (a) $XeOF_2$; (b) XeF_4; (c) $XeOF_4$.

2.64 Write the Lewis structure and state the number of lone pairs on the central atom of each of the following compounds: (a) IF_3; (b) AsF_3; (c) OF_2.

2.65 In each of these ions and compounds, an atom violates the octet rule. Identify the atom and explain the deviation from the octet rule: (a) $BeCl_2$; (b) ClO_2.

2.66 In each of these ions and compounds, an atom violates the octet rule. Identify the atom and explain the deviation from the octet rule: (a) BrF_3; (b) BH_3.

2.67 Two contributions to the resonance structure are shown below for each species. Determine the formal charge on each atom and then, if possible, identify the Lewis structure of lower energy for each species.

(a) 
(b) 
2.68 Two Lewis structures are shown below for each species. Determine the formal charge on each atom and then, if appropriate, identify the Lewis structure of lower energy for each species.

(a)

(b) 
2.69 Select from each of the following pairs of Lewis structures the one that is likely to make the dominant contribution to a resonance hybrid. Explain your selection.

(a)

(b) 
2.70 Select from each of the following pairs of Lewis structures the one that is likely to make the dominant contribution to a resonance hybrid. Explain your selection.

(a)

(b) 
Ionic Versus Covalent Bonds

2.71 Place the following elements in order of increasing electronegativity: antimony, tin, selenium, indium.

2.72 Place the following elements in order of increasing electronegativity: oxygen, carbon, nitrogen, fluorine, silicon, phosphorus, sulfur.

2.73 Just as some elements are electronegative, others can be *electropositive*, a term meaning that the element will readily give up electrons. Elements that are least electronegative are the most electropositive. What trend exists among the alkali metals and the alkaline earth metals with respect to their electropositive character?

2.74 Compare the electronegativites of the following Group 3 elements with those of the Group 2 elements in Periods 4, 5, and 6: Sc, 1.36; Y, 1.22; La 1.10. (a) Which group contains

the more electronegative elements? (b) Which element is the most electronegative? (c) Which is the most electropositive (see Exercise 2.73).

2.75 For each pair, determine which compound has bonds with greater ionic character: (a) HCl or HI; (b) CH_4 or CF_4; (c) CO_2 or CS_2.

2.76 For each pair, determine which compound has bonds with greater ionic character: (a) PH_3 or NH_3; (b) SO_2 or NO_2; (c) SF_6 or IF_5.

2.77 Compounds having bonds with a high covalent character tend to be less soluble in water than similar compounds that have low covalent character. Use electronegativities to predict which of the following compounds is the more soluble in water: (a) $AlCl_3$ or KCl; (b) MgO or BaO.

2.78 Use electronegativities to predict which of the following compounds is the more soluble in water (see Exercise 2.77): (a) LiI or MgI_2; (b) CaS or CaO.

2.79 Arrange the cations Rb^+, Be^{2+}, and Sr^{2+} in order of increasing polarizing power. Give an explanation of your arrangement.

2.80 Arrange the cations K^+, Mg^{2+}, Al^{3+}, and Cs^+ in order of increasing polarizing power. Give an explanation of your arrangement.

2.81 Arrange the anions Cl^-, Br^-, N^{3-}, and O^{2-} in order of increasing polarizability and give reasons for your decisions.

2.82 Arrange the anions N^{3-}, P^{3-}, I^-, and At^- in order of increasing polarizability and give reasons for your decisions.

The Strengths and Lengths of Covalent Bonds

2.83 Place the following molecules or ions in order of *decreasing* bond length: (a) the CO bond in CO, CO_2, CO_3^{2-}; (b) the SO bond in SO_2, SO_3, SO_3^{2-}; (c) the CN bond in HCN, CH_2NH, CH_3NH_2. Explain your reasoning.

2.84 Place the following molecules or ions in order of *decreasing* bond order: (a) NO bond in NO, NO_2, NO_3^-; (b) CC bond in C_2H_2, C_2H_4, C_2H_6; (c) CO bond in CH_3OH, CH_2O, CH_3OCH_3. Explain your reasoning.

2.85 Use the information in Fig. 2.21 to estimate the bond length of (a) the NN bond in hydrazine, H_2NNH_2; (b) the CO bond in CO_2; (c) the CO and CN bonds in urea, $OC(NH_2)_2$; (d) the NN bond in nitrogen hydride, HNNH.

2.86 Use the information in Fig. 2.21 to estimate the indicated bond length of (a) the CO bond in formaldehyde, H_2CO; (b) the CO bond in dimethyl ether, CH_3OCH_3; (c) the CO bond in methanol, CH_3OH; (d) the CS bond in methanethiol, CH_3SH.

2.87 Use the covalent radii in Fig. 2.21 to calculate the bond lengths in the following molecules. Account for the trends in your calculated values: (a) CF_4; (b) SiF_4; (c) SnF_4.

2.88 Which do you predict to have the strongest CN bond: (a) $NHCH_2$, (b) NH_2CH_3, or (c) HCN? Explain.

Integrated Exercises

2.89 Write the Lewis structure, including resonance structures where appropriate, for (a) the oxalate ion, $C_2O_4^{2-}$ (there is a C—C bond with two oxygen atoms attached to each carbon atom); (b) BrO^+; (c) the acetylide ion, C_2^{2-}. Assign formal charges to each atom.

2.90 Write three Lewis structures that follow the octet rule (including the most important structure) for the isocyanate ion, CNO^-. State which of the three Lewis structures is the most important and explain why it is probably the most important.

2.91 Draw resonance structures for the trimethylenemethane anion $C(CH_2)_3^{2-}$ in which a central carbon atom is attached to three CH_2 groups (CH_2 groups are referred to as methylene).

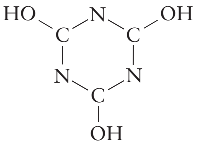
2.92 Show how resonance can occur in the following organic ions: (a) acetate ion, $CH_3CO_2^-$; (b) enolate ion, $CH_2COCH_3^-$, which has one resonance structure with a C=C double bond and an —O^- group on the central carbon atom; (c) allyl cation, $CH_2CHCH_2^+$; (d) amidate ion, CH_3CONH^- (the O and the N atoms are both bonded to the second C atom).

2.93 White phosphorus is composed of tetrahedral molecules of P_4 in which each P atom is connected to three other P atoms. Draw the Lewis structure for this molecule. Does it obey the octet rule?

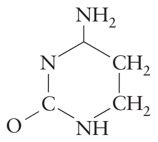
2.94 The cyclopentadienide ion, $C_5H_5^-$, is a common organic anion that forms very stable complexes with metal cations. The anion is derived by removing a proton from cyclopentadiene, C_5H_6, with strong base. The molecule has a five-membered ring of carbon atoms, with four carbon atoms attached to only one proton and one carbon atom bonded to two. Draw the Lewis structure of cyclopentadiene. Are resonance forms possible for this molecule? The ion $C_5H_5^-$ consists of a planar five-membered ring of carbon atoms, with one hydrogen atom attached to each carbon atom. Draw the Lewis structure for $C_5H_5^-$. How many resonance structures can you draw for this anion?

2.95 In 1999, Karl Christe synthesized and characterized a salt that contained the N_5^+ cation, in which the five N atoms are connected in a long chain. This cation is the first all-nitrogen species to be isolated in more than 100 years. Draw the most important Lewis structure for this ion, including all equivalent resonance structures. Calculate the formal charges on all atoms.

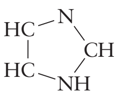
2.96 Draw the most important Lewis structure for each of the following ring molecules (which have been drawn without showing the locations of the double bonds). Show all lone pairs and nonzero formal charges. If there are equivalent resonance forms, draw them.



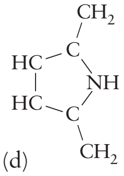
(a)



(b)



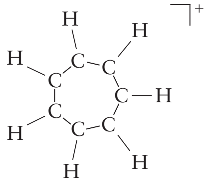
(c)



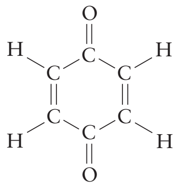
(d)

2.97 An important principle in chemistry is the *isolobal analogy*. This very simple principle states that chemical fragments with similar valence orbital structures can replace one another in molecules. For example, $\cdot\overset{\cdot}{\underset{\cdot}{C}}-H$ and $\cdot\overset{\cdot}{\underset{\cdot}{Si}}-H$ are isolobal fragments, each having three electrons with which to form bonds in addition to the bond to H. An isolobal series of molecules would be HCCH, HCSiH, HSiSiH. Similarly, a lone pair of electrons can be used to replace a bond so that $\cdot\overset{\cdot}{\underset{\cdot}{N}}\colon$ is isolobal with $\cdot\overset{\cdot}{\underset{\cdot}{C}}-H$ with the lone pair taking the place of the C—H bond. The isolobal set here is HCCH, HCN, NN. (a) Draw the Lewis structures for the molecules HCCH, HCSiH, HSiSiH, HCN, and NN. (b) Using the isolobal principle, draw Lewis structures for molecules based on the structure of benzene, C_6H_6, in which one or more CH groups are replaced with N atoms.

2.98 The framework for the tropylium cation, $C_7H_7^+$, is a seven-membered ring of carbon atoms with a hydrogen atom attached to each carbon atom. Complete the structural drawing by adding the multiple bonds as appropriate. Resonance structures are possible. Draw as many as you can find. Determine the C—C bond order.



2.99 Quinone, $C_6H_4O_2$, is an organic molecule with the structure shown below; it can be reduced to the anion $C_6H_4O_2^{2-}$. (a) Draw the Lewis structure of the reduced product. (b) On the basis of formal charges derived from the Lewis structure, predict which atoms in the molecule are most negatively charged. (c) If two protons are added to the reduced product, where are they most likely to bond?



2.100 In air, the NO radical can react with O_2. What is the most likely product of the reaction? Answer this question by drawing Lewis structures of the reactants and products.

2.101 The atomic numbers (Z), electronic configurations, and numbers of unpaired electrons for five ions are listed in the following table. Assume that all unpaired electrons have parallel spins. Indicate the element symbol, charge, and energy state (that is, ground state or excited state) for each of the five cases.

Z	Configuration	No. of unpaired electrons	Element	Charge	Energy state
26	$[Ar]3d^6$	4			
52	$[Kr]4d^{10}5s^2 5p^5 6s^1$	2			
16	$[Ne]3s^2 3p^6$	0			
39	$[Kr]4d^1$	1			
30	$[Ar]4s^2 3d^8$	2			

2.102 The atomic numbers (Z), electronic configurations, and numbers of unpaired electrons for five ions are listed in the following table. Assume that all unpaired electrons have parallel spins. Indicate the element symbol, charge, and energy state (that is, ground state, excited state, etc.) for each of the five cases.

Z	Configuration	No. of unpaired electrons	Element	Charge	Energy state
38	$[Kr]5p^1$	1			
45	$[Kr]4d^7$	3			
43	$[Kr]4d^5 5s^1$	6			
8	[Ne]	0			
21	$[Ar]3d^1 4s^1$	2			

2.103 Draw the most important Lewis structure for each of the following molecules. Show all lone pairs and formal charges. Draw all equivalent resonance forms: (a) HONCO; (b) H_2CSO; (c) H_2CNN; (d) ONCN.

2.104 Determine the formal charges for the atoms in (a) CN^-; (b) CNO^-; (c) N_3^-.

2.105 (a) Confirm that lattice energies are inversely proportional to the distance between the ions in MX (M = alkali metal, X = halide ion) by plotting the lattice energies of KF, KCl, and KI against the internuclear distances d_{M-X}. The lattice energies of KF, KCl, and KI are 826, 717, and 645 kJ·mol^{-1}, respectively. Use the ionic radii found in Appendix 2D to calculate d_{M-X}. How good is the correlation? You should use a standard graphing program to make the plot that will generate an equation for the line and calculate a correlation coefficient for the fit (see the Web site for this book). (b) Estimate the lattice energy of KBr from your graph. (c) Find an experimental value for the lattice energy of KBr in the chemical literature and compare that value with the value that you calculated in part (b). How well do they agree?

2.106 (a) Explore whether the lattice energies of the alkali metal iodides are inversely proportional to the distances between the ions in MI (M = alkali metal) by plotting the lattice energies given below against the internuclear distances d_{M-I}.

Alkali metal iodide	Lattice energy (kJ·mol^{-1})
LiI	759
NaI	700
KI	645
RbI	632
CsI	601

Use the ionic radii found in Appendix 2D to calculate d_{M-X}. How good is the correlation? Is a better fit obtained by plotting the lattice energies against $(1 - d^*/d)/d$, as suggested by the Born–Meyer equation? You should use a standard graphing program to make the plot that will generate an equation for the line and calculate a correlation coefficient for the fit (see the Web site for this book). (b) From the ionic radii given in Appendix 2D and the plot given in part (a), estimate the lattice energy for silver iodide. (c) Compare your results from part (b) with the experimentally determined value of 886 kJ·mol^{-1}. If they do not agree, provide an explanation for the deviation.

2.107 A common biologically active radical is the pentadienyl radical, RCHCHCHCHCHR′, where the carbons form a long chain, with R and R′, which can be a number of different organic groups, at each end. Draw three resonance structures for this compound that maintain carbon's valence of four.

2.108 Predict the qualitative molecular potential energy curves for the NN bond by making rough sketches on one graph for N_2H_4, N_2, and N_3^-. Explain why the energy of the lowest point on each curve is not the same.

2.109 Thallium and oxygen form two compounds with the following characteristics:

	Compound I	Compound II
Mass percentage Tl	89.49%	96.23%
Melting point	717°C	300°C

(a) Determine the chemical formulas of the two compounds.
(b) Determine the oxidation number of thallium in each

compound. (c) Assume that the compounds are ionic and write the electron configuration for each thallium ion. (d) Use the melting points to decide which compound has more covalent character in its bonds. Is your finding consistent with what you would predict from the polarizing abilities of the two cations?

2.110 How close are the Mulliken and Pauling electronegativity scales? (a) Use Eq. 6 to calculate the Mulliken electronegativities of C, N, O, and F. Use the values in $kJ \cdot mol^{-1}$ from Figs. 1.50 and 1.54 and divide each value by 230 $kJ \cdot mol^{-1}$ for this comparison. (b) Plot both sets of electronegativities as a function of atomic number on the same graph. (c) Which scale is more periodic (depends more consistently on position in the periodic table)?

2.111 The perchlorate ion, ClO_4^-, is described by resonance structures. (a) Draw the Lewis structures that contribute to the resonance hybrid and identify the most plausible Lewis structures by using formal charge arguments. (b) The average length of a single Cl—O bond is 172 pm and that of a double Cl═O bond can be estimated at 140 pm. The Cl—O bond length in the perchlorate ion is found experimentally to be 144 pm for all four bonds. Identify the most plausible Lewis structures of the perchlorate ion from these experimental data. (c) What is the oxidation number of chlorine in the perchlorate ion? Identify the most plausible Lewis structure by using the oxidation number, assuming that lone pairs belong to the atom to which they are attached but that all electrons shared in a bond belong to the atom of the more negative element. (d) Are these three approaches consistent? Explain why or why not.

2.112 Predict which bond will absorb light of shorter wavelength and explain why: C—H or C—Cl. Refer to Major Technique 1, which follows these exercises.

2.113 Infrared spectra show absorption due to C—H bond stretching at 3.38 μm for a methyl (—CH_3) group and at 3.1 μm for an alkyne (—C≡C—H) group. Which C—H bond is stiffer (has the larger force constant k), assuming that the vibrating atoms have the same effective mass? Refer to Major Technique 1, which follows these exercises.

2.114 Vibrational spectra are often so complicated that assignment of a particular absorption to a given bond is difficult. One way to confirm that an assignment is correct is to carry out selective isotopic substitution. For example, we can replace a hydrogen atom with a deuterium atom. If an iron-hydride (Fe—H) stretch occurs at 1950 cm^{-1}, at what energy will this stretch occur, approximately, for a compound that has deuterium in place of the hydrogen? Refer to Major Technique 1, which follows these exercises.

2.115 Certain gases, called greenhouse gases, contribute to global warming by absorbing infrared radiation. Only molecules with dipole moments or nonpolar molecules that undergo distortions that create momentary dipoles (such as CO_2, see Figure 2 in Major Technique 1, which follows these exercises) can absorb infrared radiation. Which of the following gases, all of which occur naturally in air, can function as greenhouse gases? (a) CO; (b) O_2; (b) O_3; (d) SO_2; (e) N_2O; (f) Ar.

2.116 One of the following compounds does not exist. Use Lewis structures to identify that compound. (a) C_2H_2; (b) C_2H_4; (c) C_2H_6; (d) C_2H_8.

2.117 Ozone in the stratosphere protects us from harmful radiation by absorbing ultraviolet radiation from the Sun. Compare the bond lengths in the ozone molecule and the oxygen molecule. (a) Are there one or two different bond lengths in ozone? (b) Which molecule has the longer bonds?

2.118 In the solid state, sulfur is sometimes found in rings of six atoms. (a) Draw a valid Lewis structure for S_6. (b) Is resonance possible in S_6? If so, draw one of the resonance structures.

2.119 Structural isomers are molecules that have the same formula but in which the atoms are connected in a different order. Two isomers of disulfur difluoride, S_2F_2, are known. In each the two S atoms are bonded to each other. In one isomer each of the S atoms is bonded to an F atom. In the other isomer, both F atoms are attached to one of the S atoms. (a) In each isomer the S—S bond length is approximately 190 pm. Are the S—S bonds in these isomers single bonds or do they have some double bond character? (b) Draw two resonance structures for each isomer. (c) Determine for each isomer which structure is favored by formal charge considerations. Are your conclusions consistent with the S—S bond lengths in the compounds?

2.120 Ionic compounds typically have higher boiling points and lower vapor pressures than covalent compounds. Predict which compound in the following pairs has the lower vapor pressure at room temperature: (a) Cl_2O or Na_2O; (b) $InCl_3$ or $SbCl_3$; (c) LiH or HCl; (d) $MgCl_2$ or PCl_3.

Chemistry Connections

2.121 The nitrogen oxides are common pollutants generated by internal combustion engines and power plants. They not only contribute to the respiratory distress caused by smog, but if they reach the stratosphere, can also threaten the ozone layer that protects Earth from harmful radiation.

(a) The bond energy in NO is 632 $kJ \cdot mol^{-1}$ and that of each N—O bond in NO_2 is 469 $kJ \cdot mol^{-1}$. Using Lewis structures and the average bond energies in Table 2.4, explain the difference in bond energies between the two molecules and the fact that the bond energies of the two bonds in NO_2 are the same.

(b) The bond length in NO is 115 pm. Use Fig. 2.21 to predict the length of a single bond and a double bond between nitrogen and oxygen. Use Table 2.5 to estimate the length of a triple bond between nitrogen and oxygen. Predict the bond order in NO from its bond length and explain any difference from the calculated values.

(c) When the NO in smog reacts with NO_2 a bond forms between the two N atoms. Draw the Lewis structure of each reactant and the product and indicate the formal charge on each atom.

(d) The NO_2 in smog also reacts with NO_3 to form a product with an O atom between the two N atoms. Draw the Lewis structure of the most likely product and indicate the formal charge on each atom.

(e) Write the balanced chemical equation for the reaction of the product from part (d) with water to produce an acid. The acid produced acts as a secondary pollutant in the environment. Name the acid.

(f) If 4.05 g of the product from part (d) reacts with water as in part (e) to produce 1.00 L of acidic solution, what will be the concentration of the acid?

(g) Determine the oxidation number of nitrogen in NO, NO_2, and the products in parts (c) and (d). Which of these compounds would you expect to be the most potent oxidizing agent?

When we feel the warmth of the Sun on our faces, we are responding to infrared radiation that has traveled nearly 150 million kilometers through space. That radiation stimulates the molecules in our skin to vibrate, and specially adapted nerve cells detect the vibration and interpret it as "warmth." The same type of radiation is used to identify molecules in samples and to determine the stiffness of bonds in molecules.

The Technique

Infrared radiation is electromagnetic radiation with longer wavelengths (lower frequencies) than red light; a typical wavelength is about 1000 nm. A wavelength of 1000 nm corresponds to a frequency of about 3×10^{14} Hz, which is comparable to the frequency at which molecules vibrate. Therefore, molecules can absorb infrared radiation and become vibrationally excited, which means they begin to vibrate.

Any bond between two atoms vibrates as the atoms move closer to each other and away again. This type of motion is called a "stretching" mode. Polyatomic molecules can also undergo "bending" vibrations in which bond angles periodically increase and decrease. The frequency at which a molecule vibrates depends on the masses of its atoms and the stiffness of its bonds: a molecule made up of light atoms joined by stiff bonds has a higher vibrational frequency than one made up of heavy atoms joined by loose bonds. The former molecule will therefore absorb higher frequency radiation than the latter. Bending motions of molecules tend to be less stiff than stretching motions; so bending vibrations typically absorb at lower frequencies than do stretching vibrations.

The stiffness of a bond is measured by its *force constant, k*. This constant is the same as that in Hooke's law for the restoring force of a spring: Hooke observed that the restoring force is proportional to the displacement of the spring from its resting position, and wrote

$$\text{Force} = -k \times \text{displacement}$$

A stiff bond (like a stiff spring) experiences a strong restoring force, even for quite small displacements, and so in this case k is large. A loose bond (like a weak spring) experiences only a weak restoring force, even for quite large displacements, so its associated k is small. In general, the force constant is larger for stretching displacements of molecules than for bending motions. The stiffness of a bond should not be confused with its strength, which is the energy required to break the bond. Typically, though, the stiffness of a bond increases with the strength of the bond (Fig. 1).

The vibrational frequency, ν (nu), of a bond between two atoms A and B of masses m_A and m_B is given by the expression

$$\nu = \frac{1}{2\pi}\sqrt{\frac{k}{\mu}} \qquad \mu = \frac{m_A m_B}{m_A + m_B}$$

The quantity μ (mu) is called the *effective mass* of the molecular vibration (some people call it the "reduced mass"). As we anticipated, the frequency is higher for stiff bonds (large k) and low atomic masses (low μ). We see that by measuring the vibrational frequency of a molecule, which involves measuring the frequency (or wavelength) at which it absorbs infrared radiation, we can measure the stiffness of its bond.

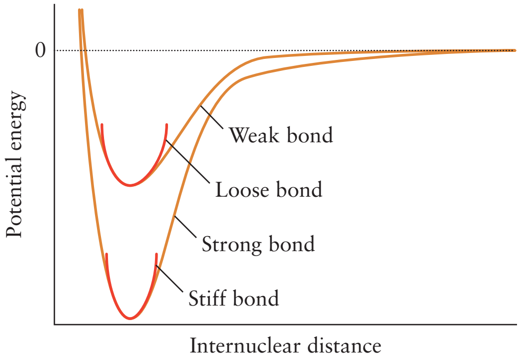


FIGURE 1 The strength of a bond is a measure of the depth of the well in the potential energy curve; the stiffness—which governs the vibrational frequency—is determined by the steepness with which the potential energy rises as the bond is stretched or compressed.

In practice, the vibrational absorption spectrum of a molecule is measured by using an infrared spectrometer. The source of infrared radiation is a hot filament, and the wavelength is selected by diffracting the radiation from a grating. Constructive interference* results in intense radiation in a given direction for a given angle of the grating; and, as that angle is changed, radiation of varying wavelength is passed through the sample. The beam is divided, one beam passing through the sample and the other beam passing through a blank; the intensities of the two beams are then compared at the detector and the reduction in intensity due to absorption by the sample is monitored. The result is a spectrum in which dips occur at the wavelengths of radiation absorbed by the sample.

Normal Modes and Polyatomic Molecules

A nonlinear molecule consisting of N atoms can vibrate in $3N - 6$ different ways, and a linear molecule can vibrate in $3N - 5$ different ways. The number of ways in which a molecule can vibrate increases rapidly with the number of atoms: a water molecule, with $N = 3$, can vibrate in 3 ways, but a benzene molecule, with $N = 12$, can vibrate in 30 different ways. Some of the vibrations of benzene correspond to expansion and contraction of the ring, others to its elongation, and still others to flexing and bending. Each way in which a molecule can vibrate is called a *normal mode*, and so we say that benzene has 30 normal modes of vibration. Each normal mode has a frequency that depends in a complicated way on the masses of the atoms that

**Interference* is discussed more fully in Major Technique 3 following Chapter 5.

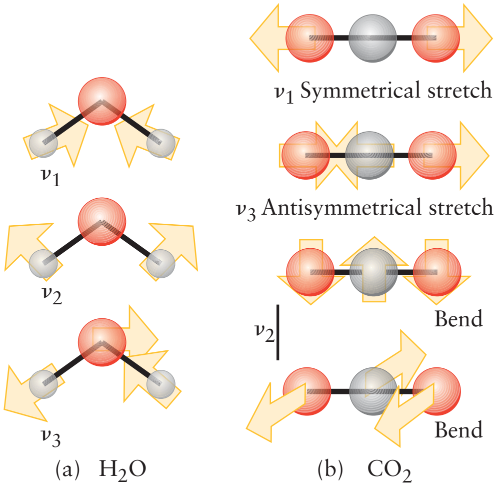

FIGURE 2 (a) The three normal vibrational modes of H_2O. Two of these modes are principally stretching motions of the bonds, but mode ν_2 is primarily bending. (b) The four normal vibrational modes of CO_2. The first two are symmetrical and antisymmetrical stretching motions, and the last two are perpendicular bending motions.

move during the vibration and the force constants associated with the motions involved (Fig. 2).

Except in simple cases, it is very difficult to predict the infrared absorption spectrum of a polyatomic molecule, because each of the modes has its characteristic absorption frequency rather than just the single frequency of a diatomic molecule. However, certain groups, such as a benzene ring or a carbonyl group, have characteristic frequencies, and their presence can often be detected in a spectrum. Thus, an infrared spectrum can be used to identify the species present in a sample by looking for the characteristic absorption bands associated with various groups. An example and its analysis are shown in Fig. 3.

A further aid to identification comes from the fact that a molecule commonly has a complex series of absorptions spanning a range of wavelengths. This *fingerprint region* of the spectrum may be too difficult to analyze in detail, but its presence enables us to recognize the substance by comparing the spectrum to an atlas of spectra.

What Are the Key Ideas? The central ideas of this chapter are, first, that electrostatic repulsions between electron pairs determine molecular shapes and, second, that chemical bonds can be discussed in terms of two quantum mechanical theories that describe the distribution of electrons in molecules.

Why Do We Need to Know This Material? The shapes of molecules determine their odors, their tastes, and their actions as drugs. Molecular shape plays an essential role in the reactions that take place throughout our bodies and are necessary for life. It also affects the properties of the materials around us, including their physical states and their solubilities. Perception, thinking, and learning depend on the shapes of molecules and how they change. Modern theories of the electronic structures of molecules can be extended to describe metals and semiconductors, and so the information in this chapter is also at the root of the development of new technologies.

What Do We Need to Know Already? This chapter uses atomic orbitals and electron configurations (Chapter 1). It also extends the concept of Lewis structures introduced in Chapter 2. The discussion of polar molecules develops the material on polar bonds described in Section 2.12.

The bright colors of flowers and the varied hues of autumn leaves have always been a cause for delight, but it was not until the twentieth century that chemists understood how these colors arise from the presence of organic compounds with common structural features. They discovered how small differences in the structures of the molecules of these compounds can enhance photosynthesis, produce important vitamins, and attract pollinating bees. They now know how the shapes of molecules and the orbitals occupied by their electrons explain the properties of these compounds and even the processes taking place in our eyes that allow us to see them.

The impact of modern theories of bonding, however, goes far beyond understanding the colors around us. Increasing knowledge of the electronic structures of the atoms and molecules in polymers and semiconductors has led to the development of new technologies. The pharmaceutical industry is increasingly turning to computer-aided design—in which molecular shape and the distribution of electrons play a crucial role—to discover new, more potent drugs (Box 3.1).

In this chapter we meet three increasingly sophisticated models of molecular shape. The first considers molecular shape to be a consequence merely of the electrostatic (coulombic) interaction between pairs of electrons. The other two models are theories that describe the distribution of electrons and molecular shape in terms of the occupation of orbitals. We shall test these models two ways: with experimental data and with the results of calculations based on computer models (see Major Technique 5, following Chapter 14). The computer models take into account all the energies of interaction between every pair of atoms in a molecule.

THE VSEPR MODEL

Lewis structures simply show the linkages between atoms and the presence of lone pairs. They do not, by themselves, show the three-dimensional arrangement of atoms in space. In this section, we develop Lewis's ideas so that we can predict the shapes of simple molecules. We proceed in three steps. First, we set up the basic model for molecules without lone pairs on the central atom. Then, we include the effects of lone pairs. Finally, we explore some of the consequences of molecular shape.

BOX 3.1 FRONTIERS OF CHEMISTRY: DRUGS BY DESIGN AND DISCOVERY

The search for new drugs relies not only on the skills of synthetic organic chemists but also on biologists, ethnobotanists, and medical researchers. Because there are so many millions of compounds, it would take too long to start with the elements, combine them in different ways, and then test them. Instead, chemists usually start either by *drug discovery*, the identification and possibly the modification of promising medicines that already exist, or by *rational drug design*, the identification of characteristics of a target enzyme, virus, bacterium, or parasite and the design of new compounds to react with it.

In drug discovery, a chemist usually begins by investigating compounds that have already shown medicinal value. A fruitful path is to find a *natural product*, an organic compound found in nature, that has been shown to have healing characteristics. Nature is the best of all synthetic chemists, with billions of chemicals that fulfill as many different needs. The challenge is to find compounds that have curative powers. These substances are found in different ways: random or "blind" collection of samples that are then tested, or collection of specific samples identified by native healers as medically effective.

Observation of the properties of plants and animals can help to guide a random search. For example, if certain types of fruits remain fresh while others rot, we might expect the former to contain antifungal agents. An example of this type of collection is the gathering of tunicates and sponges in the Caribbean. The chemists harvest the samples by diving from research vessels (see Fig. F.1). The samples are tested for antiviral and antitumor activity in a chemical laboratory on the ship. The antiviral drug didemnin-C and the anticancer drug bryostatin 1 were discovered in marine organisms.

The guided route requires fewer samples for testing because the chemist works with a native healer, the ancient lore guiding

A field biologist examines a plant in a South American rainforest. The plant produces chemicals that will be investigated for their medicinal value.

the modern chemistry. Often an ethnobotanist, a specialist in plants used for native healing, joins the team. This approach saves time for the scientists and can provide an economic benefit for the healers and their nations as well. Drugs that have been discovered in this way include a variety of anticancer and antimalarial drugs, blood-clotting agents, antibiotics, and medicines for the heart and digestive system.

Once the empirical and molecular formulas of the active compounds are determined, then their structural formulas are sought. At that point, synthetic work can begin. The chemist can identify compounds in the material that have medicinal value and find a way to *synthesize* them, or prepare them in the laboratory, so that they can be made available in large quantities.

In rational drug design, the chemist begins with the tumor or organism that the drug is intended to eradicate. Virtually all processes in living cells depend on specific *enzymes*, types of proteins with very large molecules having specific shapes. Usually there is an *active site* on the enzyme into which only specific molecules can fit and react. If the enzymes that control the growth of parasites or bacteria can be identified and their shapes known, compounds that fit into the active sites and block the reactions can be designed. The chemist taking this route begins by identifying key enzymes in the bacterium or parasite. Then the molecular structure of the enzyme is determined. A computer program is used to design molecules with structures that fit into the active site. Structure–activity relationships (SAR) are investigated to find out which aspects of the structure are important to the activity of the drug. The new compounds are synthesized, and their effects and side effects tested.

? HOW MIGHT YOU CONTRIBUTE?

Despite all the medicines in a modern pharmacy, there is still a great need for specific chemotherapeutic agents with few side effects. We are beginning to see the investigation of a wide array of natural products and the rational drug design of new therapeutic agents. The selection of good candidates for drug development from these large numbers of compounds and synthetic routes to duplicate them need to be optimized.

3.1 The Basic VSEPR Model

We begin by looking at molecules that consist of one central atom to which all the other atoms are attached. Many of these molecules have the shapes of the geometrical figures shown in Fig. 3.1; thus, CH_4 (**1**) is tetrahedral, SF_6 (**2**) is octahedral, and PCl_5

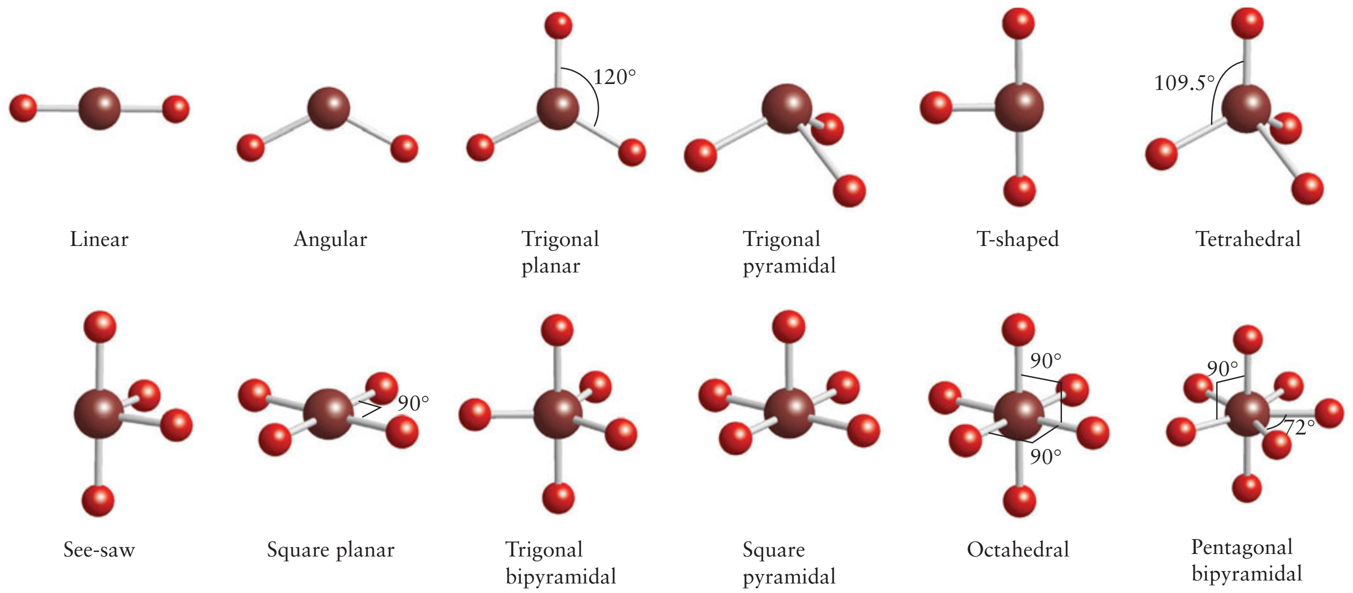

FIGURE 3.1 The names of the shapes of simple molecules and their bond angles. Lone pairs of electrons are not shown, because they are not included when identifying molecular shapes.

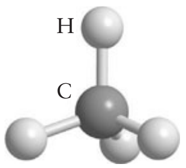
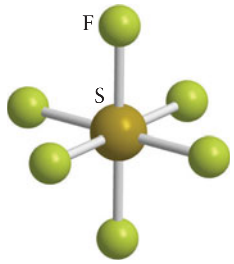
(**3**) is trigonal bipyramidal. In a number of these cases the **bond angles,** the angles between the bonds (the straight lines that join the atom centers), are fixed by the symmetry of the molecule; these bond angles are indicated in Fig. 3.1. Thus, the HCH angle in CH_4 is 109.5° (the "tetrahedral angle"), the FSF angles in SF_6 are 90° and 180°, and the ClPCl angles in PCl_5 are 90°, 120°, and 180°. The bond angles of molecules that are not fixed by symmetry must be determined experimentally. The HOH bond angle in the angular H_2O molecule, for instance, has been found to be 104.5° and the HNH angle in the trigonal pyramidal NH_3 molecule is measured as 107°. The principal technique for determining bond angles in small molecules is spectroscopy, especially rotational and vibrational spectroscopy; x-ray diffraction is used for larger molecules.



1 Methane, CH_4



2 Sulfur hexafluoride, SF_6

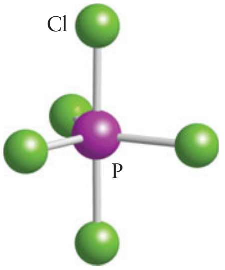
The VSEPR model was first explored by the British chemists Nevil Sidgwick and Herbert Powell and has been developed by the Canadian chemist Ronald Gillespie.

The Lewis structures encountered in Chapter 2 are two-dimensional representations of the links between atoms—their connectivity—and except in the simplest cases do not depict the arrangement of atoms in space. The **valence-shell electron-pair repulsion model** (VSEPR model) extends Lewis's theory of bonding to account for molecular shapes by adding rules that account for bond angles. The model starts from the idea that because electrons repel one another, the pairs of bonding electrons in simple molecules lie as far apart as possible. Specifically:

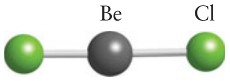
> **Rule 1** Regions of high electron concentration (bonds and lone pairs on the central atom) repel one another and, to minimize their repulsions, these regions move as far apart as possible while maintaining the same distance from the central atom (Fig. 3.2).

Once we have identified the arrangement of the "most distant" locations of these regions, which is called the **electron arrangement** of the molecule, we note where the atoms lie and identify the shape of the molecule by giving it the name of the corresponding shape in Fig. 3.1. In naming the molecular shape, we consider only the positions of atoms, not any lone pairs that may be present on the central atom, even though they affect the shape.

A molecule with only two atoms attached to the central atom is $BeCl_2$. The Lewis structure is $:\ddot{\underset{\cdot\cdot}{\mathrm{Cl}}}-\mathrm{Be}-\ddot{\underset{\cdot\cdot}{\mathrm{Cl}}}:$, and there are no lone pairs on the central atom. To be as far apart as possible, the two bonding pairs lie on opposite sides of the Be atom, and so the electron arrangement is linear. The Cl atoms lie on opposite sides of the Be atom and so the VSEPR model predicts a linear shape for the $BeCl_2$ molecule, with a bond angle of 180° (**4**). That shape is confirmed by experiment.



3 Phosphorus pentachloride, PCl_5



4 Beryllium chloride, $BeCl_2$

A boron trifluoride molecule, BF_3, has the Lewis structure shown in (**5**). There are three bonding pairs attached to the central atom and no lone pairs. To be as far apart as possible, the three bonding pairs must lie at the corners of an equilateral triangle.

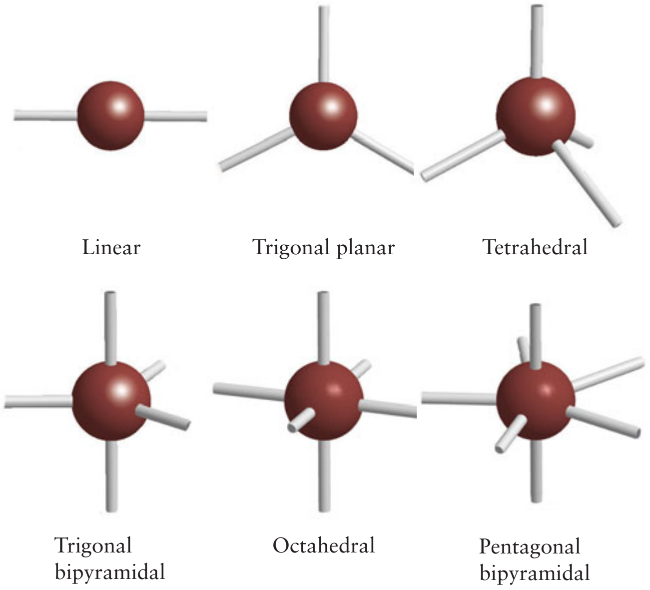


FIGURE 3.2 The positions that two to seven regions of high electron concentration (atoms and lone pairs) take around a central atom. The regions are denoted by the straight lines sticking out of the central atom. Use this diagram to identify the electron arrangement of a molecule, and then use Fig. 3.1 to identify the shape of the molecule from the locations of its atoms. The seven-region pentagonal bipyramidal arrangement is not unique: several arrangements have about the same energy.

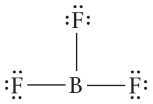
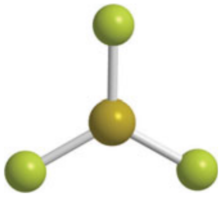
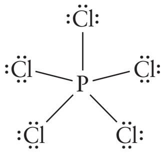


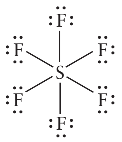
5 Boron trifluoride, BF_3



6 Boron trifluoride, BF_3



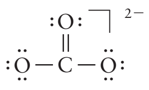
7 Phosphorus pentachloride, PCl_5



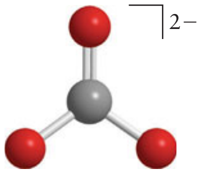
8 Sulfur hexafluoride, SF_6

9 Carbon dioxide, CO_2

All six terminal atoms are equivalent in a regular octahedral molecule.



10 Carbonate ion, CO_3^{2-}



11 Carbonate ion, CO_3^{2-}

The electron arrangement is trigonal planar. Because an F atom is attached to each bonding pair, the BF_3 molecule is trigonal planar (**6**), and all three FBF angles are 120°, as confirmed experimentally.

Methane, CH_4, has four bonding pairs on the central atom. To be as far apart as possible, the four pairs must take up a tetrahedral arrangement around the C atom. Because the electron arrangement is tetrahedral and an H atom is attached to each bonding pair, we expect the molecule to be tetrahedral (see **1**), with bond angles of 109.5°. That is the shape found experimentally.

In a phosphorus pentachloride molecule, PCl_5 (**7**), there are five bonding pairs and no lone pairs on the central atom. According to the VSEPR model, the five pairs and the atoms that they carry are farthest apart in a trigonal bipyramidal arrangement (see Fig. 3.2). In this arrangement, three atoms (the "equatorial" atoms) lie at the corners of an equilateral triangle and the other two atoms (the "axial" atoms) lie above and below the plane of the triangle (see **3**). This structure has three different bond angles: the bond angles in the equatorial plane are 120°; the angle between the axial and the equatorial atoms is 90°; the one axial ClPCl bond angle is 180°. This structure is also confirmed experimentally.

A sulfur hexafluoride molecule, SF_6, has six atoms attached to the central S atom and no lone pairs on that atom (**8**). According to the VSEPR model, the electron arrangement is octahedral, with four pairs at the corners of a square on the equator and the remaining two pairs above and below the plane of the square (see Fig. 3.2). An F atom is attached to each electron pair, and so the molecule is predicted to be octahedral. All its bond angles are either 90° or 180°, and all the F atoms are equivalent.

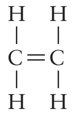
The second rule of the VSEPR model concerns the treatment of multiple bonds:

> **Rule 2** There is no distinction between single and multiple bonds: a multiple bond is treated as a single region of high electron concentration.

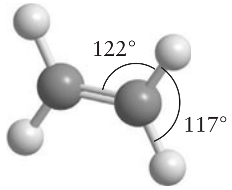
That is, the two electron pairs in a double bond stay together and repel other bonds or lone pairs as a unit. The three electron pairs in a triple bond also stay together and act like a single region of high electron concentration. For instance, a carbon dioxide molecule, $\ddot{O}{=}C{=}\ddot{O}$, has a linear structure similar to that of $BeCl_2$, even though both bonds are double bonds (**9**). One of the Lewis structures of a carbonate ion, CO_3^{2-}, is shown in (**10**). The two pairs of electrons in the double bond are treated as a unit, and the resulting shape (**11**) is trigonal planar. Because each bond, whether single or multiple, acts as a single unit, to count the number of regions of high electron concentration we simply count the number of atoms attached to the central atom and add the number of lone pairs.

When there is more than one central atom, we consider the bonding about each atom independently. For example, to predict the shape of an ethene (ethylene) molecule, $CH_2{=}CH_2$, we consider each carbon atom separately. From the Lewis structure

(**12**) we note that each carbon atom has three atoms attached but no lone pairs. The arrangement around each carbon atom is therefore trigonal planar. We predict that the HCH and HCC angles will both be close to 120° (**13**); this prediction is confirmed experimentally (the actual values being 117° and 122°, respectively).



12 Ethene, C_2H_4



13 Ethene, C_2H_4

EXAMPLE 3.1 Predicting the shape of a molecule with no lone pairs on the central atom

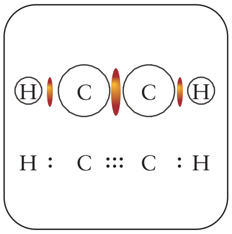
Suggest a shape for the ethyne (acetylene) molecule, HC≡CH.

PLAN Write down the Lewis structure and identify the electron arrangement around each "central" atom (each C atom, in this case). Treat each multiple bond as a single unit. Then identify the overall shape of the molecule (refer to Fig. 3.2 if necessary).

SOLVE

Write the Lewis structure of the molecule.

H—C≡C—H

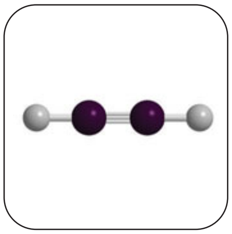


Identify the electron arrangement around each "central" atom.

Linear: Each C atom is attached to two other atoms (one H atom and one C atom), and there are no lone pairs.

Identify the arrangement of atoms around each C atom.

Linear, and the molecule is linear overall.

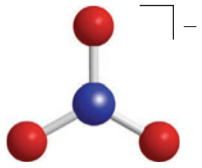


Self-Test 3.1A Predict the shape of an arsenic pentafluoride molecule, AsF_5.

[*Answer:* Trigonal bipyramidal]

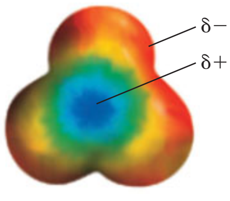
Self-Test 3.1B Predict the shape of a formaldehyde molecule, CH_2O.

Because we treat single bonds and multiple bonds as equivalent in the VSEPR model, it does not matter which of the Lewis structures contributing to a resonance structure we consider. For example, although we can write several different Lewis structures for a nitrate ion, all of them have three regions of electron concentration around the central N atom—all of them have three atoms attached to the central atom—and in each case we expect a trigonal planar structure (**14**). That the three N—O bonds are all equivalent is confirmed experimentally by the fact that all three have the same length and the three bond angles are identical. It is also confirmed by calculation: an electrostatic potential diagram (Section C) shows the symmetry of the calculated electron distribution (**15**). The equivalence of the three bonds is what we would expect in a resonance structure.



14 Nitrate ion, NO_3^-

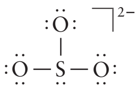
Recall that red regions indicate negative electrical potential (an accumulation of electrons) and blue regions indicate positive potential (a deficiency of electrons).



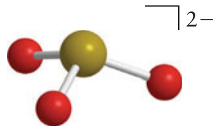
15 Nitrate ion

Thinking point: Can you think of a way to present VSEPR theory without having to deal with Lewis structures?

According to the VSEPR model, regions of high electron concentration take up positions that maximize their separations; electron pairs in a multiple bond are treated as a single unit. The shape of the molecule is then identified from the relative locations of its atoms.

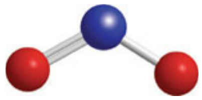


16 Sulfite ion, SO_3^{2-}



17 Sulfite ion, SO_3^{2-}

18 Nitrogen dioxide, NO_2



19 Nitrogen dioxide, NO_2

3.2 Molecules with Lone Pairs on the Central Atom

To help us predict the shapes of molecules, we use the generic "VSEPR formula" AX_nE_m to identify the different combinations of atoms and lone pairs attached to the central atom. We let A represent a central atom, X an attached atom, and E a lone pair. For example, the BF_3 molecule, with three attached fluorine atoms and no lone pairs on B, is an example of an AX_3 species. The sulfite ion, SO_3^{2-} (**16**), which has one lone pair, is an example of an AX_3E species. Molecules with the same VSEPR formula have essentially the same electron arrangement and the same shape; so by recognizing the formula we can immediately predict the shape (but not necessarily the precise numerical values of bond angles that are not governed by symmetry).

If there are no lone pairs on the central atom (an AX_n molecule), each region of high electron concentration corresponds to an atom, and so the molecular shape is the same as the electron arrangement. However, if lone pairs are present, the molecular shape differs from the electron arrangement because only the positions of the atoms are considered when naming the shape. For example, the four regions of high electron concentration in SO_3^{2-} are farthest apart if they adopt a tetrahedral arrangement (see Fig. 3.2). However, the *shape* of the ion is described by the locations of the atoms, not the lone pair. Because only three of the tetrahedral locations are occupied by atoms, the shape of an SO_3^{2-} ion is trigonal pyramidal (**17**). The rule to remember is

> **Rule 3** All regions of high electron density, lone pairs and bonds, are included in a description of the electronic arrangement, but *only the positions of atoms are considered when identifying the shape of a molecule.*

A single unpaired electron on the central atom also is a region of high electron density and is treated like a lone pair when determining molecular shape. For example, radicals such as NO_2 have a single nonbonding electron, a "lone half-pair." Thus, NO_2 (**18**) has a trigonal planar electron arrangement (including the unpaired electron on N), but its shape is angular (**19**).

EXAMPLE 3.2 Predicting the shape of a molecule with lone pairs on the central atom

Predict the electron arrangement and the shape of a nitrogen trifluoride molecule, NF_3.

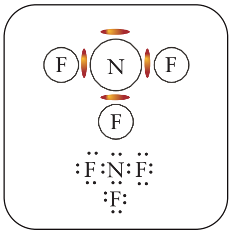
Anticipate The formula resembles that of ammonia, NH_3, which is trigonal pyramidal; so we should suspect that NF_3 will also be trigonal pyramidal.

PLAN For the electron arrangement, draw the Lewis structure and then use the VSEPR model to decide how the bonding pairs and lone pairs are arranged around the central atom (consult Fig. 3.2 if necessary). Identify the molecular shape from the layout of atoms, as in Fig. 3.1.

SOLVE

Draw the Lewis structure.
Count the bonds and lone pairs on the central atom.

The central N atom has one electron pair and three bonds, corresponding to four regions of high electron density.

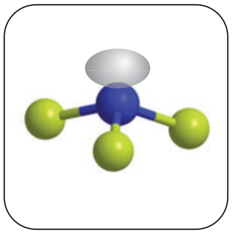


Assign the electron arrangement.

Tetrahedral

Identify the shape considering only atoms.

The three atoms bonded to N form a trigonal pyramid.



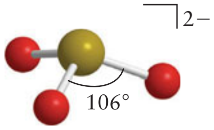
Note that normally lone pairs are not shown explicitly when drawing molecular structures.

Evaluate Spectroscopic measurements confirm the prediction of a trigonal pyramidal shape for NF_3. The value of the bond angle found experimentally is 102°.

Self-Test 3.2A Predict (a) the electron arrangement and (b) the shape of an IF_5 molecule.

[***Answer:*** (a) Octahedral; (b) square pyramidal]

Self-Test 3.2B Predict (a) the electron arrangement and (b) the shape of an SO_2 molecule.



20 Sulfite ion, SO_3^{2-}

So far we have regarded lone pairs as equivalent to atoms, but is that really the case? We have predicted, for instance, that the electron arrangement of an SO_3^{2-} ion is tetrahedral, and so we might expect OSO angles of 109.5°. However, experimental findings have shown that, although the sulfite ion is indeed trigonal pyramidal, its bond angle is 106° (**20**). Such experimental evidence tells us that the VSEPR model as we have described it is incomplete and needs to be refined.

To account for the fact that bond angles in molecules with lone pairs are typically smaller than expected, the VSEPR model treats lone pairs as having a more strongly repelling effect than do electrons in bonds. That is, the lone pairs push the atoms bonded to the central atom closer together. One possible rationalization for this effect is that the electron cloud of a lone pair can spread over a larger volume than a bonding pair, because a bonding pair (or several bonding pairs in a multiple bond) is pinned down by two atoms, not one (Fig. 3.3). In summary, the VSEPR model provides reasonably reliable predictions if we adopt the following rule:

Rule 4 The strengths of repulsions are in the order lone pair–lone pair > lone pair–atom > atom–atom.

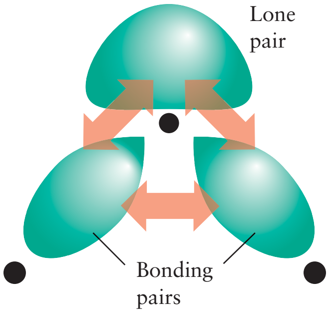


FIGURE 3.3 A possible explanation of why lone pairs have a greater repelling effect than that of bonding electrons. A lone pair is less restrained than bonding pairs and so takes up more space; the bonding pairs (with their atoms) move away from the lone pair in an attempt to lower the repulsion that they experience, thus compressing the bond angle slightly.

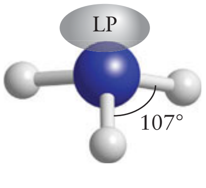
Therefore, the lowest energy is achieved when lone pairs are as far from each other as possible. The energy is also lowest if the atoms bonded to the central atom are far from lone pairs, even though that might bring the atoms closer to other atoms.

Our improved model helps to account for the bond angle of the AX_3E sulfite ion. The atoms and the lone pair adopt a tetrahedral arrangement around the S atom. However, the lone pair exerts a strong repulsion on the O atoms, forcing them to move together slightly, reducing the OSO angle from the 109.5° of the regular tetrahedron to 106°. Note that, although the VSEPR model can predict the direction of the distortion, it cannot predict its extent. We can predict that, in any AX_3E species, the XAX angle will be less than 109.5°, but we cannot predict its actual value; we must measure it experimentally or calculate it by solving the Schrödinger equation numerically on a computer.

Self-Test 3.3A (a) Give the VSEPR formula of an NH_3 molecule. Predict (b) its electron arrangement and (c) its shape.

[***Answer:*** (a) AX_3E; (b) tetrahedral; (c) trigonal pyramidal (**21**, LP is lone pair), HNH angle less than 109.5°]

Self-Test 3.3B (a) Give the VSEPR formula of a ClO_2^- ion. Predict (b) its electron arrangement and (c) its shape.



21 Ammonia, NH_3

Rule 4 allows us to predict the position in which a lone pair will be found. For example, the electron arrangement in an AX_4E molecule or ion, such as IF_4^+, is trigonal bipyramidal, but there are two different possible locations for the lone pair. An

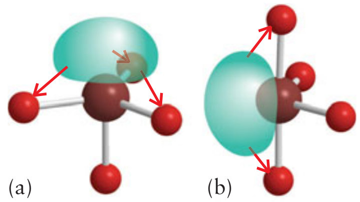


FIGURE 3.4 (a) A lone pair in an axial position is close to three equatorial atoms. (b) In an equatorial position, a lone pair is close to only two atoms, a more favorable arrangement.

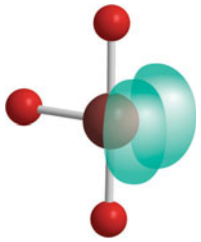

FIGURE 3.5 Two lone pairs in an AX_3E_2 molecule adopt equatorial positions and move away from each other slightly. As a result, the molecule is approximately T-shaped.

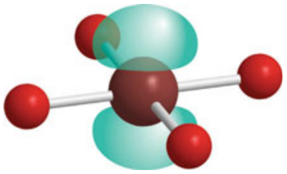

FIGURE 3.6 The square planar arrangement of atoms taken up in AX_4E_2 molecules: the two lone pairs are farthest apart when they are on opposite sides of the central atom.

axial lone pair lies on the axis of the molecule, where it repels three electron pairs strongly; an **equatorial lone pair** lies on the molecule's equator, on the plane perpendicular to the molecular axis, where it repels only two electron pairs strongly (Fig. 3.4). Experimental evidence for this difference in repulsion is the fact that the axial P–Cl bond length in PCl_5 is 219 pm, but the equatorial P—Cl bond length is only 204 pm. Therefore, the lowest energy is achieved when a lone pair is equatorial, producing a seesaw-shaped molecule. An AX_3E_2 molecule, such as ClF_3, also has a trigonal bipyramidal arrangement of electron pairs, but two of the pairs are lone pairs. These two pairs are farthest apart if they occupy two of the three equatorial positions but move away from each other slightly. The result is a T-shaped molecule (Fig. 3.5). Now consider an AX_4E_2 molecule, which has an octahedral arrangement of electron pairs, two of which are lone pairs. The two lone pairs are farthest apart when they lie opposite each other, and so the molecule is square planar (Fig. 3.6).

Molecules with the same VSEPR formula all have the same general shape, although their bond angles generally differ slightly. For example, O_3 is an AX_2E species $(:\ddot{O}-\ddot{O}=\ddot{O})$; it has a trigonal planar electron arrangement and an angular molecular shape (**22**). The nitrite ion, NO_2^-, has the same general formula $[:\ddot{O}-\ddot{N}=\ddot{O}]^-$ and the same shape (**23**); so too does sulfur dioxide, SO_2 $(:\ddot{O}-\ddot{S}=\ddot{O})$, (**24**). Exceptions sometimes arise when the energy difference between two possible structures is small. For example, the energy of an AX_4E square planar structure is only very slightly higher than that of an AX_4E seesaw structure and some AX_4E species, such as the $InCl_4^-$ ion, are square pyramidal (**25**). Exceptions to the VSEPR rules are also found for atoms that are so large that lone pairs do not affect the shape of the molecule. For example, The $SeCl_6^{2-}$ ion is octahedral, even though the Se atom contains a lone pair as well as bonds to six atoms.

TOOLBOX 3.1 HOW TO USE THE VSEPR MODEL

CONCEPTUAL BASIS

Regions of high electron concentration—bonds and lone pairs attached to a central atom in a molecule—arrange themselves in such a way as to minimize mutual repulsions.

PROCEDURE

The general procedure for predicting the shape of a molecule is as follows:

Step 1 Decide how many atoms and lone pairs are present on the central atom by writing a Lewis structure for the molecule.

Step 2 Identify the electron arrangement, including lone pairs and atoms, and treating a multiple bond as equivalent to a single bond (see Fig. 3.2).

Step 3 Locate the atoms and identify the molecular shape (according to Fig. 3.1). The molecular shape describes only the positions of the atoms, not the lone pairs.

Step 4 Allow the molecule to distort so that lone pairs are as far from one another and from bonding pairs as possible. The repulsions are in the order

Lone pair–lone pair > lone pair–atom > atom–atom

Example 3.3 shows how this procedure is used.

EXAMPLE 3.3 **Predicting a molecular shape**

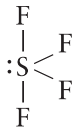
Predict the shape of a sulfur tetrafluoride molecule, SF_4.

PLAN We use the procedure in Toolbox 3.1.

SOLVE

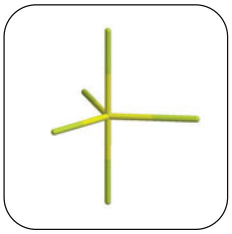
Step 1 Draw the Lewis structure.

Because we are focusing on the central atom, there is no need to show the lone pairs on the F atoms.



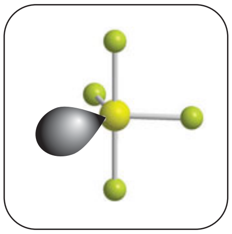
Step 2 Assign the electron arrangement around the central atom.

Each F atom should have three lone pairs of electrons, leaving 5 regions of high electron density (4 atoms and 1 lone pair) on the S atom; so trigonal bipyramidal.



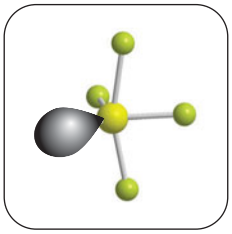
Step 3 Identify the molecular shape. AX_4E.

To minimize electron pair repulsions, the lone pair occupies an equatorial location. SF_4 has a seesaw shape.



Step 4 Allow for distortions.

The atoms move slightly away from the lone pair.



Evaluate The slightly bent seesaw shape shown is the one found experimentally.

Self-Test 3.4A Predict the shape of an I_3^- ion.

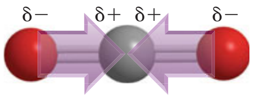
[*Answer:* Linear]

Self-Test 3.4B Predict the shape of a xenon tetrafluoride molecule, XeF_4.

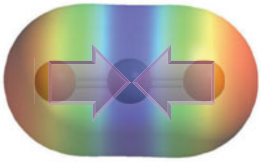
In a molecule that has lone pairs or a single nonbonding electron on the central atom, the valence electrons contribute to the electron arrangement about the central atom but only bonded atoms are considered in the identification of the shape. Lone pairs distort the shape of a molecule so as to reduce lone pair–bonding pair repulsions.

3.3 Polar Molecules

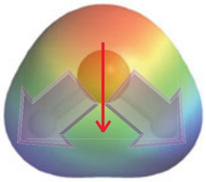
In Section 2.12, we saw that a polar covalent *bond* in which electrons are not evenly distributed has a nonzero dipole moment. A **polar molecule** is a *molecule* with a nonzero dipole moment. A diatomic molecule is polar if its bond is polar. An HCl molecule, with its polar covalent bond ($^{\delta+}H{-}Cl^{\delta-}$), is a polar molecule. Its dipole moment of 1.1 D is typical of polar diatomic molecules (Table 3.1). All diatomic molecules composed of atoms of two different elements are at least slightly polar. A **nonpolar molecule** is a molecule that has no electric dipole moment. A **homonuclear diatomic molecule**, a diatomic molecule built from two atoms of the same element, such as O_2, N_2, and Cl_2, is nonpolar, because its bond is nonpolar.



26 Carbon dioxide, CO_2



27 Carbon dioxide, CO_2



28 Water, H_2O

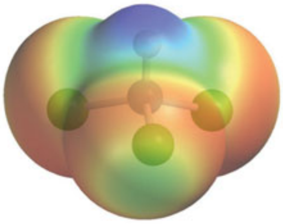
31 Tetrachloromethane, CCl_4



32 Trichloromethane, CH_3Cl

TABLE 3.1 Dipole Moments of Selected Molecules

Molecule	Dipole moment (D)	Molecule	Dipole moment (D)
HF	1.91	PH_3	0.58
HCl	1.08	AsH_3	0.20
HBr	0.80	SbH_3	0.12
HI	0.42	O_3	0.53
CO	0.12	CO_2	0
ClF	0.88	BF_3	0
NaCl*	9.00	CH_4	0
CsCl*	10.42	*cis*-CHCl=CHCl	1.90
H_2O	1.85	*trans*-CHCl=CHCl	0
NH_3	1.47		

*For pairs of ions in the gas phase, not the bulk ionic solid.

A polyatomic molecule may be nonpolar even if its bonds are polar. For example, the two $^{\delta+}C—O^{\delta-}$ dipole moments in carbon dioxide, a linear molecule, point in opposite directions, and so they cancel each other (**26**). and CO_2 is a nonpolar molecule. Even though there are positive and negative regions of charge within the molecule, the center of positive charge and the center of negative charge coincide, so the molecule itself is nonpolar. The electrostatic potential diagram (**27**) illustrates this conclusion. As noted in Section C, the colors show how electron density is distributed in the molecule. Partially positive regions are blue and partially negative regions red. In contrast, the two $^{\delta+}H—O^{\delta-}$ dipole moments in H_2O lie at 104.5° to each other and do not cancel, and so H_2O is a polar molecule (**28**). This polarity is part of the reason why water is such a good solvent for ionic compounds.

Thinking point: Can you justify that last remark?

As we have seen by comparing CO_2 and H_2O, the shape of a polyatomic molecule affects whether or not it is polar. The same is true of more complicated molecules. For instance, the atoms and bonds are the same in *cis*-dichloroethene (**29**) and *trans*-dichloroethene (**30**); but in the latter, the C—Cl bonds point in opposite directions and the dipoles (which point along the C—Cl bonds) cancel. Thus, whereas *cis*-dichloroethene is polar, *trans*-dichloroethene is nonpolar. Because dipole moments are directional, we can treat each bond dipole moment as a vector. The molecule *as a whole* will be nonpolar if the vector sum of the dipole moments of the bonds is zero.

If the four atoms attached to the central atom in a tetrahedral molecule are the same, as in tetrachloromethane (carbon tetrachloride), CCl_4 (**31**), the dipole moments cancel and the molecule is nonpolar. However, if one or more of the atoms are replaced by different atoms, as in trichloromethane (chloroform), $CHCl_3$, or by lone pairs, as in NH_3, then the dipole moments associated with the bonds are not all the same, so they do not cancel. Thus, the $CHCl_3$ molecule is polar (**32**).

Figure 3.7 summarizes the shapes of simple molecules that result in their being polar or nonpolar.

EXAMPLE 3.4 Predicting the polar character of a molecule

Predict whether (a) a boron trifluoride molecule, BF_3, and (b) an ozone molecule, O_3, are polar.

PLAN In each case, we must decide on the shape of the molecule by using the VSEPR model and then decide whether the symmetry of the molecule results in the cancellation of the dipole moments associated with the bonds. If necessary, refer to Fig. 3.7.

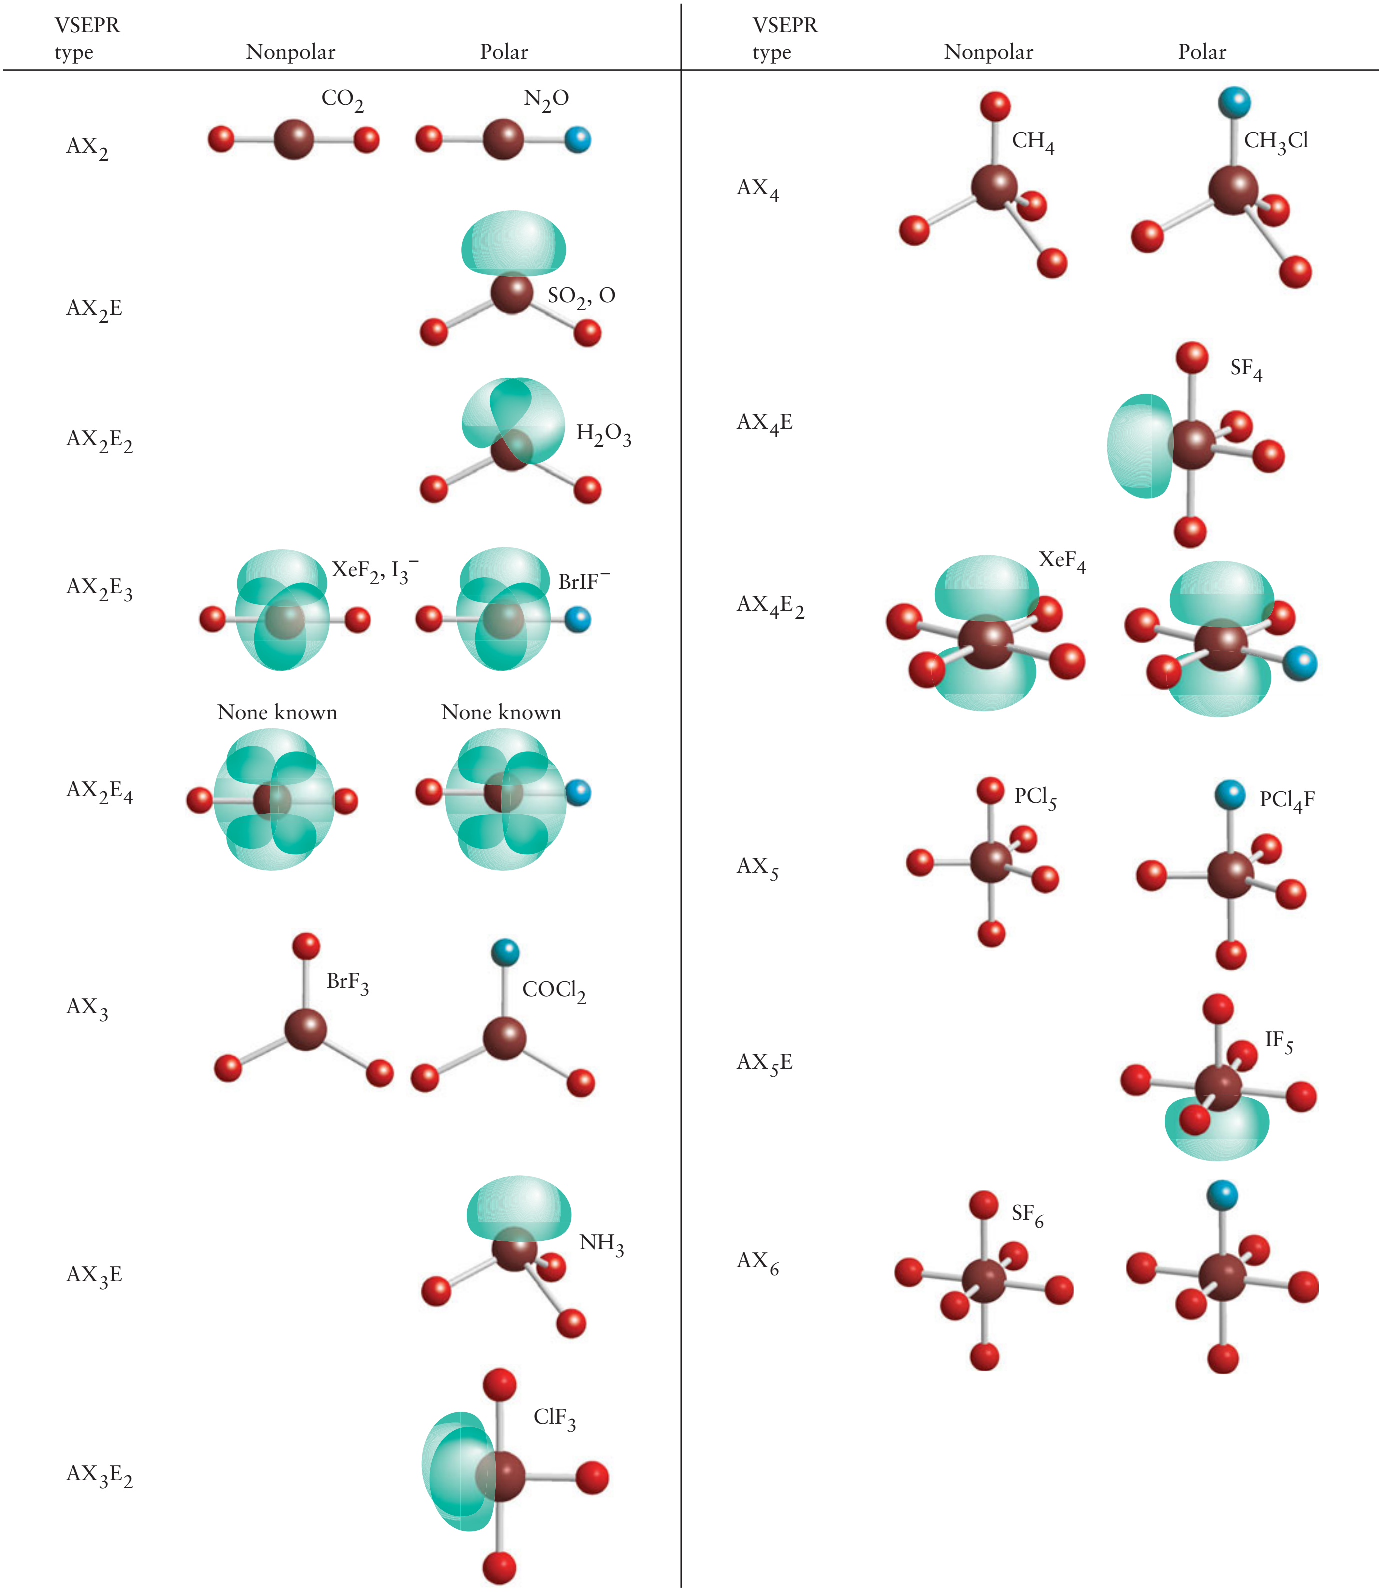


FIGURE 3.7 Arrangements of atoms that give rise to polar and nonpolar molecules. In the VSEPR formulas, A stands for a central atom, X for an attached atom, and E for a lone pair. Identical atoms are the same color; attached atoms colored differently belong to different elements. The green lobes represent lone pairs of electrons.

SOLVE

	BF_3	O_3
Draw the Lewis structure.		Assign the electron arrangement.		Identify the VSEPR formula.	AX_3	AX_2E
Name the molecular shape.	 Trigonal planar	 Angular
Identify the polarity.	 Nonpolar: The symmetry allows all three B—F dipoles to cancel.	 Polar: The dipoles do not cancel.

Evaluate This example shows that a homonuclear polyatomic molecule (O_3) can be polar: shape is more important than differences in atoms and O_3 is polar despite all three atoms being oxygen. In this case, the central O atom has a different electron density associated with it than the outer two O atoms: it is bonded to two O atoms whereas the outer atoms are bonded only to one O atom.

Self-Test 3.5A Predict whether (a) SF_4, (b) SF_6 is polar or nonpolar.

[***Answer:*** (a) Polar; (b) nonpolar]

Self-Test 3.5B Predict whether (a) PCl_5, (b) IF_5 is polar or nonpolar.

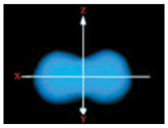
A diatomic molecule is polar if its bond is polar. A polyatomic molecule is polar if it has polar bonds arranged in space in such a way that the dipole moments associated with the bonds do not cancel.

VALENCE-BOND THEORY

The Lewis model of the chemical bond assumes that each bonding electron pair is located between the two bonded atoms—it is a *localized electron model*. However, we know from the wave–particle duality of the electron (Sections 1.5–1.7) that the location

of an electron in an atom cannot be described in terms of a precise position, but only in terms of the *probability* of finding it somewhere in a region of space defined by its orbital. The same principles apply to electrons in molecules, except that the electrons are distributed over more than one atom.

The first description of covalent bonding to be devised in terms of atomic orbitals, by Walter Heitler, Fritz London, John Slater, and Linus Pauling in the late 1920s, is called **valence-bond theory** (VB theory). This theory is a quantum mechanical description of the distribution of electrons in bonds that goes beyond Lewis's theory and the VSEPR model by providing a way of calculating the numerical values of bond angles and bond lengths. We shall not go into the actual calculations, which are very complicated, but shall concentrate instead on some of the qualitative concepts. These bonding concepts are used throughout chemistry, so it is important to know how to apply them.



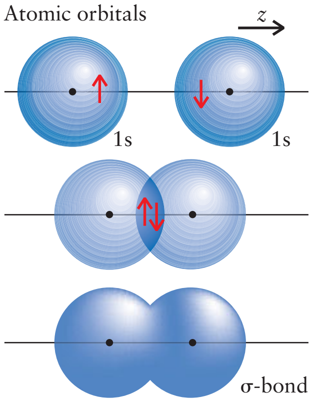


FIGURE 3.8 When electrons with opposite spins (depicted as ↑ and ↓) in two hydrogen 1s-orbitals pair and the s-orbitals overlap, they form a σ-bond, which is depicted here by the boundary surface of the electron cloud. The cloud has cylindrical symmetry around the internuclear axis and spreads over both nuclei. In the illustrations in this book, σ-bonds are usually colored blue.

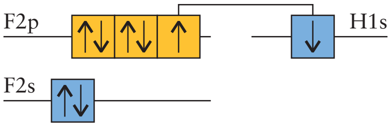
Animation 3.8

3.4 Sigma and Pi Bonds

We begin with H_2, the simplest molecule of all, and start by thinking about the two hydrogen atoms from which it is formed. Each hydrogen atom in its ground state has one electron in a 1s-orbital. In valence-bond theory, we suppose that, as two H atoms come together, their 1s-electrons pair (denoted ↑↓, as in the discussion of atomic structure in Section 1.10), and the atomic orbitals merge together (Fig. 3.8). The resulting sausage-shaped distribution of electrons, with an accumulation of electron density between the nuclei, is called a "σ-bond" (a sigma bond). More formally, a **σ-bond** is cylindrically symmetrical (the same in all directions around the long axis of the bond), with no nodal planes containing the internuclear axis. A hydrogen molecule is held together by a σ-bond. The merging of the two atomic orbitals is called the **overlap** of orbitals. A general point to keep in mind throughout this section is that, the greater the extent of orbital overlap, the stronger the bond.

The Greek letter sigma, σ, is the equivalent of our letter s. It reminds us that, looking along the internuclear axis, the electron distribution resembles that of an s-orbital.

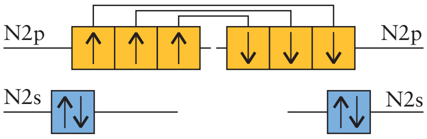
Much the same kind of σ-bond formation ("σ-bonding") occurs in the hydrogen halides. For example, before an H and F atom combine to form hydrogen fluoride, the unpaired electron on the fluorine atom occupies a $2p_z$-orbital, and the unpaired electron on the hydrogen atom occupies a 1s-orbital. These two electrons are the ones that pair to form a bond (**33**). They pair as the orbitals that they occupy overlap and merge into a cloud that spreads over both atoms (Fig. 3.9). When viewed from the side, the resulting bond has a more complicated shape than that of the σ-bond in H_2; however, the bond looks much the same—it has cylindrical symmetry and no nodal planes containing the internuclear axis—when viewed along the internuclear (z) axis; hence it too is a σ-bond. All *single* covalent bonds are σ-bonds.



33 Hydrogen fluoride, HF

By convention, the bond direction in a linear molecule defines the *z*-axis.

We encounter a different type of bond in a nitrogen molecule, N_2. There is a single electron in each of the three 2p-orbitals on each atom (**34**). However, when we try to pair them and form three bonds, only one of the three orbitals on each



34 Nitrogen, N_2

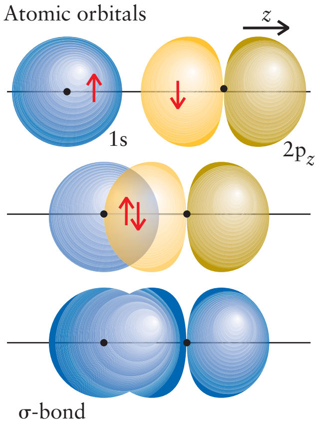


FIGURE 3.9 A σ-bond can also be formed when electrons in 1s- and $2p_z$-orbitals pair (where z is the direction along the internuclear axis). The two electrons in the bond are generally found spread over the entire region of space enclosed by the boundary surface.

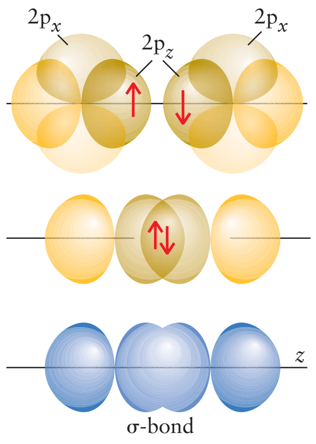

FIGURE 3.10 A σ-bond is formed by the pairing of electron spins in two $2p_z$-orbitals on neighboring atoms. At this stage, we are ignoring the interactions of any $2p_x$- (and $2p_y$-) orbitals that also contain unpaired electrons, because they cannot form σ-bonds. Most of the time the bonding electron pair is found within the boundary surface shown in the bottom diagram. Notice that the nodal plane of each p_z-orbital survives in the σ-bond.

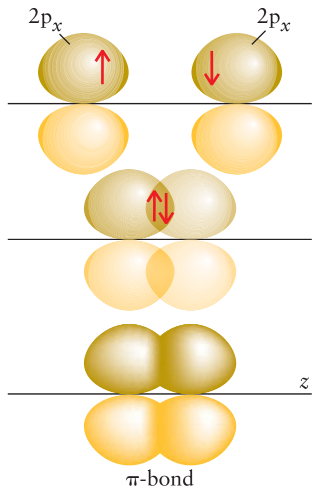

FIGURE 3.11 A π-bond is formed when electrons in two 2p-orbitals pair and overlap side by side. The middle diagram shows the extent of the overlap, and the bottom diagram shows the corresponding boundary surface. Even though the bond has a complicated shape, with two lobes, it is occupied by one pair of electrons and counts as one bond. In this text, π-bonds are usually colored a shade of yellow.

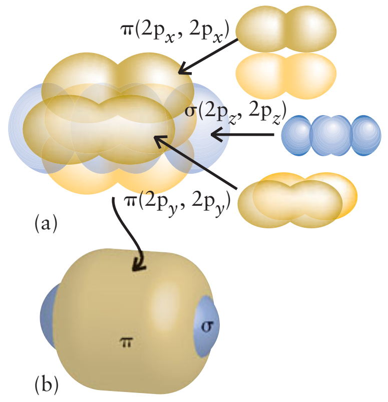

FIGURE 3.12 The bonding pattern in a nitrogen molecule, N_2. (a) The two atoms are held together by one σ-bond (blue) and two perpendicular π-bonds (yellow). (b) When the three bonds form, the two π-bonds merge to form a long doughnut-shaped cloud surrounding the σ-bond cloud; so the overall structure resembles a cylindrical hot dog.

atom can overlap end to end to form a σ-bond (Fig. 3.10). Two of the 2p-orbitals on each atom ($2p_x$ and $2p_y$) are perpendicular to the internuclear axis, and each one contains an unpaired electron (Fig. 3.11, top). When the electrons in the p-orbitals on one N atom pair with the p-electrons on the other N atom, the orbitals can overlap only in a side-by-side arrangement. This overlap results in a "π-bond," a bond in which the two electrons lie in two lobes, one on each side of the internuclear axis (Fig. 3.11, bottom). More formally, a **π-bond** has a single nodal plane containing the internuclear axis. Although a π-bond has electron density on each side of the internuclear axis, it is only one bond, with the electron cloud in the form of two lobes, just as a p-orbital is one orbital with two lobes. In a molecule with two π-bonds, such as N_2, the electron densities in the two perpendicular π-bonds merge, and the two atoms appear to be surrounded by a cylinder of electron density (Fig. 3.12).

The Greek letter pi, π, is the equivalent of our letter p. When we imagine looking along the internuclear axis, a π-bond resembles a pair of electrons in a p-orbital.

Thinking point. How do you think a δ-bond (a delta bond) might be formed?

We can generalize from these examples to the description of a multiply bonded species according to valence-bond theory:

A **single bond** is a σ-bond.
A **double bond** is a σ-bond plus one π-bond.
A **triple bond** is a σ-bond plus two π-bonds.

There are a few exceptions to the rule about double bonds: in a very few instances both bonds of a double bond are π-bonds.

Self-Test 3.6A How many σ-bonds and how many π-bonds are there in (a) CO_2 and (b) CO?

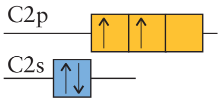
[*Answer:* (a) Two σ, two π; (b) one σ, two π]

Self-Test 3.6B How many σ-bonds and how many π-bonds are there in (a) NH_3 and (b) HCN?

In valence-bond theory, we assume that bonds form when unpaired electrons in valence-shell atomic orbitals pair; the atomic orbitals overlap end to end to form σ-bonds or side by side to form π-bonds.

3.5 Electron Promotion and the Hybridization of Orbitals

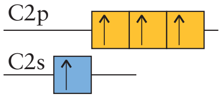
When we try to apply VB theory to methane we run into difficulties. A carbon atom has the configuration $[He]2s^22p_x^{\ 1}2p_y^{\ 1}$ with four valence electrons (**35**). However, two valence electrons are already paired and only the two half-filled 2p-orbitals appear to be available for bonding. It looks as though a carbon atom should have a valence of 2 and form two perpendicular bonds, but in fact it almost always has a valence of 4 (it is commonly "tetravalent") and in CH_4 has a tetrahedral arrangement of bonds.



35 Carbon, $[He]2s^22p_x^{\ 1}2p_y^{\ 1}$

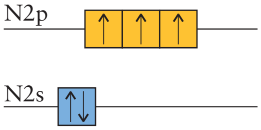
Carbon monoxide, CO, is the only common exception to the tetravalence of carbon.

To account for the four bonds we note that a carbon atom would have four unpaired electrons available for bonding if an electron is **promoted**—that is, has been relocated to a higher-energy orbital. When we promote a 2s-electron into an empty 2p-orbital, we get the configuration $[He]2s^12p_x^{\ 1}2p_y^{\ 1}2p_z^{\ 1}$ (**36**). Without promotion, a carbon atom can form only two bonds; after promotion, it can form four bonds. Although it takes energy to promote an electron, the overall energy of the CH_4 molecule is lower than if carbon formed only two C—H bonds.



36 Carbon, $[He]2s^12p_x^{\ 1}2p_y^{\ 1}2p_z^{\ 1}$

The characteristic tetravalence of carbon is due to the small promotion energy of a carbon atom. The promotion energy is small because a 2s-electron is transferred from an orbital that it shares with another electron to an empty 2p-orbital. Although the promoted electron enters an orbital of higher energy, it experiences less repulsion from other electrons than before it was promoted. As a result, only a small energy is needed to promote the electron. Nitrogen, carbon's neighbor, cannot use promotion to increase the number of bonds that it can form, because it has no empty p-orbitals (**37**). The same is true of oxygen and fluorine. Promotion of an electron is possible if the overall change, taking account of all contributions to the energy and especially the greater number of bonds that can thereby be formed, is toward lower energy. Boron, $[He]2s^22p^1$, like carbon, is an element in which promotion can lead to the formation of more bonds (three in its case), and boron does typically form three bonds.



37 Nitrogen, $[He]2s^22p_x^{\ 1}2p_y^{\ 1}2p_z^{\ 1}$

At this stage, it looks as though electron promotion should result in two different types of bonds in methane, one bond from the overlap of a hydrogen 1s-orbital and a carbon 2s-orbital, and three more bonds from the overlap of hydrogen 1s-orbitals with each of the three carbon 2p-orbitals. The overlap with the 2p-orbitals should result in three σ-bonds at 90° to one another. However, this arrangement is inconsistent with the known tetrahedral structure of methane with four equivalent bonds.

38 sp^3 hybridized carbon

To improve our model we note that s- and p-orbitals are waves of electron density centered on the nucleus of an atom. We imagine that the four orbitals interfere with one another and produce new patterns where they intersect, like waves in water. Where the wavefunctions are all positive or all negative, the amplitudes are increased by this interference; where the wavefunctions have opposite signs, the overall amplitude is reduced and might even be canceled completely. As a result, the interference between the atomic orbitals results in new patterns. These new patterns are called **hybrid orbitals.** Each of the four hybrid orbitals, designated h_i, is formed from a linear combination of the four atomic orbitals (note that these orbitals are not normalized; see Exercises 3.47 and 3.48):

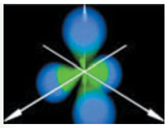
$$h_1 = s + p_x + p_y + p_z \qquad h_2 = s - p_x - p_y + p_z$$
$$h_3 = s - p_x + p_y - p_z \qquad h_4 = s + p_x - p_y - p_z$$

For instance, in h_1 the s- and p-orbitals all have their usual signs and their amplitudes add together where they are all positive. In h_2, however, the signs of p_x and p_y are reversed, and so the resulting interference pattern is different.

The four hybrid orbitals that we have constructed differ only in their orientation, with one pointing toward each corner of a tetrahedron (Fig. 3.13); in all other respects, they are identical. These four hybrid orbitals are called **sp^3 hybrids** because they are formed from one s-orbital and three p-orbitals. In an orbital-energy diagram, we represent the hybridization as the formation of four orbitals of equal energy intermediate between the energies of the s- and p-orbitals from which they are constructed (**38**). The hybrids are colored green to remind us that they are a blend of (blue) s-orbitals and

FIGURE 3.13 These contours indicate the amplitude of the sp^3 hybrid orbital wavefunction in a plane that bisects it and passes through the nucleus. The colors indicate the variation of electron density in the orbital: regions of high electron density are red and regions of low electron density blue. Each sp^3 hybrid orbital points toward the corner of a tetrahedron.

Animation 3.13



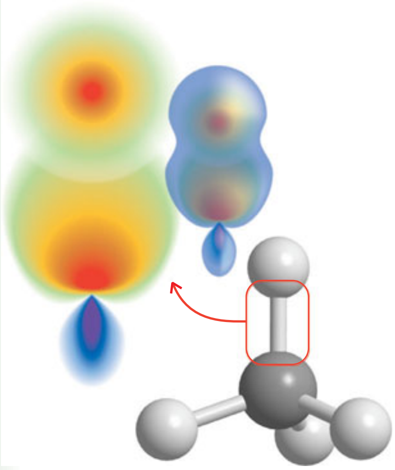


FIGURE 3.14 Each C—H bond in methane is formed by the pairing of an electron in a hydrogen 1s-orbital and an electron in one of the four sp^3 hybrid orbitals of carbon. Therefore, valence-bond theory predicts four equivalent σ-bonds in a tetrahedral arrangement, which is consistent with experimental results. The sp^3 orbital is shown in both contour form (see Fig. 3.13) and as a boundary surface.

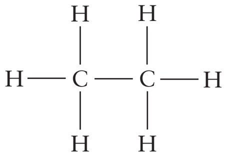
Animation 3.14



39 Ethane, CH_3CH_3

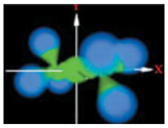


FIGURE 3.15 The valence-bond description of bonding in an ethane molecule, C_2H_6. The boundary surfaces of only two of the bonds are shown. Each pair of neighboring atoms is linked by a σ-bond formed by the pairing of electrons in either H1s-orbitals or $C2sp^3$ hybrid orbitals. All the bond angles are close to 109.5° (the tetrahedral angle).

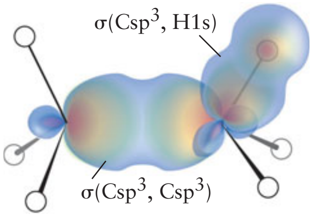


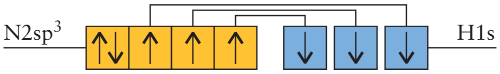
Animation 3.15

(yellow) p-orbitals. An sp^3 hybrid orbital has two lobes, but one lobe extends farther than those of the contributing p-orbitals and the other lobe is shortened. The fact that hybrid orbitals have their amplitudes concentrated on one side of the nucleus allows them to overlap more effectively with other orbitals, and as a result the bonds that they form are stronger than in the absence of hybridization.

We are now ready to account for the bonding in methane. In the promoted, hybridized atom each of the electrons in the four sp^3 hybrid orbitals can pair with an electron in a hydrogen 1s-orbital. Their overlapping orbitals form four σ-bonds that point toward the corners of a tetrahedron (Fig. 3.14). The valence-bond description is now consistent with experimental data on molecular geometry.

When there is more than one "central" atom in a molecule, we concentrate on each atom in turn and match the hybridization of each atom to the shape at that atom predicted by VSEPR. For example, in ethane, C_2H_6 (**39**), the two carbon atoms are both "central" atoms. According to the VSEPR model, the four electron pairs around each carbon atom take up a tetrahedral arrangement. This arrangement suggests the same sp^3 hybridization of the carbon atoms as in methane (see Fig. 3.14). Each C atom has one unpaired electron in each of its four sp^3 hybrid orbitals and can therefore form four σ-bonds that point toward the corners of a regular tetrahedron. The C—C bond is formed by spin-pairing of the electrons in one sp^3 hybrid orbital of each C atom. We label this bond $\sigma(C2sp^3,C2sp^3)$ to show its composition: $C2sp^3$ denotes an sp^3 hybrid orbital composed of 2s- and 2p-orbitals on a carbon atom, and the parentheses show which orbitals on each atom overlap (Fig. 3.15). Each C—H bond is formed by spin-pairing of an electron in one of the remaining sp^3 hybrid orbitals with an electron in a 1s-orbital of an H atom (denoted H1s). These bonds are denoted $\sigma(C2sp^3,H1s)$.

We can extend these ideas to molecules, such as ammonia, that have a lone pair of electrons on the central atom. According to the VSEPR model, the four electron pairs in NH_3 take up a tetrahedral electron arrangement, so we describe the nitrogen atom in terms of four sp^3 hybrid orbitals. Because nitrogen has five valence electrons, one of these hybrid orbitals is already doubly occupied (**40**). The three unpaired electrons in the remaining sp^3 hybrid orbitals pair with the 1s-electrons of the three hydrogen atoms to form three N—H σ-bonds. *Whenever an atom in a molecule has a tetrahedral electron arrangement, we say that it is sp^3 hybridized.*



40 Ammonia, NH_3

The promotion of electrons will occur if, overall, it leads to a lowering of energy by permitting the formation of more bonds. Hybrid orbitals are constructed on an atom to reproduce the electron arrangement characteristic of the experimentally determined shape of a molecule.

3.6 Other Common Types of Hybridization

We use different hybridization schemes to describe other arrangements of electron pairs (Fig. 3.16). For example, to explain a trigonal planar electron arrangement, like that in BF_3 and each carbon atom in ethene, we mix one s-orbital with two p-orbitals and so produce three **sp^2 hybrid orbitals:**

$$h_1 = s + 2^{1/2}p_y$$
$$h_2 = s + \left(\tfrac{3}{2}\right)^{1/2}p_x - \left(\tfrac{1}{2}\right)^{1/2}p_y$$
$$h_3 = s - \left(\tfrac{3}{2}\right)^{1/2}p_x - \left(\tfrac{1}{2}\right)^{1/2}p_y$$

These identical orbitals (which are not normalized in these expressions) all lie in the same plane and point toward the corners of an equilateral triangle.

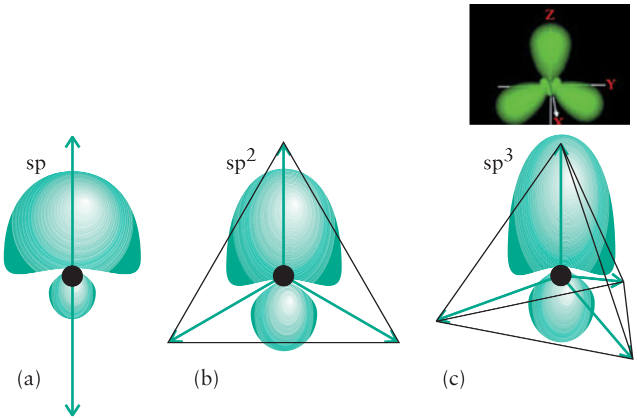


FIGURE 3.16 Three common hybridization schemes shown as outlines of the amplitude of the wavefunction and in terms of the orientations of the hybrid orbitals. (a) An s-orbital and a p-orbital hybridize into two sp hybrid orbitals that point in opposite directions, forming a linear molecular shape. (b) An s-orbital and two p-orbitals can blend together to give three sp^2 hybrid orbitals that point to the corners of an equilateral triangle. (c) An s-orbital and three p-orbitals can blend together to give four sp^3 hybrid orbitals that point to the corners of a tetrahedron.

Animation 3.16

A linear arrangement of electron pairs requires two hybrid orbitals, and so we mix an s-orbital with a p-orbital to obtain two **sp hybrid orbitals:**

$$h_1 = s + p \qquad h_2 = s - p$$

These two (unnormalized) sp hybrid orbitals point away from each other at 180° and result in a linear molecule. This is the arrangement we see in CO_2.

Self-Test 3.7A Suggest a structure in terms of hybrid orbitals for BF_3.

[***Answer:*** Three σ-bonds formed from F2p_z-orbitals and B2sp^2 hybrids in a trigonal planar arrangement]

Self-Test 3.7B Suggest a structure in terms of hybrid orbitals for each carbon atom in ethyne, C_2H_2.

Some of the elements in Period 3 and later periods can accommodate five or more electron pairs, as in PCl_5. We can devise a hybridization scheme to describe these types of bonds by using the d-orbitals of the central atom. To account for a trigonal bipyramidal arrangement of five electron pairs, we use one d-orbital as well as all the valence s- and p-orbitals of the atom. The resulting five orbitals are called **sp^{3}d hybrid orbitals** (Fig. 3.17).

We need six orbitals to accommodate six electron pairs around an atom in an octahedral arrangement, as in SF_6 and XeF_4, and so we need to use two d-orbitals in addition to the valence s- and p-orbitals to form six **sp^{3}d^2 hybrid orbitals** (Fig. 3.18). These identical orbitals point toward the six corners of a regular octahedron.

Table 3.2 summarizes the relation between electron arrangement and hybridization type. No matter how many atomic orbitals we mix together, the number of hybrid orbitals is always the same as the number of atomic orbitals with which we started:

N atomic orbitals always produce *N* hybrid orbitals.

So far, we have not considered whether terminal atoms, such as the Cl atoms in PCl_5, are hybridized. Because they are bonded to only one other atom, we cannot use bond angles to predict a hybridization scheme. However, spectroscopic data and calculations suggest that both s- and p-orbitals of terminal atoms take part in bond formation, and

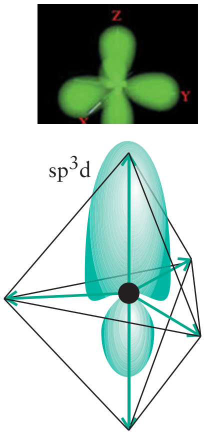

FIGURE 3.17 One of the five sp^{3}d hybrid orbitals, and their five directions, that account for a trigonal bipyramidal arrangement of electron pairs. The sp^{3}d hybridization scheme can be applied only when d-orbitals are available on the central atom.

Animation 3.17

TABLE 3.2 Hybridization and Molecular Shape*

Electron arrangement	Number of atomic orbitals	Hybridization of the central atom	Number of hybrid orbitals
linear	2	sp	2
trigonal planar	3	sp^2	3
tetrahedral	4	sp^3	4
trigonal bipyramidal	5	sp^{3}d	5
octahedral	6	sp^{3}d^2	6

*Other combinations of s-, p-, and d-orbitals can give rise to the same or different shapes, but the combinations in the table are the most common.

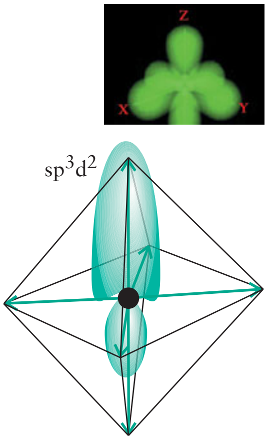

FIGURE 3.18 One of the six sp^{3}d^2 hybrid orbitals, and their six directions, that may be formed when d-orbitals are available and we need to account for an octahedral arrangement of electron pairs.

Animation 3.18

so it is reasonable to suppose that their orbitals are hybridized. The simplest model is to suppose that the three lone pairs and the bonding pair are arranged tetrahedrally and therefore that the chlorine atoms bond to the phosphorus atom by using sp^3 hybrid orbitals.

EXAMPLE 3.5 Assigning a hybridization scheme

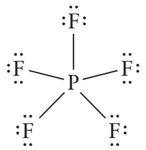
What is the hybridization of phosphorus in PF_5?

Anticipate To form five bonds we need five hybrid orbitals, which suggests that a d-orbital should be involved as well as the four s- and p-orbitals of a shell.

PLAN Choose the hybridization scheme to match the electron arrangement predicted by the VSEPR model, using N atomic orbitals to form N hybrid orbitals.

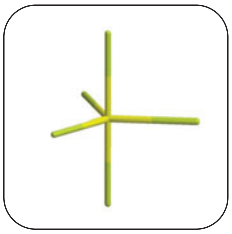
SOLVE

Draw the Lewis structure.



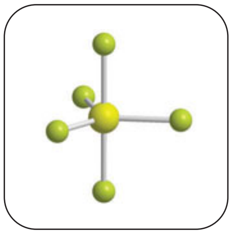
Determine the electron arrangement about the central atom.

Trigonal bipyramidal



Identify the molecular shape.

Trigonal bipyramidal

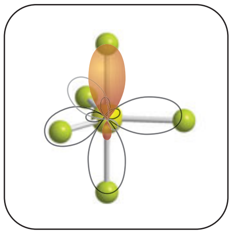


Select the same number of atomic orbitals as there are hybrid orbitals.

5

Construct the hybrid orbitals, starting with the s-orbital, and proceeding to the p- and d-orbitals.

sp^3d



Evaluate As predicted, a d-orbital is required to accommodate all the valence electrons.

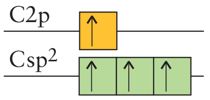
Self-Test 3.8A Describe (a) the electron arrangement, (b) the molecular shape, and (c) the hybridization of the central chlorine atom in chlorine trifluoride.

[***Answer:*** (a) Trigonal bipyramidal; (b) T-shaped; (c) sp^3d]

Self-Test 3.8B Describe (a) the electron arrangement, (b) the molecular shape, and (c) the hybridization of the central atom in BrF_4^-.

A hybridization scheme is adopted to match the electron arrangement of the molecule. Valence-shell expansion requires the use of d-orbitals.

3.7 Characteristics of Multiple Bonds



41 sp^2 hybridized carbon

Atoms of the Period 2 elements C, N, and O readily form double bonds with one another, with themselves, and (especially for oxygen) with atoms of elements in later periods. However, double bonds are rarely found between atoms of elements in Period 3 and later periods, because the atoms are so large and bond lengths consequently so great that it is difficult for their p-orbitals to take part in effective side-by-side overlap.

To describe carbon–carbon double bonds, we use the pattern provided by ethene, $CH_2{=}CH_2$. We know from experimental data that all six atoms in ethene lie in the same plane, with bond angles very close to 120°. Bond angles of 120° suggest a trigonal planar electron arrangement and sp^2 hybridization for each C atom (**41**). Each of the three hybrid orbitals on the C atom has one electron available for bonding; the fourth valence electron of each C atom occupies the unhybridized 2p-orbital, which is perpendicular to the plane formed by the hybrids. The two carbon atoms form a σ-bond by overlap of an sp^2 hybrid orbital on each atom. The H atoms form σ-bonds with the remaining lobes of the sp^2 hybrids. The electrons in the two unhybridized 2p-orbitals form a π-bond through side-by-side overlap. Figure 3.19 shows how the electron density in the π-bond lies above and below the axis of the C—C σ-bond.

In benzene, the C atoms and their attached H atoms all lie in the same plane, with the C atoms forming a hexagonal ring. To describe the bonding in the Kekulé structures of benzene (Section 2.8) in terms of VB theory, we need hybrid orbitals that match the 120° bond angles of the hexagonal ring. Therefore, we take each carbon atom to be sp^2 hybridized, as in ethene (Fig. 3.20). The three hybrid orbitals each have one electron, with the fourth valence electron in an unhybridized 2p-orbital perpendicular to the plane of the hybrids. The sp^2 hybrid orbitals on each carbon atom overlap with those of their neighbors, which results in six σ-bonds between them. The remaining sp^2 hybrid orbital on each carbon atom overlaps with a hydrogen 1s-orbital, resulting in six carbon–hydrogen bonds. Finally, the side-by-side overlap of the 2p-orbitals on each C atom results in a π-bond between each carbon atom and one of its neighbors (Fig. 3.21). The resulting pattern of π-bonds matches either of the two Kekulé structures, and the overall structure is a resonance hybrid of the two. This resonance ensures that the electrons in the π-bonds are spread around the entire ring (Fig. 3.22).

The presence of a carbon–carbon double bond strongly influences the shape of a molecule because it prevents one part of a molecule from rotating relative to another part. The double bond of ethene, for example, holds the entire molecule flat. Figure 3.19 shows that the two 2p-orbitals overlap best if the two CH_2 groups lie in the same plane. In order for the molecule to rotate about the double bond, the π-bond would need to break and reform.

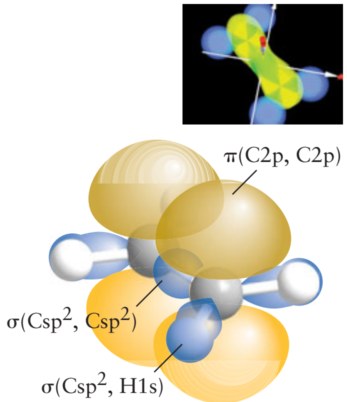


FIGURE 3.19 A view of the bonding pattern in ethene (ethylene), showing the framework of σ-bonds and the single π-bond formed by side-to-side overlap of unhybridized C2p-orbitals. The double bond is resistant to twisting because twisting would reduce the overlap between the two C2p-orbitals and weaken the π-bond. Here the bonding structure is superimposed over a ball-and-stick model.

Animation 3.19

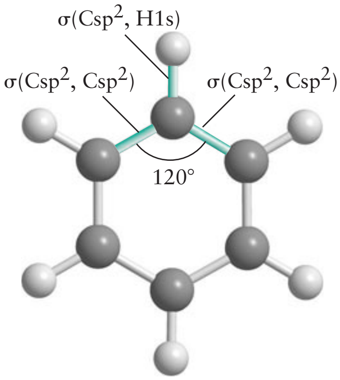

FIGURE 3.20 The framework of σ-bonds in benzene: each carbon atom is sp^2 hybridized, and the array of hybrid orbitals matches the bond angles (of 120°) in the hexagonal molecule. The bonds around only one carbon atom are labeled; all the others are the same.

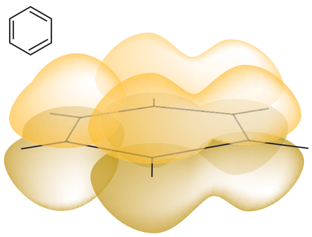

FIGURE 3.21 Unhybridized carbon 2p-orbitals can form a π-bond with either of their immediate neighbors. Two arrangements are possible, each one corresponding to a different Kekulé structure. One Kekulé structure and the corresponding π-bonds are shown here.

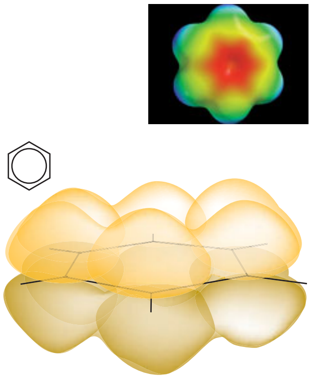

FIGURE 3.22 As a result of resonance between two structures like the one shown in Fig. 3.21 (corresponding to resonance of the two Kekulé structures), the π-electrons form a double doughnut-shaped cloud above and below the plane of the ring.

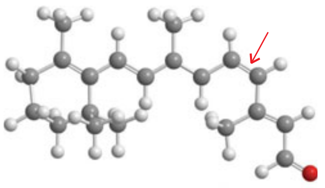
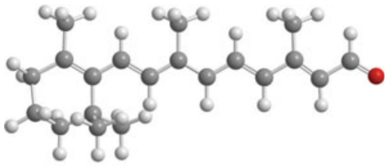
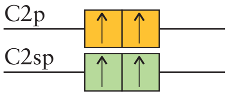
Animation 3.22



42 *cis*-Retinal



43 *trans*-Retinal



44 sp hybridized carbon

Double bonds and their influence on molecular shape are vitally important for living organisms. For instance, they enable you to read these words. Vision depends on the shape of the molecule retinal in the retina of the eye. *cis*-Retinal is held rigid by its double bonds (**42**). When light enters the eye, it excites an electron out of the π-bond marked by the arrow. The double bond is now weaker, and the molecule is free to rotate about the remaining σ-bond. When the excited electron falls back, the molecule has rotated about the double bond and is now trapped in its trans shape (**43**). This change in shape triggers a signal along the optic nerve and is interpreted by the brain as the sensation of vision.

Now consider the alkynes, hydrocarbons with carbon–carbon triple bonds. The Lewis structure of the linear molecule ethyne (acetylene) is H—C≡C—H. A linear molecule has two equivalent orbitals at 180° from each other: this is sp hybridization. Each C atom has one electron in each of its two sp hybrid orbitals and one electron in each of its two perpendicular unhybridized 2p-orbitals (**44**). The electrons in the sp hybrid orbitals on the two carbon atoms pair and form a carbon–carbon σ-bond. The electrons in the remaining sp hybrid orbitals pair with hydrogen 1s-electrons to form two carbon–hydrogen σ-bonds. The electrons in the two perpendicular sets of 2p-orbitals pair with a side-by-side overlap, forming two π-bonds at 90° to each other. As in the N_2 molecule, the electron density in the π-bonds forms a cylinder about the C—C bond axis. The resulting bonding pattern is shown in Fig. 3.23.

Thinking point: What shape do the atoms connected to two triply bonded carbon atoms impose on a molecule that contains such a group?

We can now understand why a carbon–carbon double bond is stronger than one carbon–carbon single bond but weaker than the sum of two single bonds (Section 2.15), and why a carbon–carbon triple bond is weaker than the sum of three carbon–carbon single bonds. Recall that a single C—C bond is a σ-bond, but the additional bonds in a multiple bond are π-bonds. One reason for the difference in strength is that because the p-orbitals overlap in a side-by-side fashion, the overlap in a π-bond is smaller and weaker than the end-to-end overlap that results in a σ-bond. The side-by-side overlap also explains why double bonds are rarely formed between elements in periods later than Period 3. The atoms are too large for the overlap to be strong enough to form a bond.

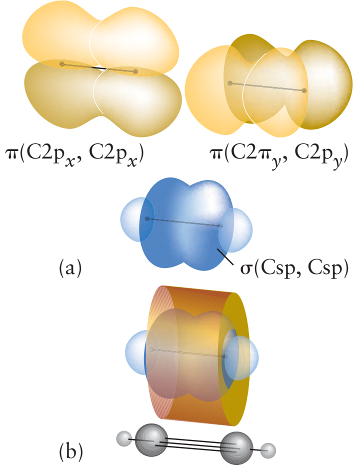


FIGURE 3.23 The pattern of bonding in ethyne (acetylene). The carbon atoms are sp hybridized, and the two remaining p-orbitals on each C atom form two π-bonds. (a) The resulting pattern is very similar to that for N_2 (Fig. 3.12), but C—H groups replace the two N atoms. (b) Although the two π-orbitals are built from p-orbitals, the overall electron density turns out to have cylindrical symmetry.

Animation 3.23

EXAMPLE 3.6 Accounting for the structure of a molecule with multiple bonds

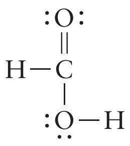
Account for the structure of a formic acid molecule, HCOOH, in terms of hybrid orbitals, bond angles, and σ- and π-bonds. The C atom is attached to an H atom, a terminal O atom, and an —OH group.

Anticipate Because the C atom is attached to three atoms, we should anticipate that its hybridization scheme is sp^2 and that one unhybridized p-orbital remains.

PLAN Use the VSEPR model to identify the shape of the molecule and then assign the hybridization consistent with that shape. All single bonds are σ-bonds and multiple bonds are composed of a σ-bond and one or more π-bonds. Finally, we form σ- and π-bonds by allowing the orbitals to overlap.

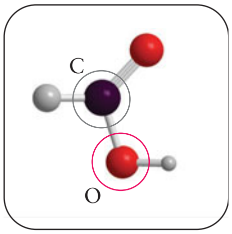
SOLVE

Draw the Lewis structure.



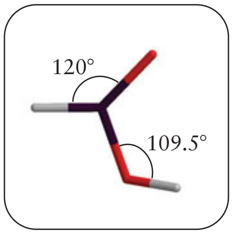
Use the VSEPR model to identify the electron arrangements around the central C and O atoms.

The C atom is bonded to 3 atoms and has no lone pairs; therefore, it has a trigonal planar arrangement. The O atom in the —OH group has two single bonds and two lone pairs; thus, it has a tetrahedral electron arrangement.



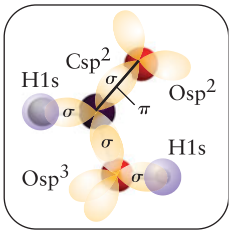
Identify the hybridization and bond angles.

C atom: trigonal planar, so 120° bond angle; sp^2 hybridized. O atom of the —OH group: tetrahedral, so bond angles close to 109.5°; sp^3 hybridized.



Form the bonds.

A π-bond forms by the overlap of the p-orbital on the C atom with the p-orbital on the terminal O atom.



Evaluate As predicted, the hybridization scheme is sp^2, leaving one unhybridized p-orbital.

Self-Test 3.9A Describe the structure of the carbon suboxide molecule, C_3O_2, in terms of hybrid orbitals, bond angles, and σ- and π-bonds. The atoms lie in the order OCCCO.

[***Answer:*** Linear; bond angles all 180°; each C atom is sp hybridized and forms one σ-bond and one π-bond to each adjacent C or O atom.]

Self-Test 3.9B Describe the structure of the propene molecule, $CH_3—CH=CH_2$, in terms of hybrid orbitals, bond angles, and σ- and π-bonds.

Multiple bonds are formed when an atom forms a σ-bond by using an sp or sp^2 hybrid orbital and one or more π-bonds by using unhybridized p-orbitals. The side-by-side overlap that forms a π-bond makes a molecule resistant to twisting, results in bonds weaker than σ-bonds, and prevents atoms with large radii from forming multiple bonds.

MOLECULAR ORBITAL THEORY

Lewis's theory of the chemical bond was brilliant, but it was little more than guesswork inspired by insight. He had no way of knowing why an electron pair was so important for the formation of covalent bonds. Valence-bond theory explained the importance of the electron pair in terms of spin-pairing but it could not explain the properties of some molecules. Molecular orbital theory, which is also based on quantum mechanics and was introduced in the late 1920s by Mulliken and Hund, has proved to be the most successful theory of the chemical bond: it overcomes all the deficiencies of Lewis's theory and is easier to use in calculations than valence-bond theory.

3.8 The Limitations of Lewis's Theory

In Lewis's approach and valence-bond theory the oxygen molecule is somewhat of a puzzle. To appreciate the puzzle, we need to know that substances can be classified according to their behavior in a magnetic field: a **diamagnetic substance** is one that tends to move out of a magnetic field and a **paramagnetic substance** is one that tends to move into a magnetic field. Diamagnetism indicates that all the electrons in a molecule are paired; paramagnetism indicates that a molecule possesses unpaired electrons (Box 3.2). According to both Lewis's approach and valence-bond theory, O_2 should be diamagnetic. In fact, it is found to be paramagnetic (Fig. 3.24).

FIGURE 3.24 The paramagnetic properties of oxygen are evident when liquid oxygen is poured between the poles of a magnet. The liquid sticks to the magnet instead of flowing past it.

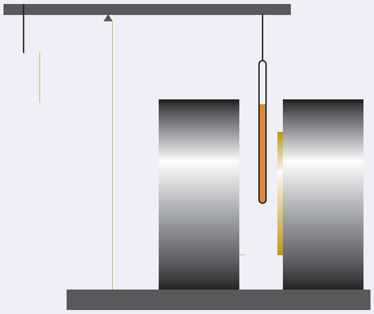
Lewis's theory also fails to account for the compound diborane, B_2H_6, a colorless gas that bursts into flame on contact with air. The problem is that diborane has only 12 valence electrons (three from each B atom, one from each H atom); but, for a Lewis structure, it needs at least seven bonds, and therefore 14 electrons, to bind the eight atoms together! Diborane is an example of an **electron-deficient compound,** a compound with too few valence electrons to be assigned a valid Lewis structure. Valence-bond theory can account for the structures of electron-deficient compounds in terms of resonance, but the explanation is not straightforward.

BOX 3.2 HOW DO WE KNOW . . . THAT ELECTRONS ARE NOT PAIRED?

Most common materials are diamagnetic. The tendency of a diamagnetic substance to move out of a magnetic field can be detected by hanging a long, thin sample from the pan of a balance and letting it lie between the poles of an electromagnet. This arrangement, which was once the primary technique used to measure the magnetic properties of samples, is called a *Gouy balance*. When the electromagnet is turned on, a diamagnetic sample tends to move upward, out of the field, so it appears to weigh less than in the absence of the field. The diamagnetism arises from the effect of the magnetic field on the electrons in the molecule: the field forces the electrons to circulate through the nuclear framework. Because electrons are charged particles, this circulation corresponds to an electric current circulating within the molecule. That current gives rise to its own magnetic field, which opposes the applied field. The sample tends to move out of the field so as to minimize this opposing field.

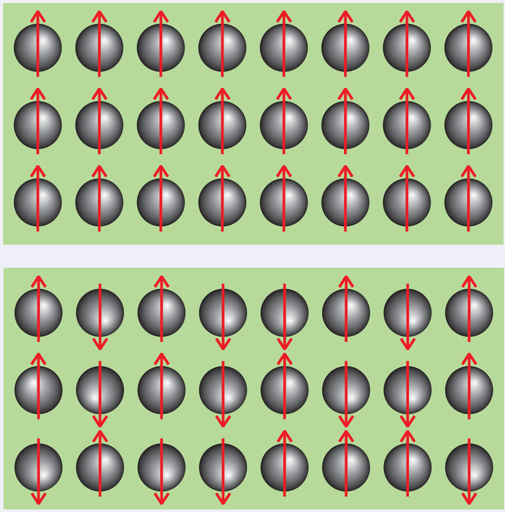
Compounds with unpaired electrons are *paramagnetic*. They tend to move into a magnetic field and can be identified because they seem to weigh more in a Gouy balance when a magnetic field is applied than when it is absent. Paramagnetism arises from the electron spins, which behave like tiny bar magnets that tend to line up with the applied field. The more that can line up in this way, the greater the lowering of energy and the heavier the sample appears to weigh. Oxygen is a paramagnetic substance because it has two unpaired electrons: this property is used to detect the concentration of oxygen in incubators. All radicals are paramagnetic. Many compounds of the d-block elements are paramagnetic because they have various numbers of unpaired d-electrons.

The modern approach to measuring magnetic properties is to use a *superconducting quantum interference device* (a SQUID), which is highly sensitive to small magnetic fields and can make very precise measurements on small samples.



A Gouy balance is used to observe the magnetic character of a sample by detecting the extent to which it is drawn into (paramagnetic substances) or driven out of (diamagnetic substances) a magnetic field.

(a)



(b)

(a) In a magnetic field, the spins of electrons in both paramagnetic and ferromagnetic substances are aligned (ferromagnetism is described in Chapter 6). (b) The spins of electrons in a paramagnetic substance return to a random orientation after an applied magnetic field is removed. However, the spins of electrons in a ferromagnetic substance remain aligned after a magnetic field is removed.

The development of **molecular orbital theory** (MO theory) in the late 1920s overcame these difficulties. It explains why the electron pair is so important for bond formation and predicts that oxygen is paramagnetic. It accommodates electron-deficient compounds such as the boranes just as naturally as it deals with methane and water. Furthermore, molecular orbital theory can be extended to account for the structures and properties of metals and semiconductors. It can also be used to account for the electronic spectra of molecules, which arise when an electron makes a transition from an occupied molecular orbital to a vacant molecular orbital.

The VB and MO theories are both procedures for constructing approximations to the wavefunctions of electrons, but they construct these approximations in different ways. The language of valence-bond theory, in which the focus is on bonds between pairs of atoms, pervades the whole of organic chemistry, where chemists speak of σ- and π-bonds between particular pairs of atoms, hybridization, and resonance. However, molecular orbital theory, in which the focus is on electrons that spread throughout the nuclear framework and bind the entire collection of atoms together, has been developed far more extensively than valence-bond theory and is the procedure almost universally used in calculations of molecular structures, like those described in Major Technique 5 following Chapter 14.

Unlike Lewis's theory, molecular orbital theory can account for the paramagnetism of oxygen and the existence of electron-deficient compounds.

3.9 Molecular Orbitals

In molecular orbital theory, electrons occupy orbitals called **molecular orbitals** that spread throughout the entire molecule. In other words, whereas in the Lewis and valence-bond models of molecular structure the electrons are localized on atoms or between pairs of atoms, in molecular orbital theory all valence electrons are **delocalized** over the whole molecule, not confined to individual bonds.

In this section we start, as in valence-bond theory, with a simple molecule, H_2, and in the following sections extend the same principles to more complex molecules and solids. In every case, molecular orbitals are built from atomic orbitals belonging to the valence shells of the atoms in the molecule. For example, a molecular orbital for H_2 is

$$\psi = \psi_{A1s} + \psi_{B1s} \qquad (1)^*$$

where ψ_{A1s} is a 1s-orbital centered on one atom (A) and ψ_{B1s} is a 1s-orbital centered on the other atom (B). The technical terms for adding together wavefunctions (sometimes with different weighting coefficients) is called "forming a linear combination" and the molecular orbital in Eq. 1 is called a **linear combination of atomic orbitals** (LCAO). Any molecular orbital formed from a linear combination of atomic orbitals on different atoms is called an **LCAO-MO.** Note that at this stage there are no electrons in the molecular orbital: a molecular orbital is just a combination—in this case, a simple sum—of wavefunctions. Like atomic orbitals, the molecular orbital in Eq. 1 is a well-defined mathematical function that can be evaluated at each point in space and pictured in three dimensions.

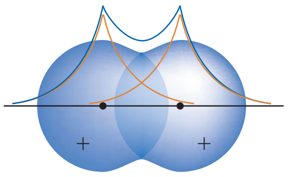


FIGURE 3.25 When two 1s-orbitals overlap in the same region of space in such a way that their wavefunctions have the same signs in that region, their wavefunctions (red lines) interfere constructively and give rise to a region of enhanced amplitude between the two nuclei (blue line).

The LCAO-MO in Eq. 1 turns out to have a lower energy than either of the atomic orbitals used in its construction. The two atomic orbitals are like waves centered on different nuclei. Between the nuclei, the waves interfere constructively with each other in the sense that the total amplitude of the wavefunction is increased where they overlap (Fig. 3.25). The increased amplitude in the internuclear region means that there is an enhanced probability density between the nuclei. Any electron that occupies that molecular orbital, therefore, is attracted to both nuclei and so has a lower energy than when it is confined to an atomic orbital on one atom. Moreover, because the electron now occupies a greater volume than when it is confined to a single atom, it also has a lower kinetic energy, just like a particle confined to a bigger box (Section 1.7). A combination of atomic orbitals that results in an overall lowering of energy, like that in Eq. 1, is called a **bonding orbital.**

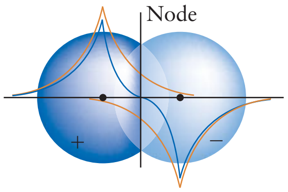

FIGURE 3.26 When two 1s-orbitals overlap in the same region of space in such a way that their wavefunctions have opposite signs, the wavefunctions interfere destructively and give rise to a region of diminished amplitude and a node between the two nuclei (blue line).

An important feature of MO theory is that

N molecular orbitals can be constructed from *N* atomic orbitals.

In molecular hydrogen, where we are building LCAO-MOs from two atomic orbitals, we expect *two* molecular orbitals. In the second molecular orbital, the two atomic orbitals interfere *destructively* where they overlap. This orbital has the form

$$\psi = \psi_{A1s} - \psi_{B1s} \qquad (2)^*$$

The negative sign indicates that the amplitude of ψ_{B1s} *subtracts* from the amplitude of ψ_{A1s} where they overlap (Fig. 3.26), and there is a nodal surface where the atomic orbitals cancel completely. In a hydrogen molecule, the nodal surface is a plane that lies halfway between the two nuclei. If an electron occupies this orbital, it is largely excluded from the internuclear region and consequently has a higher energy than when it occupies one of the atomic orbitals alone. A combination of atomic orbitals that results in an overall raising of energy, like that in Eq. 2, is called an **antibonding orbital.**

A note on good practice: What the negative sign in Eq. 2 really represents is that we reverse the sign of ψ_{B1s} everywhere (so a peak becomes a trough and vice versa), then add the resulting wavefunction to ψ_{A1s}.

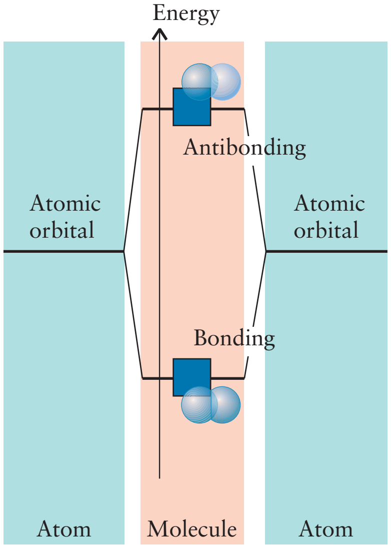

FIGURE 3.27 A molecular orbital energy-level diagram for the bonding and antibonding molecular orbitals that can be built from two s-orbitals. Different signs of the s-orbitals (reflecting how they are combined together to form the molecular orbital) are depicted by the different shades of blue.

The relative energies of the original atomic orbitals and the bonding and antibonding molecular orbitals are shown in a **molecular orbital energy-level diagram** like that in Fig. 3.27. The increased energy of an antibonding orbital is about equal to or a little greater than the lowering of the energy of the corresponding bonding orbital.

Molecular orbitals are built from linear combinations of atomic orbitals: when atomic orbitals interfere constructively, they give rise to bonding orbitals; when they interfere destructively, they give rise to antibonding orbitals. N atomic orbitals combine to give N molecular orbitals.

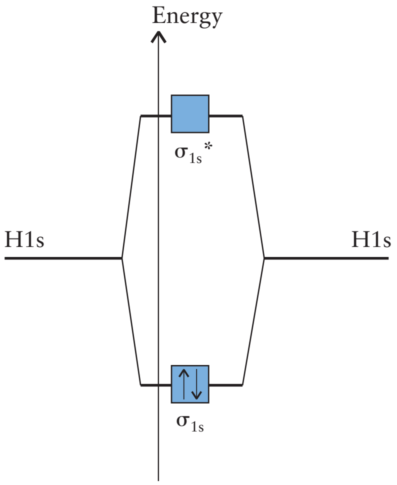

FIGURE 3.28 The two electrons in an H_2 molecule occupy the lower-energy (bonding) molecular orbital and result in a stable molecule.

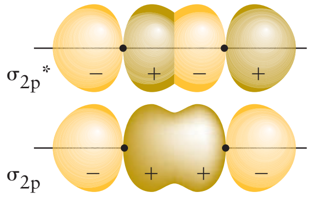

FIGURE 3.29 Two p-orbitals can overlap to give bonding (lower) and antibonding (upper) σ-orbitals. Note that the antibonding combination has a node between the two nuclei. Both σ-orbitals have nodes passing through the nuclei, but no nodes along the axis of the bond.

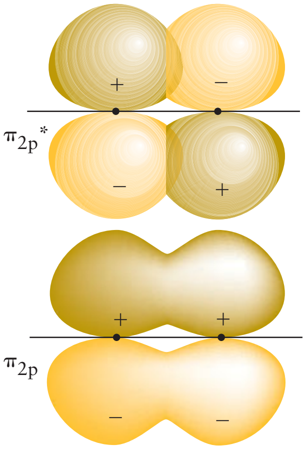

FIGURE 3.30 Two p-orbitals can overlap side by side to give bonding (below) and antibonding (above) π-orbitals. Note that the latter has a nodal plane between the two nuclei. Both orbitals have a nodal plane through the two nuclei and look like p-orbitals when viewed along the internuclear axis.

3.10 Electron Configurations of Diatomic Molecules

In the molecular orbital description of homonuclear diatomic molecules, we first build all possible molecular orbitals from the available valence-shell atomic orbitals. Then we accommodate the valence electrons in molecular orbitals by using the same procedure used in the building-up principle for atoms (Section 1.13). That is,

1 Electrons are accommodated in the lowest-energy molecular orbital, then in orbitals of increasingly higher energy.
2 According to the Pauli exclusion principle, each molecular orbital can accommodate up to two electrons. If two electrons are present in one orbital, they must be paired.
3 If more than one molecular orbital of the same energy is available, the electrons enter them singly and adopt parallel spins (Hund's rule).

We shall illustrate these rules first with H_2 and then with other diatomic molecules. The same principles apply to polyatomic molecules, but their molecular orbitals are more complicated and their energies are harder to predict. Mathematical software for calculating the molecular orbitals and their energies is now widely available, and we shall show some of the results that it provides.

In H_2, two 1s-orbitals (one on each atom) merge to form two molecular orbitals. We denote the bonding orbital σ_{1s} and the antibonding orbital σ_{1s}*. The 1s in the notation shows the atomic orbitals from which the molecular orbitals are formed. The σ indicates that we have built a "σ-orbital," a sausage-shaped orbital. More formally, a **σ-orbital** is a molecular orbital that has cylindrical symmetry and no nodal plane that contains the internuclear axis. Two electrons, one from each H atom, are available. Both occupy the bonding orbital (the lower-energy orbital) and result in the configuration σ_{1s}^2 (Fig. 3.28). Because only the bonding orbital is occupied, the energy of the molecule is lower than that of the separate atoms, and hydrogen exists as H_2 molecules. Two electrons in a σ-orbital form a σ-bond, like the σ-bond in VB theory. However, even a single electron may be able to hold two atoms together with about half the strength of an electron pair, and so—in contrast to Lewis's theory and VB theory—an electron pair is not required for a bond. A pair is just the maximum number of electrons allowed by the Pauli exclusion principle to occupy any one molecular orbital. Even a single electron can act to bond atoms together.

Now we extend these ideas to other homonuclear diatomic molecules of Period 2 elements. The first step is to build up the molecular orbital energy-level diagram from the valence-shell atomic orbitals provided by the atoms. Because Period 2 atoms have 2s- and 2p-orbitals in their valence shells, we form molecular orbitals from the overlap of these atomic orbitals. There are a total of eight atomic orbitals (one 2s- and three 2p-orbitals on each atom); so we can expect to build eight molecular orbitals. The two 2s-orbitals overlap to form two σ-orbitals, one bonding (the σ_{2s}-orbital) and the other antibonding (the σ_{2s}*-orbital); these orbitals resemble the σ_{1s}- and σ_{1s}*-orbitals in H_2. The six 2p-orbitals (three on each neighboring atom) form the remaining six molecular orbitals. They can overlap in two distinct ways. The two 2p-orbitals that are directed toward each other along the internuclear axis form a bonding σ-orbital (σ_{2p}) and an antibonding σ*-orbital (σ_{2p}*) where they overlap (Fig. 3.29). The two 2p-orbitals on each atom that are perpendicular to the internuclear axis overlap side by side to form bonding and antibonding "π-orbitals" (Fig. 3.30). A **π-orbital** is a molecular orbital with one nodal plane that contains the internuclear axis. There are two 2p-orbitals on each atom perpendicular to the internuclear axis, and so four molecular orbitals—two bonding π_{2p}-orbitals and two antibonding π_{2p}*-orbitals—are formed by their overlap.

Detailed calculation shows that there are some small differences in the order of energy levels from molecule to molecule (Box 3.3). Figure 3.31 shows the order for the Period 2 elements, with the exception of O_2 and F_2, which lie in the order shown in Fig. 3.32. The order of energy levels is easy to explain for these two molecules. First, because each O and F atom has many electrons that contribute to shielding, the 2s-orbitals lie well below the 2p-orbitals and we can think of building σ-orbitals from the two sets of atomic orbitals separately. However, because the atoms of elements earlier in the period have fewer electrons, their 2s- and 2p-orbitals have more similar energies than in O and F.

BOX 3.3 HOW DO WE KNOW . . . THE ENERGIES OF MOLECULAR ORBITALS?

The energies of orbitals are calculated today by solving the Schrödinger equation with computer software. The commercial software available is now so sophisticated that this approach can be as easy as typing in the name of the molecule or drawing it on screen. But these values are theoretical. How do we determine orbital energies experimentally?

One of the most direct methods is photoelectron spectroscopy (PES), an adaptation of the photoelectric effect (Section 1.4). A photoelectron spectrometer contains a source of high-frequency, short-wavelength radiation. Ultraviolet radiation is used most often for molecules, but x-rays are used to explore orbitals buried deeply inside solids. Photons in both frequency ranges have so much energy that they can eject electrons from the molecular orbitals they occupy.

Let's suppose that the frequency of the radiation is ν (nu), so each photon has an energy $h\nu$. An electron occupying a molecular orbital lies at an energy E_{orbital} below the zero of energy (corresponding to an electron far removed from the molecule). A photon that collides with the electron can eject it from the molecule if the photon can supply at least that much energy. The remaining energy of the photon, $h\nu - E_{\text{orbital}}$, then appears as the kinetic energy, E_k, of the ejected electron:

$$h\nu - E_{\text{orbital}} = E_k$$

We know ν, the frequency of the radiation being used to bombard the molecules; so, if we could measure the kinetic energy of the ejected electron, E_k, we could solve this expression to find the orbital energy, E_{orbital}.

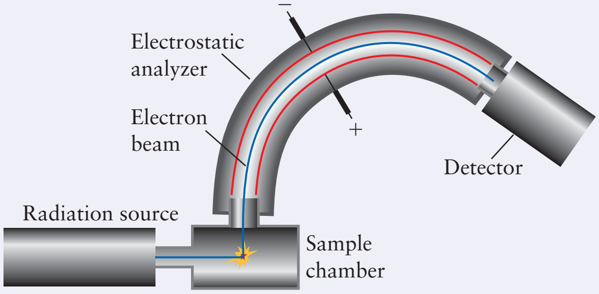

Diagram of a photoelectron spectrometer.

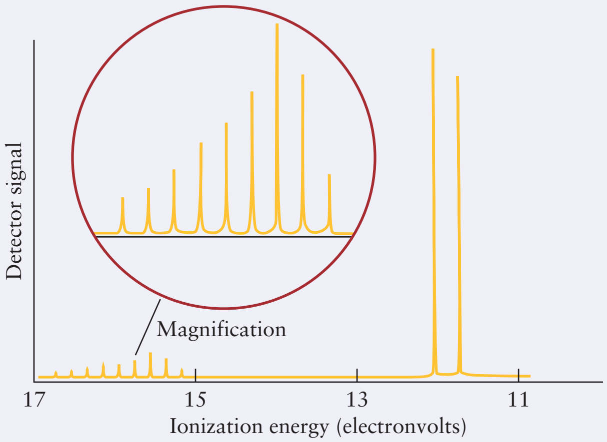
The kinetic energy of an ejected electron depends on its speed, v, because $E_k = \frac{1}{2}m_e v^2$ (Section A). A photoelectron spectrometer acts like a mass spectrometer in that it measures v for electrons just as a mass spectrometer can measure v for ions, as we saw in Section B. In this method, the electrons pass through a region of electric or magnetic field, which deflects their path. As the strength of the field is changed, the paths of the electrons change, too, until they fall on a detector and generate a signal. From the strength of the field required to obtain a signal, we can work out the speed of electrons ejected from a given orbital. From the speed, we can calculate the kinetic energy of the electrons and so obtain the energy of the orbital from which they came.

The photoelectron spectrum of nitrogen is shown below. There are several peaks, corresponding to electrons being ejected from orbitals of different energy. A detailed analysis shows that the spectrum is a good portrayal of the qualitative structure (as depicted in **45**).



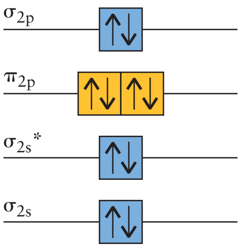
The photoelectron spectrum of nitrogen (N_2) has several peaks, a pattern indicating that electrons can be found in several energy levels in the molecule. Each main group of lines corresponds to the energy of a molecular orbital. The additional "fine structure" on some of the groups of lines is due to the excitation of molecular vibration when an electron is expelled.

As a result, it is no longer possible to think of a σ-orbital as being formed from either the 2s-orbitals or the $2p_z$-orbitals separately, and all four of these orbitals must be used to build the four σ-orbitals. It is then hard to predict without detailed calculation where these four orbitals will lie, and it turns out that they in fact lie where we show them in Fig. 3.31.

Once we know what molecular orbitals are available, we can derive the ground-state electron configurations of the molecules by using the building-up principle. For example, consider N_2. Because nitrogen belongs to Group 15/V, each atom supplies five valence electrons. A total of ten electrons must therefore be assigned to the eight molecular orbitals shown in Fig. 3.31. Two fill the σ_{2s}-orbital. The next two fill the $\sigma_{2s}{}^*$-orbital. Next in line for occupation are the two π_{2p}-orbitals, which can hold a total of four electrons. The last two electrons then enter the σ_{2p}-orbital. The ground configuration is therefore

$$N_2\text{: } \sigma_{2s}{}^2\sigma_{2s}{}^{*2}\pi_{2p}{}^4\sigma_{2p}{}^2$$

This configuration is shown as (**45**), where the boxes represent molecular orbitals.



45 Nitrogen, N_2

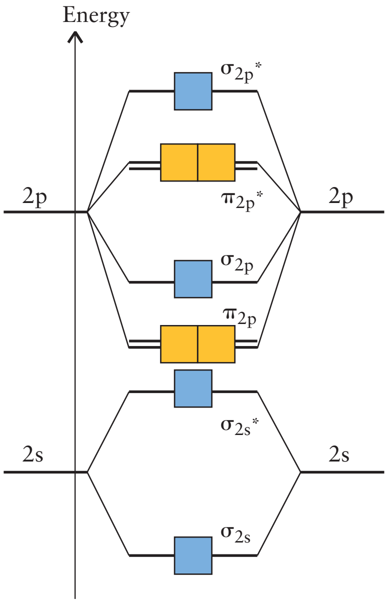


FIGURE 3.31 A typical molecular orbital energy-level diagram for the homonuclear diatomic molecules Li_2 through N_2. Each box represents one molecular orbital and can accommodate up to two electrons.

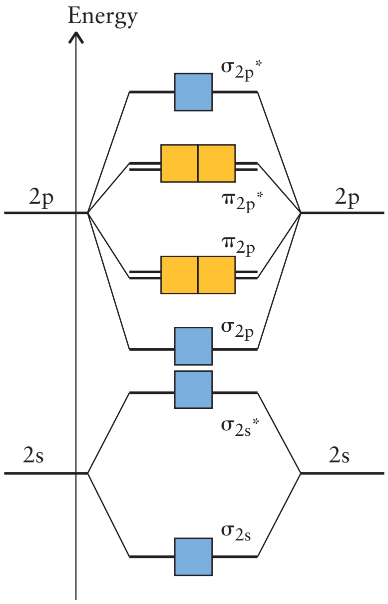

FIGURE 3.32 The molecular orbital energy-level diagram for the homonuclear diatomic molecules on the right-hand side of Period 2, specifically O_2 and F_2.

At first sight, the molecular orbital description of N_2 looks quite different from the Lewis description (:N≡N:). However, it is, in fact, very closely related. We can see their similarity by defining the **bond order** (b) in molecular orbital theory as the net number of bonds, allowing for the cancellation of bonds by antibonds:

$$\text{Bond order} = \tfrac{1}{2} \times (\text{number of electrons in bonding orbitals} - \text{number of electrons in antibonding orbitals})$$

$$b = \tfrac{1}{2} \times (N_e - N_e{}^*) \qquad (3)^*$$

Here N_e is the number of electrons in bonding molecular orbitals and $N_e{}^*$ is the number of electrons in antibonding molecular orbitals. This definition of bond order is the generalization of the one given in Section 2.6, where we simply counted shared pairs. In N_2, there are eight electrons in bonding orbitals and two in antibonding orbitals, and so the bond order is $\frac{1}{2}(8 - 2) = 3$. Because its bond order is 3, N_2 effectively has three bonds between the N atoms, just as the Lewis structure suggests.

TOOLBOX 3.2 HOW TO DETERMINE THE ELECTRON CONFIGURATION AND BOND ORDER OF A HOMONUCLEAR DIATOMIC SPECIES

CONCEPTUAL BASIS

When N valence atomic orbitals overlap, they form N molecular orbitals. The ground-state electron configuration of a molecule is deduced by using the building-up principle to accommodate all the valence electrons in the available molecular orbitals. The bond order is the net number of bonds that hold the molecule together.

PROCEDURE

Step 1 Identify *all* the atomic orbitals in the valence shells, ignoring how many electrons they contain.

Step 2 Use matching valence-shell atomic orbitals to build bonding and antibonding molecular orbitals and draw the resulting molecular orbital energy-level diagram (see Figs. 3.31 and 3.32).

Step 3 Note the total number of electrons present in the valence shells of the two atoms. If the species is an ion, adjust the number of electrons to account for the charge.

Step 4 Accommodate the electrons in the molecular orbitals according to the building-up principle.

Step 5 To determine the bond order, subtract the number of electrons in antibonding orbitals from the number in bonding orbitals and divide the result by 2 (Eq. 3).

This procedure is illustrated in Example 3.7.

EXAMPLE 3.7 Deducing the ground-state electron configuration and bond order of a diatomic molecule

Deduce the ground-state electron configuration of the fluorine molecule and calculate its bond order.

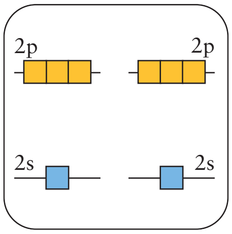
Anticipate Since the Lewis structure of F_2 is :F̤̈—F̤̈:, we should anticipate that the bond order is 1.

PLAN Set up the molecular orbital-energy level diagram and use the building-up principle to accommodate the valence electrons as described in Toolbox 3.2. Then calculate the bond order from the resulting configuration.

SOLVE

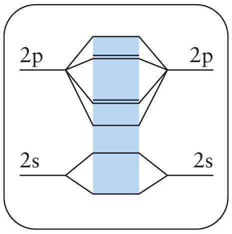
Step 1 Identify the valence atomic orbitals.

Each atom contributes a 2s-orbital and three 2p-orbitals, for a total of 8 orbitals.



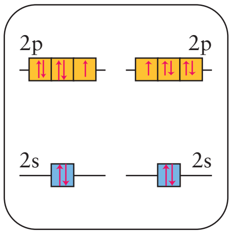
Step 2 Construct the molecular orbital energy-level diagram.

See Fig. 3.32.



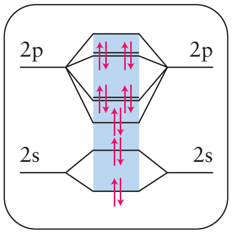
Step 3 Count the valence electrons.

$2 \times 7 = 14$



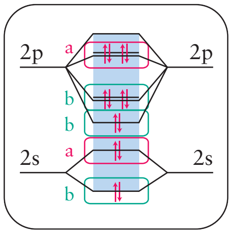
Step 4 Construct the electron configuration by filling the orbitals in order of increasing energy:

$\sigma_{2s}{}^2\sigma_{2s}{}^{*2}\sigma_{2p}{}^2\pi_{2p}{}^4\pi_{2p}{}^{*4}$

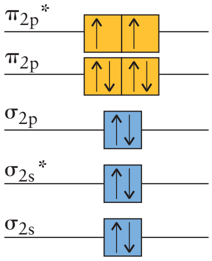


Step 5 Determine the bond order from $b = \frac{1}{2} \times (N_e - N_e{}^*)$:

$b = \frac{1}{2} \times [(2 + 2 + 4) - (2 + 4)] = 1$



Evaluate As expected, F_2 is a singly bonded molecule, in agreement with the Lewis structure. Notice that the first ten electrons repeat the N_2 configuration (apart from the change in order of the σ_{2p}- and π_{2p}-orbitals).



46 Oxygen, O_2

Self-Test 3.10A Deduce the electron configuration and bond order of the ion C_2^{2-}.

[*Answer:* $\sigma_{2s}^2\sigma_{2s}^{*2}\pi_{2p}^4\sigma_{2p}^2$, $b = 3$]

Self-Test 3.10B Suggest a configuration for the O_2^+ ion and state its bond order.

We find the ground-state electron configuration of O_2 by adding its twelve valence electrons (six from each atom) to the molecular orbitals shown in Fig. 3.32. The first ten electrons repeat the F_2 configuration, as in Example 3.7. According to the building-up principle, the last two electrons occupy the two separate π_{2p}^*-orbitals and do so with parallel spins. The configuration is therefore

$$O_2\text{: } \sigma_{2s}^2\sigma_{2s}^{*2}\sigma_{2p}^2\pi_{2p}^4\pi_{2p}^{*1}\pi_{2p}^{*1}$$

as shown in (**46**). This conclusion is a minor triumph for molecular orbital theory: because the last two spins are not paired, their magnetic fields do not cancel, and the molecule is predicted to be paramagnetic, exactly as observed. The bond order of O_2 is

$$b = \tfrac{1}{2} \times [(2 + 2 + 4) - (2 + 1 + 1)] = 2$$

The double bond in this molecule is actually a σ-bond plus two "*half* π-bonds," each "half bond" consisting of a pair of bonding electrons and one antibonding electron.

Thinking point: Can you use molecular orbital theory to explain why fluorine is such a highly reactive gas?

The ground-state electron configurations of diatomic molecules are deduced by forming molecular orbitals from all the valence-shell atomic orbitals of the two atoms and adding the valence electrons to the molecular orbitals in order of increasing energy, in accord with the building-up principle.

3.11 Bonding in Heteronuclear Diatomic Molecules

The bond in a **heteronuclear diatomic molecule,** a diatomic molecule built from atoms of two different elements, is polar, with the electrons shared unequally by the two atoms. We therefore rewrite Eq. 1 as the linear combination

$$\psi = c_A\psi_A + c_B\psi_B \qquad (4)^*$$

where the coefficients c_A and c_B are not equal. Because we always take the squares of wavefunctions when interpreting them in terms of probabilities, if c_A^2 is large, then the molecular orbital looks more like the atomic orbital of A and the electron density is greater near A; if c_B^2 is large, it looks more like the atomic orbital of B and the electron density is greater near B. In general, the atom with the atomic orbitals of lower energy dominates the molecular orbitals and the electron density is greater closer to that atom. The relative values of c_A^2 and c_B^2 determine the type of bond:

- In a *nonpolar covalent bond,* $c_A^2 = c_B^2$ and the electron pair is shared equally between the two atoms.
- In an *ionic bond,* the coefficient belonging to one ion is nearly zero because the other ion captures almost all the electron density.
- In a *polar covalent bond,* the atomic orbital belonging to the more electronegative atom has the lower energy, and so it makes the larger contribution to the lowest energy molecular orbital (Fig. 3.33). Conversely, the contribution to the highest-energy (most antibonding) orbital is greater for the higher-energy atomic orbital, which belongs to the less electronegative atom.

To find the ground-state electron configurations of heteronuclear diatomic molecules, we use the same approach that we used for homonuclear diatomic molecules; but first we must modify the energy-level diagrams. For example, consider the HF molecule. The σ-bond in this molecule consists of an electron pair in a σ-orbital built from the F2p_z-orbital and the H1s-orbital. Because the electronegativity of fluorine is 4.0 and that of hydrogen is 2.2, we can expect the bonding σ-orbital to be mainly F2p_z and the antibonding σ*-orbital to be mainly H1s in character. These expectations are confirmed by calculation (Fig. 3.34). Because the two electrons in the bonding orbital are

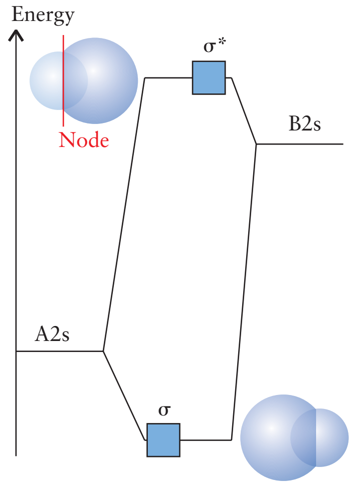


FIGURE 3.33 A typical σ molecular orbital energy-level diagram for a heteronuclear diatomic molecule AB; the relative contributions of the atomic orbitals to the molecular orbitals are represented by the relative sizes of the spheres and the horizontal position of the boxes. In this case, A is the more electronegative of the two elements.

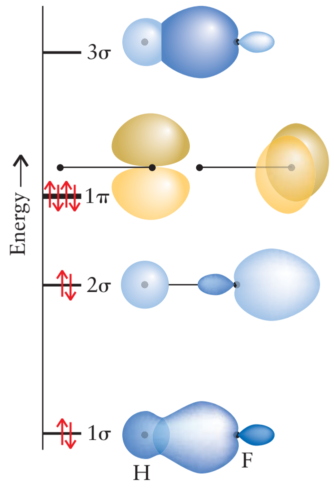

FIGURE 3.34 A schematic diagram of the molecular orbitals of HF. The orbitals are labeled by using a standard convention. The two 1π-orbitals are nonbonding; the three σ-orbitals are progressively more antibonding (1σ, bonding; 3σ, antibonding).

more likely to be found in the F2p_z-orbital than in the H1s-orbital, there is a partial negative charge on the F atom and a partial positive charge on the H atom.

The molecular orbital energy-level diagrams of heteronuclear diatomic molecules are much harder to predict qualitatively and we have to calculate each one explicitly because the atomic orbitals contribute differently to each one. Figure 3.35 shows the calculated scheme typically found for CO and NO. We can use this diagram to state the electron configuration by using the same procedure as for homonuclear diatomic molecules.

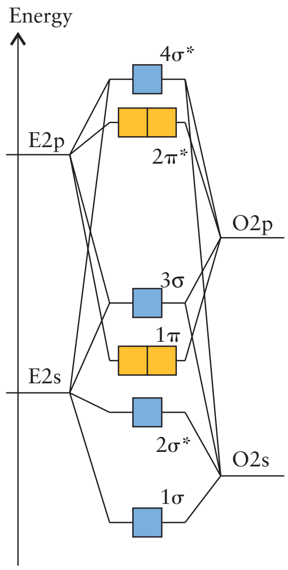

FIGURE 3.35 The molecular orbital schemes typical of those calculated for a diatomic oxide molecule, EO (where E = C for CO and E = N for NO). Note that the σ-orbitals are formed from mixtures of s- and p_z-orbitals on both atoms; accordingly, we label them simply 1σ, 2σ, etc. in order of increasing energy.

EXAMPLE 3.8 **Writing the configuration of a heteronuclear diatomic molecule or ion**

Write the electron configuration of the ground state of the carbon monoxide molecule.

PLAN Assign the electrons to the orbitals shown in Fig. 3.35, in accordance with the building-up principle.

SOLVE There are 4 + 6 = 10 valence electrons to accommodate (4 from C, 6 from O). The resulting configuration is shown in Fig. 3.35, and is

$$\text{CO: } 1\sigma^2 2\sigma^{*2} 1\pi^4 3\sigma^2$$

Self-Test 3.11A Write the configuration of the ground state of the nitric oxide (nitrogen monoxide) molecule.

[*Answer:* $1\sigma^2 2\sigma^{*2} 1\pi^4 3\sigma^2 2\pi^{*1}$]

Self-Test 3.11B Write the configuration of the ground state of the cyanide ion, CN^-, assuming that its molecular orbital energy-level diagram is the same as that for CO.

Bonding in heteronuclear diatomic molecules involves an unequal sharing of the bonding electrons. The more electronegative element contributes more strongly to the bonding orbitals, whereas the less electronegative element contributes more strongly to the antibonding orbitals.

3.12 Orbitals in Polyatomic Molecules

The molecular orbital theory of polyatomic molecules follows the same principles as those outlined for diatomic molecules, but the molecular orbitals spread over *all* the atoms in the molecule. An electron pair in a bonding orbital helps to bind together the *whole* molecule, not just an individual pair of atoms. The energies of molecular orbitals in polyatomic molecules can be studied experimentally by using ultraviolet and visible spectroscopy (see Major Technique 2, following this chapter).

The description of bonding in polyatomic molecules can be quite complex. However, we can illustrate qualitatively how to use molecular orbital theory to describe

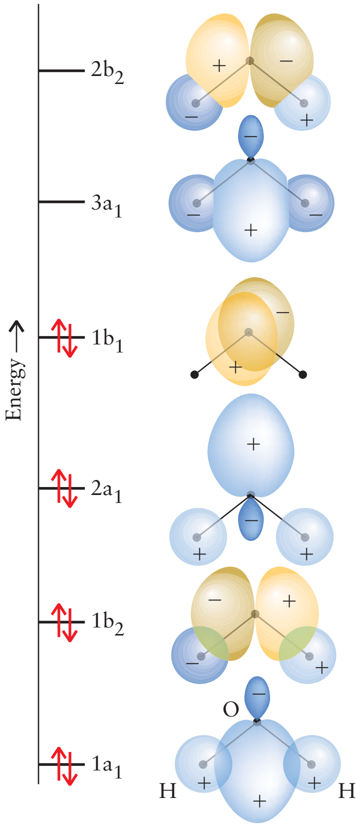

FIGURE 3.36 A schematic diagram of the molecular orbitals of H_2O. The orbitals are labeled according to the conventional notation for angular triatomic molecules. The orbitals become progressively more antibonding ($1a_1$, bonding; $2b_2$, antibonding). The orbital labeled $1b_1$ is nonbonding, because it is composed of an orbital ($O2p_x$) that does not overlap either hydrogen atom.

bonding in one of the simplest but most important polyatomic molecules, water. A water molecule has six atomic orbitals (one O2s, three O2p, and two H1s). These six orbitals are used to build six molecular orbitals in which the degree of net bonding character is related to the number of internuclear nodes (Fig. 3.36). The molecular orbital with no nodes between neighboring atoms is fully bonding and, when occupied, contributes to holding all the atoms together; the one with a node between all neighboring pairs of atoms is fully antibonding and, if occupied, contributes to pushing all the atoms apart. There are eight electrons to accommodate: six are provided by the O atom and one comes from each H atom. Two electrons in the lowest energy, most bonding orbital pull all three atoms together. Two electrons in the orbital composed purely of the $O2p_x$-orbital (where x lies perpendicular to the molecular plane) are localized completely on the oxygen atom and do not contribute directly to the bonding. An orbital such as this one that, when occupied, contributes to neither bonding nor antibonding is classified as a **nonbonding orbital.** In some cases, a nonbonding orbital is a single atomic orbital; in others, it may consist of a linear combination of atomic orbitals on atoms that are not neighbors and so overlap to a negligible extent.

Thinking point: Are the nonbonding electrons in an H_2O molecule useless, or do they play a role in the properties of water?

A note on good practice: The concepts of promotion, hybridization, and resonance belong to valence bond theory, not molecular orbital theory. Instead, molecular orbitals are built from all the available unhybridized atomic orbitals by noting whether or not they have the right shape to overlap with one another.

Another important polyatomic molecule is benzene, C_6H_6, the parent of the aromatic compounds. In the molecular orbital description of benzene, all thirty C2s-, C2p-, and H1s-orbitals contribute to molecular orbitals spreading over all twelve atoms (six C plus six H). The orbitals in the plane of the ring (the C2s-, $C2p_x$-, and $C2p_y$-orbitals on each carbon atom and all six H1s-orbitals) form delocalized σ-orbitals that bind the C atoms together and link the H atoms to the C atoms. The six $C2p_z$-orbitals, which are perpendicular to the ring, contribute to six delocalized π-orbitals that spread all the way around the ring. However, chemists (other than those carrying out detailed calculations, who use a pure MO scheme) commonly mix MO and VB descriptions when discussing organic molecules. Because the language of hybridization and orbital overlap is well suited to the description of σ-bonds, chemists typically express the σ-framework of molecules in VB terms. Thus, they think of the σ-framework of benzene as formed by the overlap of sp^2 hybridized orbitals on neighboring atoms. Then, because delocalization is such an important feature of the π-bonding component of **conjugated** double bonds, which alternate as in —C=C—C=C—C=C–, they treat such π-bonds in terms of MO theory. We shall do the same.

First, the VB part of the description of benzene. Each C atom is sp^2 hybridized, with one electron in each hybrid orbital. Each C atom has a p_z-orbital perpendicular to the plane defined by the hybrid orbitals, and it contains one electron. Two sp^2 hybrid orbitals on each C atom overlap and form σ-bonds with similar orbitals on the two neighboring C atoms, forming the 120° internal angle of the benzene hexagon. The third, outward-pointing sp^2 hybrid orbital on each C atom forms a σ-bond with a hydrogen atom. The resulting σ-framework is the same as that illustrated in Fig. 3.20.

Now for the MO part of the description. From the six $C2p_z$-orbitals, we form six delocalized π-orbitals: their shapes are shown in Fig. 3.37 and their energies are shown in Fig. 3.38. The character of the orbitals changes from net bonding to net antibonding as the number of internuclear nodes increases from none (fully bonding) to six (fully antibonding).

Each carbon atom provides one electron for the π-orbitals. Two electrons occupy the lowest energy, most bonding orbital; and the remaining four electrons occupy the next higher energy orbitals (two orbitals of the same energy). Figure 3.38 shows one of the reasons for benzene's great stability: the π-electrons occupy only orbitals with a net bonding effect; none of the destabilizing antibonding orbitals are occupied.

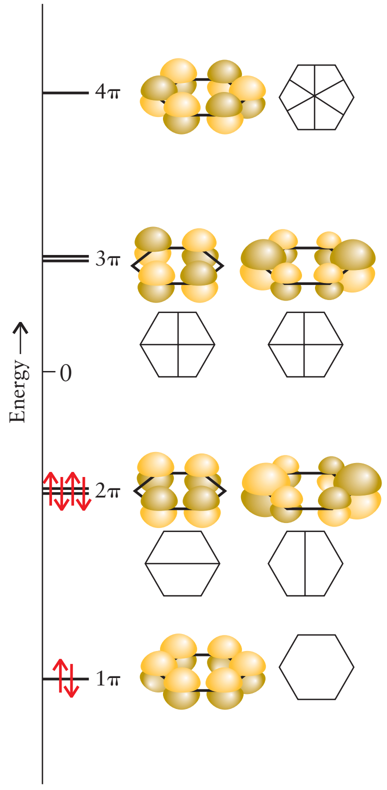

FIGURE 3.37 The six π-orbitals of benzene; locations of nodes are shown with line drawings. Note that the orbitals range from fully bonding (no internuclear nodes) to fully antibonding (six internuclear nodes). The zero of energy corresponds to the total energy of the separated atoms. The three orbitals with negative energies have net bonding character.

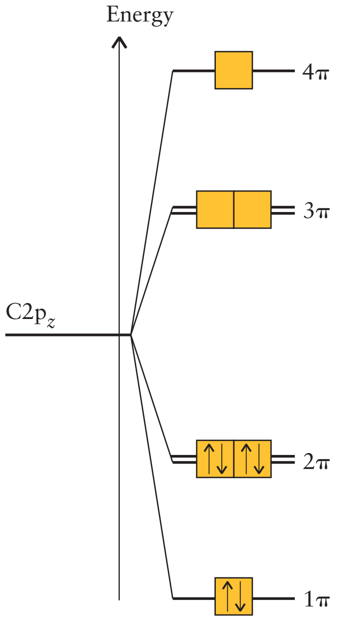

FIGURE 3.38 The molecular orbital energy-level diagram for the π-orbitals of benzene. In the ground state of the molecule, only the net bonding orbitals are occupied.

The delocalization of electrons accounts for the existence of electron-deficient molecules. Because the bonding influence of an electron pair is spread over all the atoms in the molecule, there is no need to provide one pair of electrons for each pair of atoms. A smaller number of pairs of electrons spread throughout the molecule may be able to bind all the atoms together, particularly if the nuclei are not highly charged and so do not repel one another strongly. This is the case in diborane, B_2H_6 (Section 15.11), where six electron pairs can hold the eight nuclei together.

Another mystery solved by molecular orbital theory is the existence of hypervalent compounds, compounds in which a central atom forms more bonds than allowed by the octet rule (recall Section 2.10). In valence-bond theory, hybridization schemes are required to make sense of these compounds. For example, the expanded valence shell of Period 3 elements in compounds like SF_6 is explained as sp^3d^2 hybridization. However, the d-orbitals of sulfur lie at relatively high energies and may not be accessible for bonding. In molecular orbital theory a bonding scheme can be devised for SF_6 that does not involve d-orbitals. The four valence orbitals provided by the sulfur atom and the six orbitals of the fluorine atoms that point toward the sulfur atom, a total of 10 atomic orbitals, result in 10 molecular orbitals with the energies shown in Fig. 3.39. The 12 electrons occupy the lowest six orbitals, which are either bonding or nonbonding, and so bind all the atoms together without needing to use d-orbitals. Because four bonding orbitals are occupied, the average bond order of each of the six S—F links is $\frac{2}{3}$.

Finally, we return to the opening remarks of the chapter and see how molecular orbital theory explains the colors of vegetation. The presence of highly delocalized electrons in the large molecules found in the petals of flowers and in fruits and vegetables is largely responsible for their colors. Because in each of these molecules many carbon atoms contribute p-orbitals to the π system, there are many molecular orbitals. An electron in a π system of such a molecule is like a particle in a huge one-dimensional box. Because the "box" is very large, the energy levels are very close together. In these large molecules, the **highest occupied molecular orbital** (HOMO) is very close in energy to the **lowest unoccupied molecular orbital** (LUMO). As a result, it takes very little energy to excite an electron from a HOMO to a LUMO

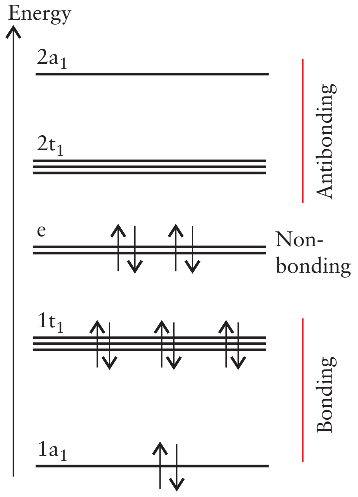

FIGURE 3.39 The molecular orbital energy-level diagram for SF_6 and the occupation of the orbitals by the 12 valence electrons of the atoms. Note that no antibonding orbitals are occupied and that there is a net bonding interaction even though no d-orbitals are involved.

(Fig. 3.40). Photons of visible light have enough energy to excite the electrons across this energy gap, and the absorption of these photons results in the colors that we perceive. The coloring agent of carrots and the precursor of vitamin A, β-carotene (**47**), has a highly delocalized π system, as does lycopene (**48**), the red compound that gives tomatoes their color.

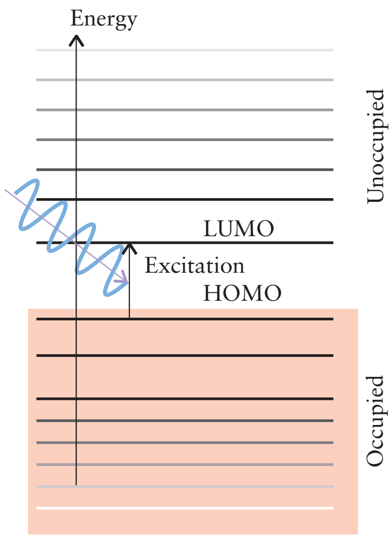

FIGURE 3.40 In large molecules, there are many closely spaced energy levels and the HOMO–LUMO gap is quite small. Such molecules are often colored because photons of visible light can be absorbed when electrons are excited from the HOMO to the LUMO.

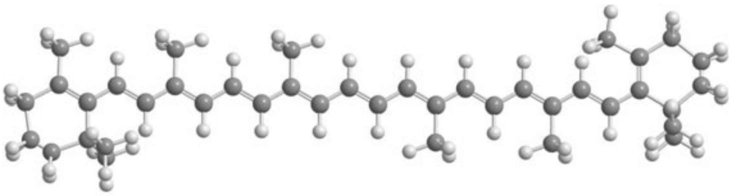
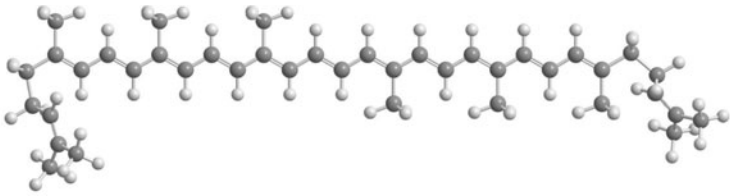


47 β-Carotene, $C_{40}H_{56}$



48 Lycopene, $C_{40}H_{58}$

According to molecular orbital theory, the delocalization of electrons in a polyatomic molecule spreads the bonding effects of electrons over the entire molecule.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Explain the basis of the VSEPR model of bonding in terms of repulsions between electrons (Section 3.1).

❑ 2 Use the VSEPR model to predict the electron arrangement and shape of a molecule or polyatomic ion from its formula (Toolbox 3.1 and Examples 3.1, 3.2, and 3.3).

❑ 3 Predict the polar character of a molecule (Example 3.4).

❑ 4 Account for the structure of a molecule in terms of hybrid orbitals and σ- and π-bonds (Examples 3.5 and 3.6).

❑ 5 Construct and interpret a molecular orbital energy-level diagram for a homonuclear diatomic species (Sections 3.9 and 3.10).

❑ 6 Deduce the ground-state electron configurations of Period 2 diatomic molecules (Toolbox 3.2 and Examples 3.7 and 3.8).

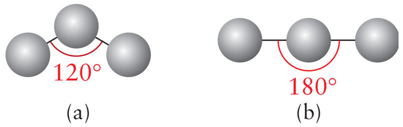
❑ 7 Use molecular orbital theory to describe bonding in polyatomic molecules such as the benzene molecule (Section 3.12).

EXERCISES

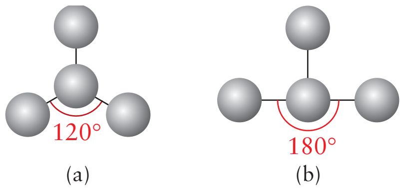
Exercises labeled **C** *require calculus.*

The Shapes of Molecules and Ions

3.1 Below are ball-and-stick models of two molecules. In each case, indicate whether or not there must be, may be, or cannot be one or more lone pairs of electrons on the central atom:



3.2 Below are ball-and-stick models of two molecules. In each case, indicate whether or not there must be, may be, or cannot be one or more lone pairs of electrons on the central atom:



3.3 (a) What is the shape of the ClO_2^+ ion? (b) What is the OClO bond angle?

3.4 (a) What is the shape of the ClO_2^- ion? (b) What values are expected for the OClO bond angles?

3.5 (a) What is the shape of the thionyl chloride molecule, $SOCl_2$? Sulfur is the central atom. (b) How many different OSCl bond angles are there in this molecule? (c) What values are expected for the OSCl and ClSCl bond angles?

3.6 (a) What is the shape of the XeF_2 molecule? (b) What values are expected for the FXeF bond angles?

3.7 (a) What is the shape of an ICl_2 molecule (iodine is the central atom)? (b) What value is expected for the ClICl angle?

3.8 (a) What is the shape of an SbF_5^{2-} ion? (b) How many different FSbF bond angles are there in this molecule? (c) What values are expected for the FSbF angles?

3.9 Using Lewis structures and VSEPR, give the VSEPR formula for each of the following species and predict its shape: (a) sulfur tetrachloride; (b) iodine trichloride; (c) IF_4^-; (d) xenon trioxide.

3.10 Using Lewis structures and VSEPR, give the VSEPR formula for each of the following species and predict its shape: (a) PF_4^-; (b) ICl_4^+; (c) phosphorus pentafluoride; (d) xenon tetrafluoride.

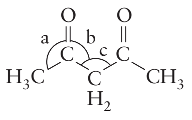
3.11 Write the Lewis structure, VSEPR formula, molecular shape, and bond angles for each of the following species: (a) I_3^-; (b) $POCl_3$; (c) IO_3^-; (d) N_2O.

3.12 Write the Lewis structure, VSEPR formula, molecular shape, and bond angles for each of the following species: (a) SiH_4; (b) $AsCl_3$; (c) SCl_2; (d) IF_4^+.

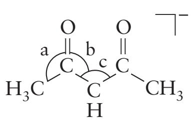
3.13 Write the Lewis structure and the VSEPR formula, list the shape, and predict the approximate bond angles for (a) CF_3Cl; (b) $TeCl_4$; (c) COF_2; (d) CH_3^-.

3.14 Write the Lewis structure and the VSEPR formula, list the shape, and predict the approximate bond angles for (a) PCl_3F_2; (b) SnF_4; (c) SnF_6^{2-}; (d) IF_5; (e) XeO_4.

3.15 The compound 2,4-pentanedione (also known as acetylacetone and abbreviated to acac) is acidic and can be deprotonated. The anion forms complexes with metals that are used in gasoline additives, lubricants, insecticides, and fungicides. (a) Estimate the bond angles marked with arcs and lowercase letters in 2,4-pentanedione and in the acac ion. (b) What are the differences, if any?

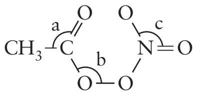


Acetylacetone



Acetylacetonate ion

3.16 Estimate the bond angles marked with arcs and lowercase letters in peroxyacetylnitrate, an eye irritant in smog:



3.17 Predict the bond angles at the central atom of the following molecules and ions: (a) ozone, O_3; (b) azide ion, N_3^-; (c) cyanate ion, CNO^-; (d) hydronium ion, H_3O^+.

3.18 Predict the bond angles at the central atom of the following molecules and ions: (a) OF_2; (b) ClO_2^-; (c) NO_2^-; (d) $SeCl_2$.

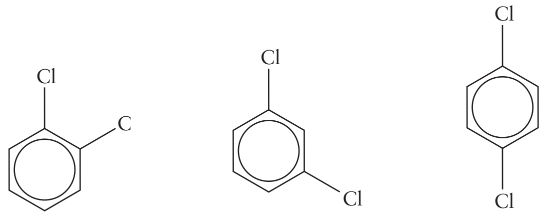
3.19 Write its Lewis structure and predict whether each of the following molecules is polar or nonpolar: (a) CH_2Cl_2; (b) CCl_4; (c) CS_2; (d) SF_4.

3.20 Write its Lewis structure and predict whether each of the following molecules is polar or nonpolar: (a) H_2Se; (b) AsF_5; (c) SiO_2; (d) NF_3.

3.21 Predict whether each of the following molecules is likely to be polar or nonpolar: (a) C_5H_5N (pyridine, a molecule like benzene except that one —CH— group is replaced by a nitrogen atom); (b) C_2H_6 (ethane); (c) $CHCl_3$ (trichloromethane, also known as chloroform, a common organic solvent and once used as an anesthetic).

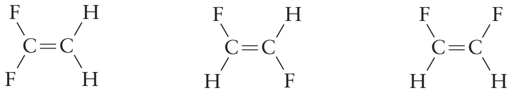
3.22 Predict whether each of the following molecules is likely to be polar or nonpolar: (a) CI_4; (b) CH_3OH (methanol, wood alcohol); (c) CH_3COCH_3 (2-propanone, acetone, a common organic solvent used in nail polish remover).

3.23 There are three different dichlorobenzenes, $C_6H_4Cl_2$, which differ in the relative positions of the chlorine atoms on the benzene ring. (a) Which of the three forms are polar? (b) Which has the largest dipole moment?



1 2 3

3.24 There are three different difluoroethenes, $C_2H_2F_2$, which differ in the locations of the fluorine atoms. (a) Which of the forms are polar? (b) Which has the largest dipole moment?



1 2 3

3.25 Acrylonitrile, CH_2CHCN, is used in the synthesis of acrylic fibers (polyacrylonitriles), such as Orlon. Write the Lewis structure of acrylonitrile and describe the hybrid orbitals on each carbon atom. What are the approximate values of the bond angles?

3.26 Xenon forms XeO_3, XeO_4, and XeO_6^{4-}, all of which are powerful oxidizing agents. Give their Lewis structures, their bond angles, and the hybridization of the xenon atom. Which would be expected to have the longest Xe–O distances?

3.27 Predict the shapes and estimate the bond angles of (a) the thiosulfate ion, $S_2O_3^{2-}$; (b) $(CH_3)_2Be$; (c) BH_2^-; (d) $SnCl_2$.

3.28 For each of the following molecules or ions, write the Lewis structure, list the number of lone pairs on the central atom, identify the shape, and estimate the bond angles: (a) PBr_5; (b) $XeOF_2$; (c) SF_5^+; (d) IF_3; (e) BrO_3^-.

3.29 Write the Lewis structure and give the approximate bond angles of (a) C_2H_4; (b) ClCN; (c) $OPCl_3$; (d) N_2H_4.

3.30 Write the Lewis structure and predict the shape of (a) TeF_4; (b) NH_2^-; (c) NO_2^+; (d) NH_4^+; (e) SnH_4; (f) OCS.

3.31 Write the Lewis structure and predict the shape of (a) $O\mathbf{Sb}Cl_3$; (b) $\mathbf{S}O_2Cl_2$; (c) $\mathbf{I}O_2F_2^-$. The atom in boldface type is the central atom.

3.32 Write the Lewis structure and predict the shape of (a) $O\mathbf{C}Cl_2$; (b) $O\mathbf{Sb}Cl_2^-$. The atom in boldface type is the central atom.

Valence-Bond Theory

3.33 State the relative orientations of the following hybrid orbitals: (a) sp^3; (b) sp; (c) sp^3d^2; (d) sp^2.

3.34 The orientation of bonds on a central atom of a molecule that has no lone pairs can be any of those listed below. What is the hybridization of the orbitals used by each central atom for its bonding pairs: (a) tetrahedral; (b) trigonal bipyramidal; (c) octahedral; (d) linear?

3.35 State the hybridization of the atom in boldface type in each of the following molecules: (a) $\mathbf{Be}Cl_2$; (b) $\mathbf{B}H_3$; (c) $\mathbf{B}H_4^-$; (d) $\mathbf{Si}F_4$.

3.36 State the hybridization of the atom in boldface type in each of the following molecules: (a) $\mathbf{S}F_6$; (b) $O_3\mathbf{Cl}$—O—ClO_3; (c) $H_2\mathbf{N}$—CH_2—COOH (glycine); (d) $O\mathbf{C}(NH_2)_2$ (urea).

3.37 Identify the hybrid orbitals used by the atom in boldface type in each of the following species: (a) $\mathbf{B}F_3$; (b) $\mathbf{As}F_3$; (c) $\mathbf{Br}F_3$; (d) $\mathbf{Se}F_3^+$.

3.38 Identify the hybrid orbitals used by the atom in boldface type in each of the following molecules: (a) $CH_3\mathbf{C}CCH_3$; (b) $CH_3\mathbf{N}NCH_3$; (c) $(CH_3)_2\mathbf{C}C(CH_3)_2$; (d) $(CH_3)_2\mathbf{N}N(CH_3)_2$.

3.39 Identify the hybrid orbitals used by the phosphorus atom in each of the following species: (a) PCl_4^+; (b) PCl_6^-; (c) PCl_5; (d) PCl_3.

3.40 Identify the hybrid orbitals used by the atom in boldface type in each of the following molecules: (a) $H_2C\mathbf{C}CH_2$; (b) $H_3C\mathbf{C}H_3$; (c) $CH_3N\mathbf{N}N$; (d) $CH_3\mathbf{C}OOH$.

3.41 White phosphorus, P_4, is so reactive that it bursts into flame in air. The four atoms in P_4 form a tetrahedron in which each P atom is connected to three other P atoms. (a) Assign a hybridization scheme to the P_4 molecule. (b) Is the P_4 molecule polar or nonpolar?

3.42 In the vapor phase, phosphorus can exist as P_2 molecules, which are highly reactive, whereas N_2 is relatively inert. Use valence-bond theory to explain this difference.

3.43 Noting that the bond angle of an sp^3 hybridized atom is 109.5° and that of an sp^2 hybridized atom is 120°, do you expect the bond angle between two hybrid orbitals to increase or decrease as the *s*-character of the hybrids is increased?

3.44 Both NH_2^- and NH_2^+ are angular species, but the bond angle in NH_2^- is less than that in NH_2^+. (a) What is the reason for this difference in bond angles? (b) Take the *x*-axis as lying perpendicular to the plane of the molecule. Does the $N2p_x$ orbital participate in the hybridization for either species? Briefly explain your answer.

3.45 Describe the structure of the formaldehyde molecule, CH_2O, in terms of hybrid orbitals, bond angles, and σ- and π-bonds. The C atom is the central atom to which the other three atoms are attached.

3.46 Describe the structure of the formamide molecule, H_2CONH_2, in terms of hybrid orbitals, bond angles, and σ- and π-bonds. The C atom is bonded to two H atoms, a terminal O atom, and the N atom. The N atom is also bonded to two H atoms.

3.47 Given that the atomic orbitals used to form hybrids are normalized to 1 and mutually orthogonal, (a) show that the two tetrahedral hybrids $h_1 = s + p_x + p_y + p_z$ and $h_3 = s - p_x + p_y - p_z$ are orthogonal. (b) Construct the remaining two tetrahedral hybrids that are orthogonal to these two hybrids. *Hint*: Two wavefunctions are orthogonal if $\int \psi_1\psi_2 d\tau = 0$, where $\int \ldots d\tau$ means "integrate over all space."

3.48 The hybrid orbital $h_1 = s + p_x + p_y + p_z$ referred to in Exercise 3.47 is not normalized. Find the normalization factor *N*, given that all the atomic orbitals are normalized to 1.

3.49 The composition of hybrids can be discussed quantitatively. The outcome is that, if two equivalent hybrids composed of an s-orbital and two p-orbitals make an angle θ to each other, then the hybrids can be regarded as sp^λ, with $\lambda = -\cos\theta/\cos^2(\frac{1}{2}\theta)$. What is the hybridization of the O orbitals that form the two O—H bonds in H_2O?

3.50 Given the information in Exercise 3.49, plot a graph showing how the hybridization depends on the angle between two hybrids formed from an s-orbital and two p-orbitals, and confirm that it ranges from 90° when no s-orbital is included in the mixture to 120° when the hybridization is sp^2.

Molecular Orbital Theory

3.51 Draw a molecular orbital energy-level diagram and determine the bond order expected for each of the following diatomic species: (a) Li_2; (b) Li_2^+; (c) Li_2^-. State whether each molecule or ion will be paramagnetic or diamagnetic. If it is paramagnetic, give the number of unpaired electrons.

3.52 Draw a molecular orbital energy-level diagram and determine the bond order expected for the following diatomic species: (a) B_2; (b) B_2^-; (c) B_2^+. State whether each molecule or ion will be paramagnetic or diamagnetic. If it is paramagnetic, give the number of unpaired electrons.

3.53 (a) On the basis of the configuration of the neutral molecule F_2, write the molecular orbital configuration of the valence molecular orbitals for (1) F_2^-; (2) F_2^+; (3) F_2^{2-}. (b) For each species, give the expected bond order. (c) Which are paramagnetic, if any? (d) Is the highest-energy orbital that contains an electron σ or π in character?

3.54 (a) On the basis of the configuration for the neutral molecule N_2, write the molecular orbital configuration of the valence molecular orbitals for (1) N_2^+; (2) N_2^{2+}; (3) N_2^{2-}. (b) For each species, give the expected bond order. (c) Which are paramagnetic, if any? (d) Is the highest-energy orbital that contains an electron σ or π in character?

3.55 The ground-state electron configuration of the ion C_2^{n-} is $\sigma_{2s}^2\sigma_{2s}^{*2}\pi_{2p}^4\sigma_{2p}^2$. What is the charge on the ion and what is its bond order?

3.56 The ground-state electron configuration of the ion B_2^{n-}: $\sigma_{2s}^2\sigma_{2s}^{*2}\pi_{2p}^3$. What is the charge on the ion and what is its bond order?

3.57 (a) Draw the molecular orbital energy-level diagram for N_2 and label the energy levels according to the type of orbitals from

which they are made, whether they are σ- or π-orbitals, and whether they are bonding or antibonding. (b) The orbital structure of the heteronuclear diatomic ion NO^+ is similar to that of N_2. How will the fact that the electronegativity of N differs from that of O affect the molecular orbital energy-level diagram of NO^+ compared with that of N_2? Use this information to draw the energy-level diagram for NO^+. (c) In the molecular orbitals, will the electrons have a higher probability of being at N or at O? Why?

3.58 (a) How does molecular orbital theory make it possible to explain both ionic *and* covalent bonding? (b) The degree of ionic character in bonding was related to electronegativity in Chapter 2. How does electronegativity affect the molecular orbital diagram so that bonds become ionic?

3.59 Write the valence-shell electron configurations and bond orders of (a) B_2; (b) Be_2; (c) F_2.

3.60 Write the valence-shell electron configurations and bond orders of (a) NO; (b) N_2^+; (c) C_2^{2+}.

3.61 Give the valence-shell electron configurations and bond orders for CO and CO^+. Use that information to predict which species has the greater bond enthalpy.

3.62 Give the valence-shell electron configurations and bond orders for CN and CN^-. Use that information to predict which species has the greater bond enthalpy.

3.63 Which of the following species are paramagnetic: (a) B_2; (b) B_2^-; (c) B_2^+? If the species is paramagnetic, how many unpaired electrons does it possess?

3.64 Which of the following species are paramagnetic: (a) N_2^-; (b) F_2^+; (c) O_2^{2+}? If the species is paramagnetic, how many unpaired electrons does it possess?

3.65 Determine the bond orders and use them to predict which species of each of the following pairs has the stronger bond: (a) F_2 or F_2^-; (b) B_2 or B_2^+.

3.66 Determine the bond orders and use them to predict which species of each of the following pairs has the stronger bond: (a) C_2^+ or C_2; (b) O_2 or O_2^+.

3.67 Based on their valence-shell electron configurations which of the following species would you expect to have the lowest ionization energy: (a) C_2^+; (b) C_2; (c) C_2^-?

3.68 Based on their valence-shell electron configurations which of the following species would you expect to have the greatest electron affinity: (a) Be_2; (b) F_2; (c) B_2^+, (d) C_2^+?

C **3.69** It is usually convenient to deal with wavefunctions that are "normalized," which means that the integral $\int \psi^2 d\tau = 1$. The bonding orbital in Eq. 1 is not normalized. A wavefunction ψ can be normalized by writing it as $N\psi$ and finding the factor N which ensures that the integral over $(N\psi)^2$ is equal to 1. Find the factor N that normalizes the bonding orbital in Eq. 1, given that the individual atomic orbitals are each normalized. Express your answer in terms of the "overlap integral" $S = \int \psi_{A1s}\psi_{B1s} d\tau$. (The notation is the same as in Exercise 3.47.)

C **3.70** The antibonding orbital in Eq. 2 is not normalized (see Exercise 3.69). Find the factor that normalizes it to 1, given that the individual atomic orbitals are each normalized. Express your answer in terms of the overlap integral $S = \int \psi_{A1s}\psi_{B1s} d\tau$. (The notation is the same as in Exercise 3.47.) Confirm that the bonding and antibonding orbitals are mutually orthogonal—that is, that the integral over the product of the two wavefunctions is zero.

Integrated Exercises

3.71 For each of the following species, write the Lewis structure, predict the shape and hybridization about each central atom, give the bond angles, and state whether it is polar or nonpolar: (a) $GaCl_4^-$; (b) TeF_4; (c) $SbCl_4^-$; (d) $SiCl_4$.

3.72 For each of the following species, write the Lewis structure, predict the shape and hybridization about each central atom, give the bond angles, and state whether it is polar or nonpolar: (a) $SnCl_3^-$; (b) TeO_3; (c) NO_3^-; (d) ICl_3.

3.73 (a) Draw a Lewis structure for each of the following species: CH_3^+; CH_4; CH_3^-; CH_2; CH_2^{2+}; CH_2^{2-}. (b) Identify each as a radical or not. (c) Rank them in order of increasing HCH bond angles. Explain your choices.

3.74 The halogens form compounds among themselves. These compounds, called the *interhalogens,* have the formulas XX′, XX'_3, and XX'_5, where X is the heavier halogen atom. (a) Predict their structures and bond angles. (b) Which of them are polar? (c) Why is the lighter halogen atom not the central atom of such molecules?

3.75 An organic compound distilled from wood was found to have a molar mass of 32.04 $g \cdot mol^{-1}$ and the following composition by mass: 37.5% C, 12.6% H, and 49.9% O. (a) Write the Lewis structure of the compound and determine the bond angles about the carbon and oxygen atoms. (b) Give the hybridization of the carbon and oxygen atoms. (c) Predict whether the molecule is polar or not.

3.76 Draw Lewis structures for each of the following species and predict the hybridization at each carbon atom: (a) H_2CCH^+; (b) $H_2CCH_3^+$; (c) $H_3CCH_2^-$.

3.77 (a) Draw the bonding and antibonding orbitals that correspond to the σ-bond in H_2. (b) Repeat this procedure for HF. (c) How do these orbitals differ?

3.78 (a) Consider a hypothetical species "HeH." What charge (magnitude and sign), if any, should be present on this combination of atoms to produce the most stable molecule or ion possible? (b) What is the maximum bond order that such a molecule or ion could have? (c) If the charge on this species were increased or decreased by one, what would be the effect on the bonding in the molecule?

3.79 (a) Order the following molecules according to increasing C—F bond length: CF^+, CF, CF^-. (b) Which of these molecules will be diamagnetic, if any? Explain your reasoning.

3.80 Describe as completely as you can the structure and bonding in a carbamate ion, $H_2NCO_2^-$. The C—O bond lengths are both 128 pm, and the C—N bond length is 136 pm.

3.81 Borazine, $B_3N_3H_6$, a compound that has been called "inorganic benzene" because of its similar hexagonal structure (but with alternating B and N atoms in place of C atoms), is the basis of a large class of boron–nitrogen compounds. Write its Lewis structure and predict the composition of the hybrid orbitals used by each B and N atom.

3.82 Given that carbon has a valence of four in nearly all its compounds and can form chains and rings of C atoms, (a) draw any two of the three possible structures for C_3H_4; (b) determine all bond angles in each structure; (c) determine the hybridization of each carbon atom in the two structures; (d) ascertain whether the two structures are resonance structures and explain your reasoning.

3.83 The two atomic orbitals that contribute to the antibonding orbital in Eq. 2 are each proportional to e^{-r/a_0}, where r is the distance of the point from its parent nucleus. Confirm that there is a nodal plane lying halfway between the two nuclei.

3.84 Use the plotting function on the Web site for this book to plot the amplitude of the bonding and antibonding orbitals in Eqs. 1 and 2, given the information in Exercise 3.83, on a line passing through the two nuclei. Ignore the normalization factors, and take the internuclear distance as (a) a_0, (b) $2a_0$, (c) $5a_0$. Which of these three bond lengths is most likely to be close to the actual bond length?

3.85 Write the Lewis structure and VSEPR formula and identify the molecular shape and bond angles of the interhalogen ion IF_6^+.

3.86 Dye molecules are of commercial importance because they are very intensely colored. Most dye molecules possess many multiple bonds and are often aromatic. Why is this type of structure important to the properties of the dye molecule?

3.87 Treat the π system of a dye molecule composed of a conjugated carbon chain of N carbon atoms as a box of length NR, where R is the average C—C bond length. Given that each C atom contributes one electron and that each state of the box can accommodate two electrons, derive an expression for the wavelength of the light absorbed by the lowest-energy transition. Should you increase or decrease the number of carbon atoms in the chain to shift the wavelength to longer values? Refer to Major Technique 2, which follows these exercises.

3.88 Show that a molecule with configuration π^4 has a cylindrically symmetrical electron distribution. *Hint:* Take the π-orbitals to be equal to xf and yf, where f is a function that depends only on distance from the internuclear axis.

3.89 In addition to forming σ and π types of bonds similar to p-orbitals, d-orbitals may overlap to form δ-bonds. (a) Draw overlap diagrams showing three different ways in which d-orbitals can combine to form bonds. (b) Place the three types of d–d bonds—σ, π, and δ—in order of strongest to weakest.

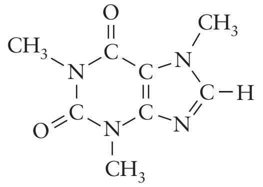
3.90 An s-orbital and a p-orbital on different atoms may overlap to form molecular orbitals. One of these interactions forms a bonding σ-orbital and the other is nonbonding. Draw diagrams to represent the two types of orbital overlap that give rise to σ-bonding and nonbonding orbitals.

3.91 (a) Describe the changes in bonding that would occur in benzene if two electrons were removed from the HOMO (highest occupied molecular orbital). This removal would correspond to an oxidation of benzene to $C_6H_6^{2+}$. (b) Describe the changes in bonding that would occur if two electrons were added to the LUMO (lowest unoccupied molecular orbital). This addition would correspond to a reduction of benzene by two electrons to give $C_6H_6^{2-}$. Do you expect these ions to be diamagnetic or paramagnetic?

3.92 (a) Confirm, by using trigonometry, that the dipoles of the three bonds in a trigonal pyrimidal AB_3 molecule do not cancel, resulting in a polar molecule. (b) Show that the dipoles of the four bonds in a tetrahedral AB_4 molecule cancel and the molecule is nonpolar.

3.93 Benzyne, C_6H_4, is a highly reactive molecule that is detected only at low temperatures. It is related to benzene in that it has a six-membered ring of carbon atoms; but, instead of three double bonds, the structure is normally drawn with two double bonds and a triple bond. (a) Draw a Lewis structure of the benzyne molecule. Indicate on the structure the hybridization at each carbon atom. (b) On the basis of your understanding of bonding, explain why this molecule might be highly reactive.

3.94 The Lewis structure of caffeine, $C_8H_{10}N_4O_2$, a common stimulant, follows. (a) Give the hybridization of each atom other than hydrogen. (b) On the basis of your answers in part (a), estimate the bond angles around each carbon and nitrogen atom. (c) Search the chemical literature for the structure of caffeine, and compare the observed structural parameters with your predictions.



3.95 Cyclopropane, C_3H_6, is a hydrocarbon composed of a three-membered ring of carbon atoms. (a) Determine the hybridization of the carbon atoms. (b) Predict the CCC and HCH bond angles at each carbon atom on the basis of your answer to part (a). (c) What must the “real” CCC bond angles in cyclopropane be? (d) What is the defining characteristic of a σ-bond compared with a π-bond, for example? (e) How do the C—C σ-bonds in cyclopropane extend the definition of conventional σ-bonds? (f) Draw a picture depicting the molecular orbitals to illustrate your answer.

3.96 The diameter of a C_{60} molecule (Section 15.12) is approximately 700 pm. (a) Could more than one lanthanum atom occupy the center of a C_{60} molecule? (b) Because it is possible for C_{60} to undergo reduction (six step-by-step reductions to give C_{60}^{6-} have been reported), it is also possible for a lanthanum ion, La^{3+}, to exist inside the C_{60} molecule. Could two La^{3+} ions be placed inside a C_{60} molecule?

3.97 In which of the following molecules could there be an n-to-π* transition? Explain your choices. (a) Formic acid, HCOOH; (b) ethyne, C_2H_2; (c) methanol, CH_3OH; (d) hydrogen cyanide, HCN. Refer to Major Technique 2, which follows these exercises.

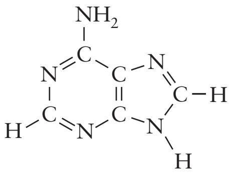
3.98 Aqueous solutions of compounds containing the Cu^{2+} ion are blue as a result of the presence of the $Cu(H_2O)_6^{2+}$ complex. Does this complex absorb in the visible region? Suggest an explanation. Refer to Major Technique 2, which follows these exercises.

3.99 Consider the bonding in $CH_2{=}CHCHO$. (a) Draw the most important Lewis structure. Include all nonzero formal charges. (b) Identify the composition of the bonds and the hybridization of each lone pair—for example, by writing σ(H1s,C2sp^2).

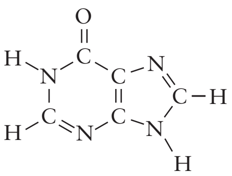
3.100 Consider the molecules H_2CCH_2, H_2CCCH_2, and H_2CCCCH_2. (a) Draw Lewis structures for these molecules. (b) What is the hybridization at each C atom? (c) What type of bond connects the carbon atoms (single, double, etc.)? (d) What are the HCH, CCH, and CCC angles in these molecules? (e) Do all the hydrogen atoms lie in the same plane? (f) A generalized formula for molecules of this type is $H_2C(C)_xCH_2$, where x is 0, 1, 2, etc. What can be said, if anything, about the relative orientation of the H atoms at the ends of the chain as a function of x?

3.101 The reaction between SbF_3 and CsF produces, among other products, the anion $[Sb_2F_7]^-$. This anion has no F—F bonds and no Sb—Sb bonds. (a) Propose a Lewis structure for the ion. (b) Assign a hybridization scheme to the Sb atoms.

3.102 The following molecules are bases that are part of the nucleic acids involved in the genetic code. Identify (a) the hybridization of each C and N atom, (b) the number of σ- and π-bonds, and (c) the number of lone pairs of electrons in the molecule.



1



2

3.103 Just as $AlCl_3$ forms dimers (Section 2.11), in the $[Bi_2Cl_4]^{2-}$ ion two of the Cl atoms form "bridges" between the two Bi atoms. Propose a structure for the $[Bi_2Cl_4]^{2-}$ ion.

3.104 Germanium forms a series of anions called "germides." In the germide ion Ge_4^{n-} the four Ge atoms form a tetrahedron in which each atom is bonded to the other three and each atom has a lone pair of electrons. What is the value of n, the charge on this anion? Explain your reasoning.

3.105 One form of the polyatomic ion I_5^- has an unusual V-shaped structure: one I atom lies at the point of the V, with a linear chain of two I atoms extending on each side. The bond angles are 88° at the central atom and 180° at the two atoms in the side chains. Draw a Lewis structure for I_5^- that explains its shape and indicate the hybridization you would assign to each nonterminal atom.

3.106 Molecules and ions, like atoms, can be isoelectronic. That is, they can have the same number of electrons. For example, CH_4 and NH_4^+ are isoelectronic. Therefore, they have the same molecular shape. Identify a molecule or ion that is isoelectronic with each of the following species and verify that each pair has the same shape: (a) CO_3^{2-}; (b) O_3; (c) OH^-.

3.107 Is the Al_2Cl_6 molecule, described in Section 2.11, polar or nonpolar? Justify your conclusion.

3.108 The molecular structure of benzene, C_6H_6, is planar. Is the molecular structure of cyclohexane, C_6H_{12}, planar as well? (a) Draw a Lewis structure for cyclohexane. (b) Indicate the bond angles about each carbon atom. (c) What is your conclusion about the shape of the cyclohexane molecule?

3.109 Complexes of d- and f-block metals can be described in terms of hybridization schemes, each associated with a particular shape. Bearing in mind that the number of atomic orbitals hybridized must be the same as the number of hybrid orbitals produced, match the hybrid orbitals sp^2d, sp^3d^3, and sp^3d^3f to the following shapes: (a) pentagonal bipyramidal; (b) cubic; (c) square planar.

3.110 (a) The formula for bromate ion (BrO_3^-) is similar to that of chlorate ion (ClO_3^-); however, the formulas of the nitrate and phosphate ions have different numbers of oxygen atoms, as do the formulas of the nitrite and phosphite ions. Draw the Lewis structures of all four ions and explain why the formulas differ. (b) Energy is supplied to muscles in the body through changes in ATP, a molecule that contains chains of phosphate ions (—PO_2—O—PO_2—O—PO_2—O—). Explain how phosphate ions can connect to one another in this way, but nitrate ions cannot.

Chemistry Connections

3.111 Hydrogen peroxide, H_2O_2, is a nontoxic bleaching agent being used as a replacement for chlorine in industry and home laundries. The bleaching process is an oxidation and when hydrogen peroxide acts as a bleaching agent, the only waste it generates is H_2O.
(a) Draw the Lewis structure of hydrogen peroxide and determine the formal charge on each atom. What is the oxidation number of oxygen in hydrogen peroxide? Which is more useful in predicting the ability of H_2O_2 to act as an oxidizing agent, formal charge or oxidation number? Explain your reasoning.
(b) Predict the bond angles about each O atom in H_2O_2. Are all the atoms in the same plane? Is the molecule polar or nonpolar? Explain your reasoning.
(c) Write the valence electron configuration of (1) O_2; (2) O_2^-; (3) O_2^+; (4) O_2^{2-}. For each species, give the expected bond order and indicate which, if any, are paramagnetic.
(d) The following bond lengths have been reported: (1) O_2, 121 pm; (2) O_2^-, 134 pm; (3) O_2^+, 112 pm; (4) O_2^{2-}, 149 pm. Suggest a reason for the differences based on the configurations in part (c).
(e) One reaction in which H_2O_2 acts as an oxidizing agent is $Fe^{2+}(aq) + H_2O_2(aq) + H^+(aq) \longrightarrow Fe^{3+}(aq) + H_2O(l)$. Balance the equation and determine what mass of iron(II) can be oxidized to iron(III) by 54.1 mL of 0.200 M $H_2O_2(aq)$. *Hint:* Make sure you balance charge as well as mass.
(f) Hydrogen peroxide can also act as a reducing agent, as in $Fe^{3+}(aq) + H_2O_2(aq) + OH^-(aq) \longrightarrow Fe^{2+}(aq) + H_2O(l) + O_2(g)$. Balance the equation and determine what mass of iron(III) can be reduced to iron(II) by 35.6 mL of 0.200 M $H_2O_2(aq)$. *Hint:* Make sure you balance charge as well as mass.
(g) Hydrogen peroxide must be kept in brown bottles because in the presence of light it can *disproportionate,* which means that it oxidizes and reduces itself in the reaction $2\,H_2O_2(aq) \longrightarrow 2\,H_2O(l) + O_2(g)$. How many electrons are transferred in the reaction represented by this equation?
(h) Although peroxides do not generate hazardous waste, they can cause problems in the atmosphere. If it makes its way to the stratosphere, a hydrogen peroxide molecule can break into two OH radicals, which threaten the ozone layer that protects Earth from harmful radiation. Use data in Table 2.4 to calculate the minimum frequency and corresponding wavelength of light needed to break the HO—OH bond.

All the colors of the vegetation around us arise from the selective absorption and reflection of visible light. If our eyes were sensitive to ultraviolet radiation—the electromagnetic radiation at shorter wavelengths (higher frequencies) than violet light—we would see an even richer tapestry of color, because substances also absorb and reflect selectively in the ultraviolet region. Honeybees do have this ability, and they can "see" radiation in the ultraviolet as well as in the visible range. The selective absorption and transmittance of visible light and ultraviolet radiation are the basis of a spectroscopic technique for identifying compounds and for determining their concentrations in samples.

The Technique

When electromagnetic radiation falls on a molecule, the electrons in the molecule can be excited to a higher energy state. Radiation of frequency ν (nu) can raise the energy of the molecule by an amount ΔE,

$$\Delta E = h\nu \qquad (1)$$

where h is Planck's constant. This equation is the *Bohr frequency condition* (Section 1.4). Provided that an empty orbital exists at the right energy, the incoming radiation can excite an electron into it and hence be absorbed. For typical ultraviolet wavelengths (of 300 nm and less, corresponding to a frequency of about 10^{15} Hz), each photon brings enough energy to excite the electrons in a molecule into a different distribution. Therefore, the study of visible and ultraviolet absorption gives us information about the electronic energy levels of molecules.

Visible and ultraviolet absorption spectra are measured in an absorption spectrometer. The source gives out intense visible light or ultraviolet radiation. The wavelengths can be selected with a glass prism for visible light and with a quartz prism or a diffraction grating for ultraviolet radiation (which is absorbed by glass). A typical absorption spectrum, that of chlorophyll, is shown in Fig. 1. Note that chlorophyll absorbs red and blue light, leaving the green light present in white light to be reflected. That is why most vegetation looks green. The spectrum can help us to assess the absorption quantitatively and to make a precise analysis of the energy-capturing power of the molecule.

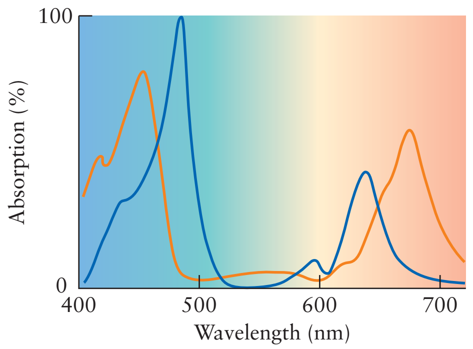


FIGURE 1 The optical absorption spectrum of chlorophyll as a plot of percentage absorption against wavelength. Chlorophyll *a* is shown in red, chlorophyll *b* in blue.

Chromophores

The presence of certain absorption bands in visible and ultraviolet spectra can often be traced to the presence of characteristic groups of atoms in the molecules. These groups of atoms are called *chromophores,* from the Greek words for "color bringer."

An important chromophore is a carbon–carbon double bond. The electronic transition that takes place when energy is absorbed is the excitation of an electron from a bonding π-orbital to the corresponding antibonding orbital, π^*. This transition is therefore known as a *π-to-π^* (pi to pi star) transition* (Fig. 2); it occurs at about 160 nm, which is in the ultraviolet region. The transition can be brought into the visible region by decreasing the separation between bonding and antibonding orbitals. These orbitals lie close in energy when the molecule has a long chain of alternating single and double bonds. Such "conjugated" double bonding occurs in the compound carotene (see structure **47** in Chapter 3), which is partly responsible for the color of carrots, mangoes, and persimmons. Related compounds account for the colors of shrimp and flamingoes. This transition is also responsible for the primary act of vision, as explained in Section 3.7.

Another important chromophore is the carbonyl group, >C=O, which absorbs at about 280 nm. The transition responsible for the absorption is the excitation of a lone-pair electron on the oxygen atom (a "nonbonding" electron, denoted n) into the empty antibonding π^*-orbital of the C=O double bond (Fig. 3). This transition is therefore called an *n-to-π^* (n to pi star) transition.*

A d-metal ion may also be responsible for color, as is apparent from the varied colors of many d-metal complexes (see

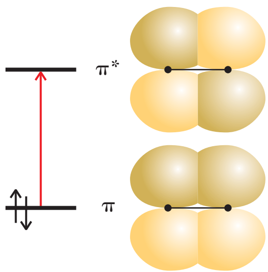

FIGURE 2 In a π-to-π^* transition, an electron in a bonding π-orbital is excited into an empty antibonding π^*-orbital.

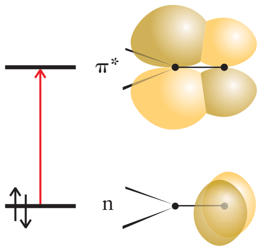

FIGURE 3 In an n-to-π^* transition of a carbonyl group, an electron in a nonbonding orbital (one localized wholly on the oxygen atom) is excited into an antibonding π^*-orbital spread over both atoms.

Chapter 16). Two types of transitions may be involved. In one, which is called a *d-to-d transition*, an electron is excited from a d-orbital of one energy to a d-orbital of higher energy. Because the energy differences between d-orbitals are quite small, visible light brings enough energy to cause this excitation, and so colors are absorbed from white light and the sample takes on colors complementary to those absorbed (Fig. 4). In a second type of transition involving d-orbitals, called a *charge-transfer transition*, electrons migrate from the atoms attached to the central metal atom into the latter's d-orbitals or vice versa. This transfer of charge can result in very intense absorption; it is responsible, for instance, for the deep purple of permanganate ions, MnO_4^-.

4.11 The Maxwell Distribution of Speeds
REAL GASES
4.12 Deviations from Ideality
4.13 The Liquefaction of Gases
4.14 Equations of State of Real Gases

What Are the Key Ideas? We can predict the physical properties of any gas by using the set of equations known as "the gas laws." These equations can be explained in terms of a model of a gas in which the molecules are in ceaseless random motion and so widely separated that they do not interact with one another except during brief collisions.

Why Do We Need to Know This Material? In the first three chapters, we investigated the nature of atoms, molecules, and ions. Bulk matter is composed of immense numbers of these particles and its properties emerge from the behavior of the constituent particles. Gases are the simplest state of matter, and so the connections between the properties of individual molecules and those of bulk matter are relatively easy to identify. In later chapters, these concepts will be used to study thermodynamics, equilibrium, and the rates of chemical reactions.

What Do We Need to Know Already? We need to be familiar with SI units (Appendix 1B) and the concepts of force and energy (Section A). This chapter also extends the techniques of reaction stoichiometry (Sections L and M) to gases.

The most important gas on the planet is the atmosphere, a thin layer of gas held by gravity to the surface of the Earth. Half the mass of the atmosphere lies below an altitude of 5.5 km. If we were to look from a point where the Earth appears to be the size of a basketball, the atmosphere would appear to be only 1 mm thick (Fig. 4.1). Yet this delicate layer is vital to life: it shields us from harmful radiation and supplies substances needed for life, such as oxygen, nitrogen, carbon dioxide, and water.

Eleven elements are gases under normal conditions (Fig. 4.2). So are many compounds with low molar masses, such as carbon dioxide, hydrogen chloride, and organic compounds such as the methane, CH_4, of natural gas and the propane, C_3H_8, of camping fuel. All substances that are gases at ordinary temperatures are molecular, except the six noble gases, which are monatomic (consist of single atoms).

FIGURE 4.1 The delicate film of the Earth's atmosphere as seen from space.

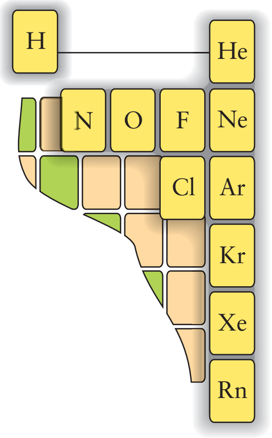

FIGURE 4.2 The 11 elements that are gases under normal conditions. Note how they lie toward the upper right of the periodic table.

In this chapter, we follow a typical scientific path. First, we collect experimental observations on the properties of gases and summarize these observations mathematically. We then formulate a simple qualitative molecular model of a gas suggested by these observations and go on to express it quantitatively. Finally, we use more detailed experimental observations to refine the model so that it accounts for the properties of real gases.

THE NATURE OF GASES

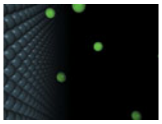
A remarkable characteristic of gases is that many of their physical properties are very similar, particularly at low pressures, regardless of the identity of the gas. Therefore, instead of having to describe the properties of each gas individually, we can describe them all simultaneously.

4.1 Observing Gases

Samples of gases large enough to study are examples of **bulk matter,** forms of matter that consist of large numbers of molecules. The properties of a gas sample emerge from the collective behavior of vast numbers of its individual particles. For example, when we push on a bicycle pump, we see that air is **compressible**—that is, it can be confined into a smaller volume. The act of reducing the volume of a sample of gas is called **compression.** The observation that gases are more compressible than solids and liquids suggests that there is a lot of space between the molecules of gases. We also know from everyday experience—by releasing air from an inflated balloon, for instance—that a gas expands rapidly to fill the space available to it. This observation suggests that the molecules are always moving rapidly and hence can respond quickly to changes in the volume available to them. Because the pressure in a balloon is the same in all directions, we can infer that the motion of the molecules is chaotic, not favoring any single direction. Our first primitive picture of a gas could therefore be as a collection of widely spaced molecules hurtling past each other in ceaseless rapid chaotic motion and changing speed and direction only when they happen to collide. We shall use more quantitative observations to refine this simple model as we proceed through the chapter.

The fact that gases are readily compressible and immediately fill the space available to them suggests that molecules of gases are widely separated and in ceaseless chaotic motion.

4.2 Pressure



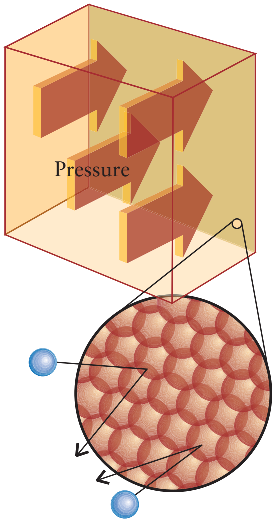


FIGURE 4.3 The pressure of a gas arises from the collisions that its molecules make with the walls of the container. The storm of collisions, shown in the inset, exerts an almost steady force on the walls.

Animation 4.3

If you have ever pumped up a bicycle tire or squeezed an inflated balloon, you have experienced an opposing force arising from the confined air. The **pressure,** P, of a gas is the force, F, exerted by the gas, divided by the area, A, on which the force is exerted:

$$P = \frac{F}{A} \quad (1)$$

The SI unit of pressure is the **pascal,** Pa:

$$1\ \text{Pa} = 1\ \text{kg·m}^{-1}\text{·s}^{-2}$$

A pascal is a rather small unit of pressure: the atmosphere exerts about 100 000 Pa (100 kPa) at sea level; 1 Pa is the pressure that would be exerted by a layer of water only 0.1 mm thick. In terms of the model that we are developing, the pressure that a gas exerts on the walls of its container results from the collisions of its molecules with the container's surface (Fig. 4.3). The more vigorous the storm of molecules on a surface, the stronger the force and hence the higher the pressure. Any object on the surface of the Earth stands in an invisible storm of molecules that beat on it incessantly and exert a force all over its surface. Even on an apparently calm day, we are in the midst of a molecular storm.

The pressure exerted by the atmosphere can be measured by various means, most commonly by using a pressure gauge. When we measure the pressure of air in a tire with a pressure gauge, we are actually measuring the "gauge pressure," the difference

between the pressure inside the tire and the atmospheric pressure. A flat tire registers a gauge pressure of zero, because the pressure inside the tire is the same as the pressure of the atmosphere. A laboratory pressure gauge attached to a piece of scientific apparatus, however, measures the *actual* pressure in the apparatus.

The pressure of the atmosphere can be measured with a **barometer,** an instrument invented in the seventeenth century by the Italian scientist Evangelista Torricelli, a student of Galileo. Torricelli (whose name coincidentally means "little tower" in Italian) formed a little tower of liquid mercury. He sealed a long glass tube at one end, filled it with mercury, and inverted it into an open container (Fig. 4.4). The column of mercury fell until the pressure that it exerted at its base matched the pressure exerted by the atmosphere. To interpret measurements with a barometer, we need to find how the height of the column of mercury depends on the atmospheric pressure.

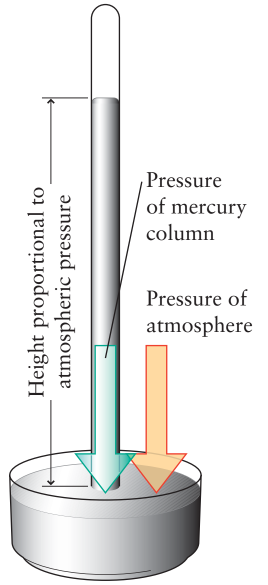

FIGURE 4.4 A barometer is used to measure the pressure of the atmosphere. The pressure of the atmosphere is balanced by the pressure exerted by the column of mercury, which falls to the appropriate height, leaving a vacuum above it. The height of the column is proportional to the atmospheric pressure.

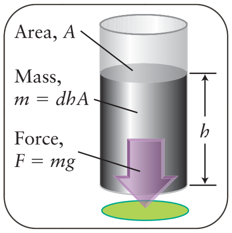
HOW DO WE DO THAT?

We want to find the relation between the height, h, of the column of mercury in a barometer and the atmospheric pressure, P. Suppose the cross-sectional area of the cylindrical column is A. The volume of mercury in the column is the height of the cylinder times this area, $V = hA$. The mass, m, of this volume of mercury is the product of mercury's density, d, and the volume; so $m = dV = dhA$. The mercury is pulled down by the force of gravity; and the total force that its mass exerts at its base is the product of the mass and the acceleration of free fall (the acceleration due to gravity), g: $F = mg$. Therefore, the pressure at the base of the column, the force divided by the area, is

From $P = F/A$ and $F = mg$:

$$P = \frac{\overbrace{F}^{mg}}{A} = \frac{mg}{A} = \frac{\overbrace{dhA}^{m}\,g}{A} = dhg$$



This equation shows that the pressure, P, exerted by a column of mercury is proportional to the height of the column. Mercury inside a tube sealed at one end and inverted in a pool of mercury will fall until the pressure exerted by the mercury balances the atmospheric pressure. Therefore, the height of the column can be used as a measure of atmospheric pressure.

We have shown that the pressure of a gas can be related to the height h of a column of liquid and its density d by

$$P = dhg \qquad (2)$$

where g is the acceleration of free fall. The pressure is obtained in pascals when the density, height, and value of g are expressed in SI units.

Thinking point: Could you use a mercury barometer to measure pressure on a space station?

EXAMPLE 4.1 Calculating atmospheric pressure from the height of a column of mercury

Suppose the height of the column of mercury in a barometer is 760. mm at 15°C. What is the atmospheric pressure in pascals? At 15°C the density of mercury is 13.595 $g{\cdot}cm^{-3}$ (corresponding to 13 595 $kg{\cdot}m^{-3}$) and the standard acceleration of free fall at the surface of the Earth is 9.806 65 $m{\cdot}s^{-2}$.

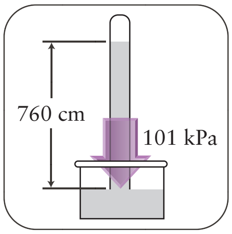
Anticipate We have remarked that atmospheric pressure is close to 100 kPa, so expect a value close to that figure.

PLAN We use Eq. 2: in this case, all we need to do is to use the data and recognize that 1 $kg{\cdot}m^{-1}{\cdot}s^{-2}$ = 1 Pa.

SOLVE

From $P = dhg$,

$$P = (13\,595\ \text{kg}\cdot\text{m}^{-3}) \times (0.760\ \text{m}) \times (9.806\,65\ \text{m}\cdot\text{s}^{-2})$$
$$= 1.01 \times 10^5\ \text{kg}\cdot\text{m}^{-1}\cdot\text{s}^{-2} = 1.01 \times 10^5\ \text{Pa}$$



Evaluate This pressure can also be reported as 101 kPa, where 1 kPa = 10^3 Pa. This value is close to the anticipated value. The acceleration of free fall varies over the surface of the Earth and depends on the altitude; however, in all calculations in this text, we assume that g has the "standard" value used here.

Self-Test 4.1A What is the atmospheric pressure in kilopascals when the height of the mercury column in a barometer at 15°C is 756 mm?

[***Answer:*** 100. kPa]

Self-Test 4.1B The density of water at 20°C is 0.998 g·cm^{-3}. What height would the column of liquid be in a water barometer at 20°C when the atmospheric pressure corresponds to 760. mm of mercury?

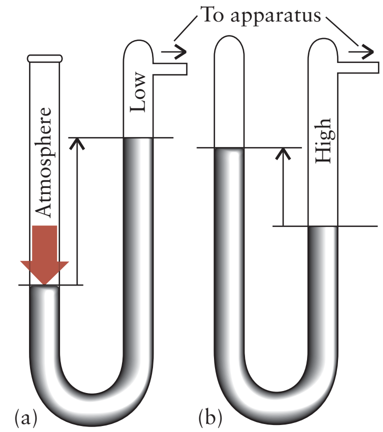


FIGURE 4.5 (a) An open-tube manometer. The pressure inside the apparatus to which the narrow horizontal tube is connected pushes against the external pressure. In this instance, the pressure inside the system is lower than the atmospheric pressure by an amount proportional to the difference in heights of the liquid in the two arms. (b) A closed-tube manometer. The pressure in the adjoining apparatus is proportional to the difference in heights of the liquid in the two arms. The space inside the closed end is a vacuum.

Although an electronic pressure gauge is more commonly used to measure the pressure inside a laboratory vessel, a **manometer** is sometimes used (Fig. 4.5). It consists of a U-shaped tube connected to the experimental system. The other end of the tube may be either open to the atmosphere or sealed. For an open-tube manometer (like that shown in Fig. 4.5a), the pressure in the system is equal to that of the atmosphere when the levels of the liquid in each arm of the U-tube are the same. If the level of mercury on the system side of an open manometer is above that of the atmosphere side, the pressure in the system is lower than the atmospheric pressure. In a closed-tube manometer (like that shown in Fig. 4.5b), one side is connected to a closed flask (the system) and the other side is vacuum. The difference in heights of the two columns is proportional to the pressure in the system.

Self-Test 4.2A What is the pressure in kilopascals in a system when the mercury level in the system-side column in an open-tube mercury manometer is 25 mm lower than the mercury level in the atmosphere-side column and the atmospheric pressure corresponds to 760. mm of mercury at 15°C?

[***Answer:*** 105 kPa]

Self-Test 4.2B What is the pressure in pascals inside a system when a *closed* mercury manometer shows a height difference of 10. cm at 15°C?

The pressure of a gas, the force that it exerts divided by the area subjected to the force, arises from the impacts of its molecules.

4.3 Alternative Units of Pressure

Although the SI unit of pressure is the pascal (Pa), there are several other units in common use. Normal atmospheric pressure is close to 100 kPa, and it is useful to have a unit, the **bar,** for exactly 100 kPa:

$$1\ \text{bar} = 10^5\ \text{Pa}$$

Weather charts commonly report pressures in millibars (1 mbar = 10^{-3} bar = 10^2 Pa), with typical atmospheric pressures close to 1000 mbar.

The **standard pressure** for reporting data is now defined as 1 bar exactly and denoted $P°$. However, it had long been conventional to report data in terms of a pressure

corresponding to 760 mm of mercury (written 760 mmHg), corresponding to just over 101 kPa. This convention inspired the use of the unit the **atmosphere** (atm), which is now defined by the exact relation

$$1 \text{ atm} = 1.013\,25 \times 10^5 \text{ Pa}$$

Note that 1 atm = 1.013 25 bar, and so 1 atm is slightly greater than 1 bar.

The unit **millimeter of mercury** (mmHg) is defined in terms of the pressure exerted by a column of mercury 1 mm high under certain conditions (15°C and in a standard gravitational field), but it has now been largely displaced by a unit of similar magnitude, the **torr** (Torr). This unit is defined by the exact relation

$$760 \text{ Torr} = 1 \text{ atm}$$

It is normally safe to use the units mmHg and Torr interchangeably, but in very precise work you should note that they are not exactly the same (they differ by less than 1 part in a million).

A note on good practice: The name of the unit torr, like all names derived from the names of people, has a lowercase initial letter; likewise, the symbol for the unit, like all symbols derived from proper names, has an uppercase initial letter (Torr).

Pressure units are summarized in Table 4.1. It is important to be familiar with them and to be able to make conversions between them. For example, a pressure of 746 Torr is converted into a pressure in pascals by using a conversion factor derived from Table 4.1:

$$P = 746 \text{ Torr} \times \frac{133.322 \text{ Pa}}{1 \text{ Torr}} = 9.95 \times \overbrace{10^4 \text{ Pa}}^{10 \text{ kPa}} \quad \text{or} \quad 99.5 \text{ kPa}$$

The actual pressure exerted by the atmosphere varies with altitude and weather. The pressure of the atmosphere at the cruising height of a commercial jetliner (10 km) is only about 200 Torr (about 0.3 atm), and so airplane cabins must be pressurized. A very low pressure atmospheric region, such as an area of low pressure on the weather chart in Fig. 4.6, typically has a pressure of about 0.98 atm at sea level. A typical region of high pressure is about 1.03 atm.

TABLE 4.1 Pressure Units*

SI unit: pascal (Pa)	
1 Pa = 1 $\text{kg·m}^{-1}\text{·s}^{-2}$ = 1 N·m^{-2}	
Conventional units	
1 bar = 10^5 Pa = **100** kPa	
1 atm = **1.013 25** × **10**^{5} Pa	
= **101.325** kPa	
1 atm = **760** Torr	
1 Torr (1 mmHg) = 133.322 Pa	
1 atm = 14.7 lb·inch^{-2} (psi)	

*Figures in **bold** are exact. See inside back cover for more relations. N, newton. Note that 1 mmHg is the same as 1 Torr to within 1 part in 10^7.

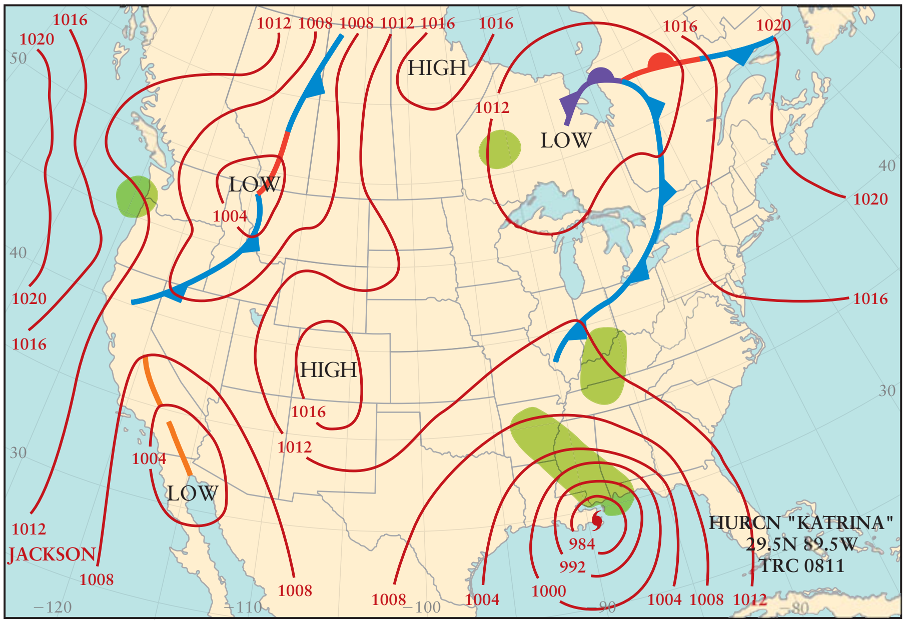

FIGURE 4.6 A weather map showing North America during Hurricane Katrina in 2005. The curves are called isobars and are contours of constant atmospheric pressure. Regions of low pressure (seen over southern Louisiana) are called cyclones and regions of high pressure (seen over Canada) are called anticyclones. All pressures are in millibars. The lowest pressure on the map is 984 mbar, at the center of the hurricane. Before making landfall, the pressure at the center of the hurricane had fallen to as low as 902 mbar.

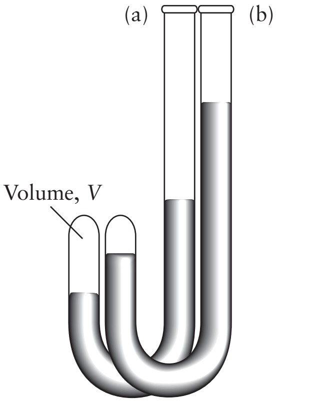

FIGURE 4.7 (a) In Boyle's experiment, a gas was trapped by mercury inside the closed end of a J-shaped tube. (b) The volume of the trapped gas decreased as the pressure on it was increased by adding more mercury to the open end of the tube.

Self-Test 4.3A The U.S. National Hurricane Center reported that the pressure in the eye of Hurricane Katrina (2005) fell as low as 902 mbar. What is that pressure in atmospheres?

[***Answer:*** 0.890 atm]

Self-Test 4.3B The atmospheric pressure in Denver, Colorado, on a certain day was 630. Torr. Express this pressure in pascals.

The principal units for reporting pressure are torr, atmosphere, and (the SI unit) pascal. Pressure units can be interconverted by using the information in Table 4.1.

THE GAS LAWS

Summaries of the properties of gases, particularly the variation of pressure with volume and temperature, are known as the "gas laws." The first reliable measurements of the properties of gases were made by the Anglo-Irish scientist Robert Boyle in 1662 when he examined the effect of pressure on volume. A century and a half later, a new pastime, hot-air ballooning, motivated two French scientists, Jacques Charles and Joseph-Louis Gay-Lussac, to formulate additional gas laws. They measured how the temperature of a gas affects its pressure, volume, and density. The Italian scientist Amedeo Avogadro made a further contribution that established the relation between the volume and the amount of molecules in the sample and thereby helped to establish belief in the reality of atoms.

4.4 The Experimental Observations

Boyle took a long tube of glass curved into a J-shape, with the short end sealed (Fig. 4.7). He then poured mercury into the tube, trapping air in the short end of the J. The more mercury he added, the more the air was compressed. He concluded that at constant temperature the volume of a fixed amount of gas (the air in this case) decreases as the pressure on it increases. Figure 4.8 shows a graph of the dependence. The curve shown there is called an **isotherm,** which is a general term for a constant-temperature plot. An **isothermal change** is one that takes place at constant temperature. Scientists often look for ways of plotting experimental data in a manner that gives straight lines, because such graphs are easier to identify, analyze, and interpret. Boyle's data give a straight line when we plot the pressure against 1/volume (Fig. 4.9). This result implies

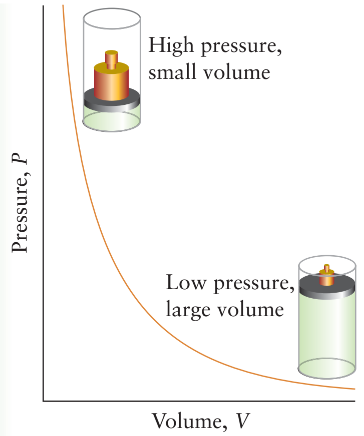

FIGURE 4.8 Boyle's law summarizes the effect of pressure on the volume of a fixed amount of gas at constant temperature. As the pressure of a gas sample is increased (as depicted by the increasing size of the weight pressing on the piston), the volume of the gas decreases.

Living Graph 4.8

Boyle's law: For a fixed amount of gas at constant temperature, volume is inversely proportional to pressure.

Boyle's law is written

$$\text{Volume} \propto \frac{1}{\text{pressure}} \quad \text{or, more simply,} \quad V = \frac{\text{constant}}{P}$$

or equivalently

$$PV = \text{constant (at constant } n \text{ and } T) \qquad \textbf{(3a)}$$

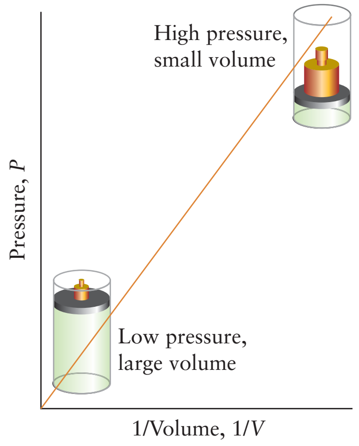

FIGURE 4.9 When the pressure is plotted against 1/volume, a straight line is obtained. Boyle's law breaks down at high pressures, and a straight line is not obtained in these regions (not shown).

Suppose the pressure and volume of a fixed amount of gas at the start of an experiment are P_1 and V_1, then at the start P_1V_1 = constant. At the end of the experiment the pressure and volume have become P_2 and V_2, but P_2V_2 is equal to the same constant (provided the temperature has not changed). It follows that we can write

$$P_2V_2 = P_1V_1 \qquad \text{(3b)}$$

for this isothermal change.

Self-Test 4.4A A sample of neon of volume 10.0 L at 300. Torr is allowed to expand isothermally into an evacuated tube with a volume of 20.0 L. What is the final pressure of the neon in the tube?

[*Answer:* 150. Torr]

Self-Test 4.4B In a petroleum refinery a 750.-L container containing ethylene gas at 1.00 bar was compressed isothermally to 5.00 bar. What was the final volume of the container?

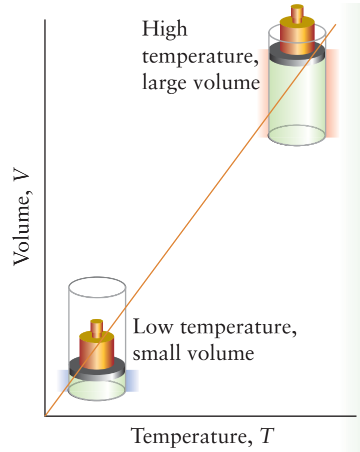

FIGURE 4.10 When the temperature a gas is increased and its volume is free to change at constant pressure (as depicted by the constant weight acting on the piston), the volume increases. A graph of volume against temperature is a straight line.

Living Graph 4.10

Charles and Gay-Lussac carried out a number of experiments with the hope of improving the performance of their balloons. They found that, provided the pressure is kept constant, the volume of a gas increases as its temperature is raised. In this case, a straight-line graph is obtained when the volume is plotted against the temperature (Fig. 4.10). This result implies

Charles's law: For a fixed amount of gas under constant pressure, the volume varies linearly with the temperature.

Gay-Lussac's name is sometimes associated with the law, but "Charles's law" is now more common.

Charles's law has a very important implication. When the straight lines obtained by plotting volume against temperature for different gases and at various pressures are extrapolated (that is, extended beyond the range of the data), it is found that they all reach zero volume at −273.15°C (Fig. 4.11). This point cannot be reached in practice, because no real gas has zero volume and all real gases condense to a liquid before such low temperatures are reached. Because a volume cannot be negative, −273.15°C must be the lowest possible temperature. It is the value corresponding to zero on the Kelvin scale. It follows that, if we use the absolute temperature, T, then we can write Charles's law as

The Kelvin scale of absolute temperatures is described in Appendix 1B: the temperature in kelvins (K) is obtained by adding 273.15 to the temperature in degrees Celsius (°C).

$$\text{Volume} \propto \text{absolute temperature} \quad \text{or, more simply,} \quad V = \text{constant} \times T \qquad \text{(4a)}$$

A similar expression summarizes the linear variation in pressure of a sample of gas when it is heated in a container of fixed volume. The pressure is found experimentally to extrapolate to zero pressure at −273.15°C (Fig. 4.12). Therefore, as Gay-Lussac was able to show

$$\text{Pressure} \propto \text{absolute temperature} \quad \text{or, more simply,} \quad P = \text{constant} \times T \qquad \text{(4b)}$$

It follows that doubling the absolute temperature doubles the pressure of a gas, provided the amount and volume are constant.

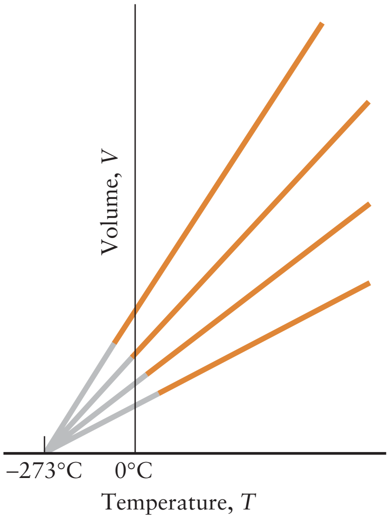

FIGURE 4.11 The extrapolation of data like those in Fig. 4.10 for a number of gases suggests that the volume of each gas should become 0 at T = 0 (−273°C). Extrapolated data are shown in gray. In practice, all gases condense to liquids before that temperature is reached.

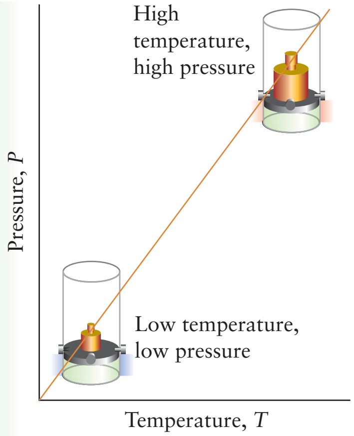

FIGURE 4.12 The pressure of a fixed amount of gas in a vessel of constant volume is proportional to the absolute temperature. Notice the increase in the pressure on the cylinder (represented by the increasing mass of the weight on the piston) as the temperature increases. The pressure extrapolates to 0 at $T = 0$.

Living Graph 4.12

Avogadro's principle is not a law because it is based not on observation alone but also on a model of matter—namely that matter consists of molecules. Even though there is no longer any doubt that matter consists of atoms and molecules, it remains a principle rather than a law.

A note on good practice: Note that the volume (or the pressure) doubles when the temperature is doubled on the *absolute* (Kelvin) scale, not when it is doubled on the Celsius scale. An increase from 20°C to 40°C corresponds to an increase from 293 K to 313 K, an increase of only 7%.

Self-Test 4.5A A rigid oxygen tank stored outside a building has a pressure of 20.00 atm at 6:00 am, when the temperature is 10.°C. What will be the pressure in the tank at 6:00 pm, when the temperature is 30.°C?

[*Answer:* 21.4 atm]

Self-Test 4.5B A sample of hydrogen gas at 760. mmHg and 20.°C is heated to 300.°C in a container of constant volume. What is the final pressure of the sample?

A further contribution was made by the Italian scientist Amedeo Avogadro:

> **Avogadro's principle:** Under the same conditions of temperature and pressure, a given number of gas molecules occupy the same volume regardless of their chemical identity.

Avogadro's principle is commonly expressed in the terms of the **molar volume,** V_m, the volume occupied per mole of molecules:

$$\text{Molar volume} = \frac{\text{volume}}{\text{amount}} \quad \text{or, more simply,} \quad V_m = \frac{V}{n} \tag{5a}$$

for then we can write

$$V = nV_m \tag{5b}$$

The molar volume of gases are all close to 22 L·mol^{-1} at 0°C and 1 atm (Fig. 4.13).

Self-Test 4.6A A helium weather balloon was filled at −20.°C and a certain pressure to a volume of 2.5×10^4 L with 1.2×10^3 mol He. What is the molar volume of helium under those conditions?

[*Answer:* 21 L·mol^{-1}]

Self-Test 4.6B A large natural gas storage tank contains 200. mol CH_4(g) at 1.20 atm. An additional 100. mol CH_4(g) is pumped into the tank at constant temperature. What is the final pressure in the tank?

Each of the properties we have summarized is consistent with our molecular model of a gas as widely spaced molecules in ceaseless motion. Boyle's law is consistent with this model because compression increases the number of molecules in a given region of the sample and hence increases the number of collisions that the molecules make with the walls. As a result, the pressure they exert increases (Fig. 4.14). The effect of temperature on the pressure of a gas in a constant-volume container suggests a new feature: *as the temperature of a gas is raised, the average speed of the molecules increases*. As a result of this increase in average speed, each molecule strikes the walls more often and with greater force. Therefore, the gas exerts a greater pressure as the temperature is increased at

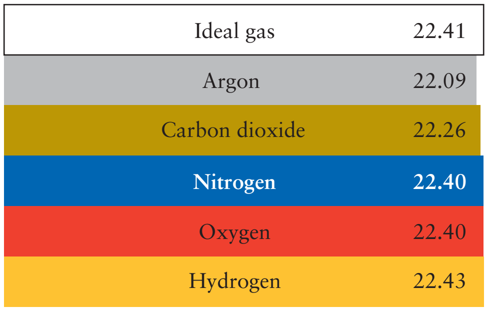

FIGURE 4.13 The molar volumes (in liters per mole) of various gases at 0°C and 1 atm. The values are all very similar and close to the molar volume of an ideal gas under these conditions, 22.41 L·mol^{-1} (Section 4.5).

constant volume. We can use this same model of a gas to explain the effect of temperature on the volume when the pressure is held constant. To counteract the increase in pressure as the temperature is raised, the space available to the gas must increase so that fewer molecules are available to strike the walls in a given time interval. Finally, Avogadro's principle is consistent with the model because, in order to keep the pressure constant as more molecules are added to a container, the size of the container must increase.

The three properties of a gas expressed by Eqs. 3, 4, and 5 can all be combined into a single expression relating pressure (P), volume (V), temperature (T), and amount (n) of a gas:

$$PV = \text{constant} \times nT$$

Thus, if the temperature and amount are constant, PV is a constant (Boyle's law), if the amount and pressure are constant, V is proportional to T (Charles' law), and if the pressure and temperature are constant, the volume is proportional to n (Avogadro's principle). When the constant of proportionality for the laws is written as R, this expression becomes the **ideal gas law:**

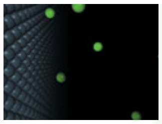
$$PV = nRT \qquad \textbf{(6)*}$$

The constant R is called the **gas constant** and has the same value for all gases; because R is independent of the identity of the gas, we say that it is a "universal constant." The value of the gas constant can be found by measuring P, V, n, and T and substituting their values into $R = PV/nT$. When we use SI units (pressure in pascals, volume in meters cubed, temperature in kelvins, and amount in moles), R is obtained in joules per kelvin per mole: $R = 8.314\ \text{J·K}^{-1}\text{·mol}^{-1}$. Table 4.2 lists the values of R when the volume and pressure are reported in other than SI units.

A note on good practice: To avoid overwhelming you with data we usually quote the values of fundamental constants to three decimal places. In actual calculations you should use the more precise values given in tables, including those inside the back cover.

The ideal gas law is an example of an **equation of state**, an expression showing how the pressure of a substance—in this case, a gas—is related to its temperature, volume, and amount of substance. A hypothetical gas that obeys the ideal gas law under all conditions is called an **ideal gas.** All real gases are found to obey Eq. 6 with increasing accuracy as the pressure is reduced toward zero (which we write $P \longrightarrow 0$). Therefore, the ideal gas law is an example of a **limiting law,** a law that is strictly valid only in some limit—in this case, as $P \longrightarrow 0$. Although the ideal gas law is a limiting law, it is in fact reasonably reliable at normal pressures, and so we can use it to describe the behavior of most gases under normal conditions.

The ideal gas law, PV = nRT, is an equation of state that summarizes the relations describing the response of an ideal gas to changes in pressure, volume, temperature, and amount of molecules; it is an example of a limiting law.



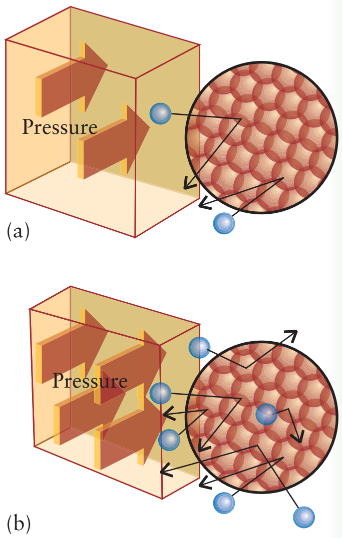


FIGURE 4.14 (a) The pressure of a gas arises from the impact of its molecules on the walls of the container. (b) When the volume of the sample is decreased, there are more molecules in a given volume and so there are more collisions with the same area of the wall in a given time interval. Because the impact on the walls is now greater, so is the pressure.

Animation 4.14

TABLE 4.2	**The Gas Constant, *R***
$8.205\,74 \times 10^{-2}$ L·atm·K^{-1}·mol^{-1}	
$8.314\,47 \times 10^{-2}$ L·bar·K^{-1}·mol^{-1}	
8.314 47 L·kPa·K^{-1}·mol^{-1}	
8.314 47 J·K^{-1}·mol^{-1}

4.5 Applications of the Ideal Gas Law

We have seen how to use the individual laws to make predictions when only one variable is changed, such as heating a fixed amount of gas at constant volume. The ideal gas law enables us to make predictions when two or more variables are changed.

To do such calculations, we note that, if the initial conditions of a gas are n_1, P_1, V_1, and T_1, then from Eq. 6 we can write $P_1V_1 = n_1RT_1$, or $P_1V_1/n_1T_1 = R$. After the change, the conditions become n_2, P_2, V_2, and T_2; and, because the ideal gas law still applies, we know that $P_2V_2/n_2T_2 = R$. Because R is a constant, we can equate P_1V_1/n_1T_1 and P_2V_2/n_2T_2 and hence obtain

$$\frac{P_1V_1}{n_1T_1} = \frac{P_2V_2}{n_2T_2} \qquad \textbf{(7)*}$$

This expression is called the **combined gas law.** However, it is a direct consequence of the ideal gas law and is not a new law.

TOOLBOX 4.1 HOW TO USE THE IDEAL GAS LAW

CONCEPTUAL BASIS

The ideal gas law, Eq. 6 ($PV = nRT$), summarizes the observation that the pressure is inversely proportional to the volume and directly proportional to the amount of gas and the absolute temperature. It can be used for real gases at low pressures.

PROCEDURE

To calculate the pressure, volume, or temperature of a given sample

Step 1 Express the temperatures in kelvins and the amount in moles.

Step 2 To use Eq. 6, rearrange the equation $PV = nRT$ to give the desired quantity on the left and all other quantities on the right (such as $P = nRT/V$).

Step 3 Substitute the data, if necessary converting from mass of gas to the amount in moles. Select the value of R from Table 4.2 that matches the units of pressure and volume you need to use. Alternatively, convert the pressure units to match the value of R you prefer to use.

The procedure is illustrated in Example 4.2.

To calculate the response of a gas to a change in conditions

The initial and final conditions for a gas undergoing a change are related by Eq. 7 ($P_1V_1/n_1T_1 = P_2V_2/n_2T_2$). To use this relation:

Step 1 Rearrange the relation so that the quantity required is on the left and all other quantities are on the right. Cancel any quantities that are unchanged and, if necessary, express the temperatures in kelvins.

Step 2 Substitute the data and check to see whether the answer agrees with your predictions.

The procedure is illustrated in Examples 4.3 and 4.4.

EXAMPLE 4.2 Calculating the pressure of a given sample

In a cathode-ray tube, which until recently was widely used in TV sets and computer monitors, the beam of electrons is directed toward a screen that emits light where they strike it. Have you ever wondered what the pressure is inside the tube? Estimate the pressure (in atmospheres), given that the volume of the tube is 5.0 L, its temperature is 23°C, and it contains 0.10 µg of nitrogen gas.

Anticipate We should suspect that the pressure will be very low, for any collisions between the electron beam and the gas molecules would blur the picture.

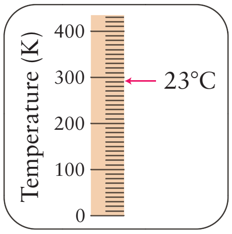
PLAN Convert mass into amount of N_2 and convert the temperature into kelvins; then proceed as in Toolbox 4.1.

SOLVE

Step 1 Convert mass to amount ($n = m/M$) and temperature from degrees Celsius to kelvins by adding 273.15.

$$n = \frac{\overbrace{1.0 \times 10^{-7}\,\text{g}}^{0.10\ \mu\text{g}}}{28.02\ \text{g}\cdot\text{mol}^{-1}} = \frac{1.0 \times 10^{-7}}{28.02}\ \text{mol}$$

$$T = (23 + 273.15)\ \text{K} = 296\ \text{K}$$

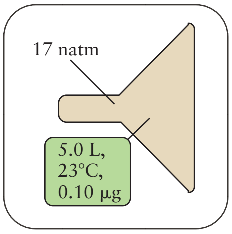


Step 2 From $PV = nRT$, $P = nRT/V$.

Step 3 Substitute the data, using R in L·atm·K^{-1}·mol^{-1}.

$$P = \left(\frac{1.0 \times 10^{-7}}{28.02}\ \text{mol}\right) \times \frac{(8.206 \times 10^{-2}\ \text{L}\cdot\text{atm}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}) \times (296\ \text{K})}{5.0\ \text{L}}$$

$$= 1.7 \times 10^{-8}\ \text{atm}$$



Evaluate The pressure of 1.7×10^{-8} atm corresponds to 1.7 mPa, a very low pressure, as we anticipated. Most CRTs were designed to operate close to this pressure.

Self-Test 4.7A Calculate the pressure (in kilopascals) exerted by 1.0 g of carbon dioxide in a flask of volume 1.0 L at 300.°C.

[***Answer:*** 1.1×10^2 kPa]

Self-Test 4.7B An idling, badly tuned automobile engine can release as much as 1.00 mol CO per minute into the atmosphere. At 27°C, what volume of CO, adjusted to 1.00 atm, is emitted per minute?

EXAMPLE 4.3 Using the combined gas law when one variable is changed

Assume that, when you press in the piston of a bicycle pump, the volume inside the pump is decreased from about 100. cm^3 to 20. cm^3 before the air flows into the tire. Suppose that the compression is isothermal; estimate the final pressure of the compressed air in the pump, given an initial pressure of 1.00 atm.

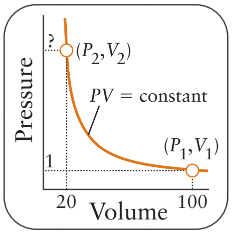
Anticipate The volume is reduced by a factor of 5, so we should expect a fivefold increase in pressure.

PLAN Follow the second procedure in Toolbox 4.1. Only the pressure and volume change, so all other variables cancel, resulting in Boyle's law.

SOLVE

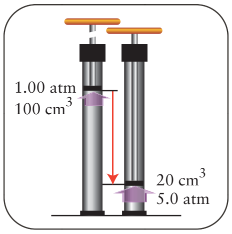
Step 1 Rearrange $P_1V_1/n_1T_1 = P_2V_2/n_2T_2$ to find P_2 by multiplying both sides by n_2T_2/V_2, and set $n_2 = n_1$ (no change in the amount) and $T_2 = T_1$ (no change in temperature):

$$P_2 = \frac{P_1V_1}{n_1T_1} \times \frac{n_2T_2}{V_2} \xrightarrow[T_2 = T_1]{n_2 = n_1} \frac{P_1V_1}{n_1T_1} \times \frac{n_1T_1}{V_2} = P_1 \times \frac{V_1}{V_2}$$



Step 2 Substitute the data:

$$P_2 = (1.00\text{ atm}) \times \frac{100\text{ cm}^3}{20\text{ cm}^3} = 5.0\text{ atm}$$



Evaluate The final pressure is higher by a factor of 5 (more precisely, 5.0), as expected.

Self-Test 4.8A A sample of argon gas of volume 10.0 mL at 200. Torr is allowed to expand isothermally into an evacuated tube with a volume of 0.200 L. What is the final pressure of the argon in the tube?

[***Answer:*** 10.0 Torr]

Self-Test 4.8B A sample of dry air in the cylinder of a test engine at 80. cm^3 and 1.00 atm is compressed isothermally to 3.20 atm by pushing a piston into the cylinder. What is the final volume of the sample?

EXAMPLE 4.4 Using the combined gas law when two variables are changed

In an investigation of the properties of the coolant gas used in an air-conditioning system, a sample of volume 500. mL at 28.0°C was found to exert a pressure of 92.0 kPa. What pressure will the sample exert when it is compressed to 300. mL and cooled to −5.0°C?

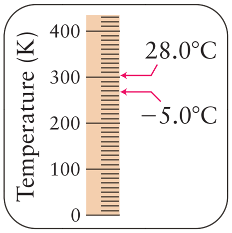
Anticipate Our problem is to judge whether the compression, which will increase the pressure, dominates the cooling, which will decrease the pressure. On the Kelvin scale, the change in temperature is quite small, so we should suspect that the compression will dominate.

PLAN Follow the procedure set out in Toolbox 4.1.

SOLVE

Step 1 Convert the temperatures into kelvins.

$$T_1 = (273.15 + 28.0)\text{ K} = 301.2\text{ K}$$
$$T_2 = (273.15 - 5.0)\text{ K} = 268.2\text{ K}$$

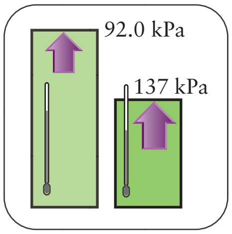


Step 2 Rearrange $P_1V_1/n_1T_1 = P_2V_2/n_2T_2$ to find P_2, as in Example 4.3, but only set $n_1 = n_2$.

$$P_2 = \frac{P_1V_1}{n_1T_1} \times \frac{n_2T_2}{V_2} \xrightarrow{n_2=n_1} P_1 \times \frac{V_1}{V_2} \times \frac{T_2}{T_1}$$

Step 3 Substitute the data:

$$P_2 = (92.0\text{ kPa}) \times \frac{500.\text{ mL}}{300.\text{ mL}} \times \frac{268.2\text{ K}}{301.2\text{ K}}$$
$$= 137\text{ kPa}$$



Evaluate The net outcome is an increase in pressure, so, in this instance, compression has a greater effect than cooling, as we suspected.

Self-Test 4.9A A parcel of air (the technical term in meteorology for a small region of the atmosphere) of volume 1.00×10^3 L at 20.°C and 1.00 atm rises up the side of a mountain range. At the summit, where the pressure is 0.750 atm, the parcel of air has cooled to −10.°C. What is the volume of the parcel at that point?

[***Answer:*** 1.20×10^3 L]

Self-Test 4.9B A weather balloon is filled with helium gas at 20.°C and 1.00 atm. The volume of the balloon is 250. L. When the balloon rises to a layer of air where the temperature is −30.°C, it has expanded to 800. L. What is the pressure of the atmosphere at that point?

The ideal gas law can also be used to predict the molar volume of an ideal gas under any conditions of temperature and pressure. To do so, we combine Eq. 5a ($V_m = V/n$) and Eq. 6 (as $V = nRT/P$) by writing

$$V_m = \frac{V}{n} = \frac{nRT/P}{n} = \frac{RT}{P} \qquad (8)$$

At **standard ambient temperature and pressure** (SATP), which means exactly 25°C (298.15 K) and exactly 1 bar, the conditions commonly used to report data in chemistry, the molar volume of an ideal gas is 24.79 $L\cdot mol^{-1}$, which is about the volume of a cube 1 ft on a side (Fig. 4.15). The common expression **standard temperature and pressure** (STP) means 0°C and 1 atm (both exactly), the conditions formerly used to report data and still widely used in some calculations. At STP, the molar volume of an ideal gas is 22.41 $L\cdot mol^{-1}$. Note the slightly smaller value: the temperature is lower and the pressure is slightly higher, and so the same amount of gas molecules occupies a smaller volume than at SATP.

Table 4.3 gives values of the molar volume of an ideal gas under a variety of common conditions. To obtain the volume of a known amount of gas at a specified temperature and pressure, we simply multiply the molar volume *at that temperature and pressure* by the amount in moles. Alternatively, we can use the ideal gas law to calculate the volume.

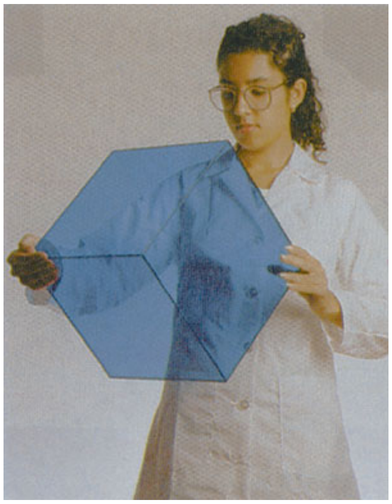


FIGURE 4.15 The blue cube is the volume (25 L) occupied by 1 mol of ideal gas molecules at 25°C and 1 bar.

TABLE 4.3 Molar Volume of an Ideal Gas

Temperature	Pressure	Molar volume ($L \cdot mol^{-1}$)
0 K	0	0
0°C	1 atm	22.4140
0°C	1 bar	22.7110
25°C	1 atm	24.4654
25°C	1 bar	24.7896

Self-Test 4.10A Calculate the volume occupied by 1.0 kg of hydrogen at 25°C and 1.0 atm.

[*Answer:* 1.2×10^4 L]

Self-Test 4.10B Calculate the volume occupied by 2.0 g of helium at 25°C and 1.0 atm.

The combined gas law describes how a gas responds to changes in conditions. Standard ambient temperature and pressure (SATP) are 25°C (298.15 K) and 1 bar; standard temperature and pressure (STP) are 0°C (273.15 K) and 1 atm.

4.6 Gas Density

As we saw in Section G, the molar concentration of any substance is the amount of molecules (n, in moles) divided by the volume that they occupy (V). It follows from the ideal gas law that, for a gas behaving ideally (so we can write $n = PV/RT$),

$$\text{Molar concentration} = \frac{\text{amount}}{\text{volume}} = \frac{n}{V} = \frac{PV/RT}{V} = \frac{P}{RT} \tag{9}$$

Thinking point: Should you be surprised that the molar concentration of a gas is the inverse of its molar volume?

This expression shows that, for a given pressure and temperature, the molar concentration should be the same for every gas. That is, two gas samples of equal volume at the same temperature and pressure should contain the same amount of gas molecules, regardless of the identities of the gases (this, of course, is just Avogadro's principle). However, if their molar masses are different, the gas samples will have different masses.

The density, d, of a gas, like that of any substance, is the mass of the sample divided by its volume, $d = m/V$. Because the densities of gases are so low, they are usually expressed in grams per liter ($g \cdot L^{-1}$). The density of air, for instance, is about 1.6 $g \cdot L^{-1}$ at SATP. Because the mass of the sample is equal to the amount in moles times the molar mass, $m = nM$, and $n = PV/RT$, it follows that

$$\text{Density} = \frac{\text{mass}}{\text{volume}} = \frac{m}{V} = \frac{nM}{V} = \frac{(PV/RT)M}{V} = \frac{MP}{RT} \tag{10}^*$$

We see that:

- For a given pressure and temperature, the greater the molar mass of the gas, the greater its density.
- At constant temperature, the density of a gas increases with pressure. In this case, the pressure is increased either by adding more material or by compression (reduction of volume).
- Raising the temperature of a gas that is free to expand at constant pressure increases the volume occupied by the gas and therefore reduces its density.

Equation 10 is the basis for using density measurements to determine the molar mass of a gas or vapor.

Thinking point: Why do hot-air balloons float in air?

EXAMPLE 4.5 Calculating the molar mass of a gas from its density

The volatile organic compound geraniol, a component of oil of roses, is used in perfumery. The density of the vapor at 260.°C and 103 Torr is 0.480 $g{\cdot}L^{-1}$. What is the molar mass of geraniol?

Anticipate Because the compound is volatile, we anticipate that it will have a moderately low molar mass.

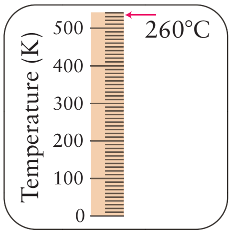
PLAN List the information given and convert the temperature into kelvins. Then rearrange Eq. 10 into an expression for M, select a value of R with appropriate units, and substitute the data.

SOLVE

Assemble the data:

$$d = 0.480\ g{\cdot}L^{-1},\ P = 103\ \text{Torr, and}$$

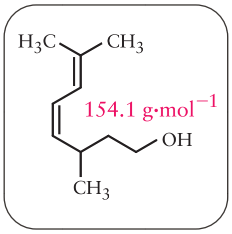
$$T = (273.15 + 260.)\ K = 533\ K$$



Rearrange $d = MP/RT$ into $M = dRT/P$ and substitute the data:

$$M = \frac{(0.480\ g{\cdot}L^{-1}) \times (62.364\ L{\cdot}Torr{\cdot}K^{-1}{\cdot}mol^{-1}) \times (533\ K)}{103\ Torr}$$

$$= 155\ g{\cdot}mol^{-1}$$



Evaluate This value, 155 $g{\cdot}mol^{-1}$, is close to the value that could be calculated from the molecular formula (154.1 $g{\cdot}mol^{-1}$, see the illustration).

Self-Test 4.11A The oil produced from eucalyptus leaves contains the volatile organic compound eucalyptol. At 190.°C and 60.0 Torr, a sample of eucalyptol vapor had a density of 0.320 $g{\cdot}L^{-1}$. Calculate the molar mass of eucalyptol.

[***Answer:*** 154 $g{\cdot}mol^{-1}$]

Self-Test 4.11B The *Codex Ebers*, an Egyptian medical papyrus, describes the use of garlic as an antiseptic. Chemists today have verified that the oxide of diallyl disulfide (the volatile compound responsible for garlic odor) is a powerful antibacterial agent. At 177°C and 200. Torr, a sample of diallyl disulfide vapor has a density of 1.04 $g{\cdot}L^{-1}$. What is the molar mass of diallyl disulfide?

The density of the atmosphere varies greatly from place to place, as does its composition and temperature. The average composition of dry air (air from which water vapor has been removed) is shown in Table 4.4. One reason for the nonuniformity of

TABLE 4.4 Composition of Dry Air at Sea Level

		Composition (%)	
Constituent	Molar mass* ($g{\cdot}mol^{-1}$)	Volume	Mass
nitrogen, N_2	28.02	78.09	75.52
oxygen, O_2	32.00	20.95	23.14
argon, Ar	39.95	0.93	1.29
carbon dioxide, CO_2	44.01	0.03	0.05

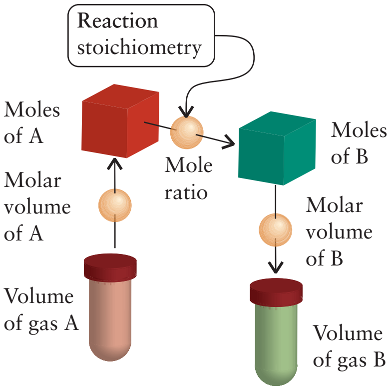
*The average molar mass of molecules in the air, taking into account the relative amounts of the different components, is 28.97 $g{\cdot}mol^{-1}$. The percentage of water vapor in ordinary air varies with the humidity.

air is the effect of solar radiation, which causes different chemical reactions at different altitudes. The density of air also varies with altitude. For example, the air outside an airplane cruising at 10 km is only 25% as dense as air at sea level.

The molar concentrations and densities of gases increase as they are compressed but decrease as they are heated. The density of a gas depends on its molar mass.

4.7 The Stoichiometry of Reacting Gases

We can use the ideal gas law in combination with mole ratios to calculate the volume of gas consumed or produced in a reaction. For example, we might need to know the volume of carbon dioxide produced when a fuel burns or the volume of oxygen needed to react with a given mass of hemoglobin in the red cells of our blood. To answer this kind of question, we have to combine the mole-to-mole calculations of the type described in Sections L and M with the conversion of moles of gas molecules into the volume that they occupy. The diagram in (**1**) extends the stoichiometry strategy introduced in Section L to include the volume of a gas.



1

EXAMPLE 4.6 Calculating the mass of reagent needed to react with a specified volume of gas

The carbon dioxide generated by the personnel in the artificial atmosphere of submarines and spacecraft must be removed from the air and the oxygen recovered. Submarine design teams have investigated the use of potassium superoxide, KO_2, as an air purifier because this compound reacts with carbon dioxide and releases oxygen (Fig. 4.16):

$$4\ KO_2(s) + 2\ CO_2(g) \longrightarrow 2\ K_2CO_3(s) + 3\ O_2(g)$$

Calculate the mass of KO_2 needed to react with 50. L of carbon dioxide at 25°C and 1.0 atm.

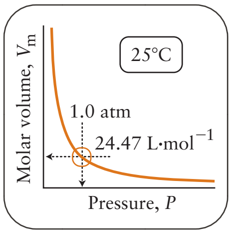
Anticipate A volume of 50 L under normal conditions corresponds to about 2 mol CO_2, and the stoichiometry of the equation indicates that about 4 mol KO_2 would be needed. Because the molar mass of KO_2 is about 70 $g\cdot mol^{-1}$, we can suspect that the answer will be close to 280 g.

PLAN We convert from the given volume of gas into moles of molecules (by using the molar volume), then into moles of reactant molecules or formula units (by using a mole ratio), and then into the mass of reactant (by using its molar mass). If the molar volume at the stated conditions is not available, then use the ideal gas law to calculate the amount of gas molecules.

SOLVE

Find the molar volume under the stated conditions from a table or calculation.

Table 4.3 gives $V_m = 24.47\ L\cdot mol^{-1}$.



Find the stoichiometric relation between CO_2 and KO_2 from the chemical equation.

$$2\ mol\ CO_2 \simeq 4\ mol\ KO_2,\ or\ 1\ mol\ CO_2 \simeq 2\ mol\ KO_2$$

Find the molar mass of KO_2 (Section E).

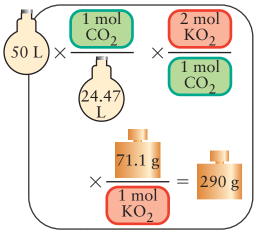
$$39.10 + 2(16.00)\ g\cdot mol^{-1} = 71.10\ g\cdot mol^{-1}$$

FIGURE 4.16 When carbon dioxide is passed over potassium superoxide (the yellow solid), it reacts to form colorless potassium carbonate (the white solid coating the walls of the tube) and oxygen gas. The reaction is used to remove carbon dioxide from the air in a closed-system breathing environment.

FIGURE 4.17 An explosion caused by the ignition of coal dust. A shock wave is created by the tremendous expansion of volume as large numbers of gas molecules form.

Convert from volume of CO_2 to mass of KO_2.

$$\text{Mass of } KO_2 = (50.\ \text{L}) \times \left(\frac{1\ \text{mol } CO_2}{24.47\ \text{L}}\right) \times \left(\frac{2\ \text{mol } KO_2}{1\ \text{mol } CO_2}\right) \times \left(\frac{71.1\ \text{g}}{1\ \text{mol } KO_2}\right) = 2.9 \times 10^2\ \text{g}$$



Evaluate The answer, 290 g, is close to the 280 g that we anticipated.

Self-Test 4.12A Calculate the volume of carbon dioxide, adjusted to 25°C and 1.0 atm, that plants need to make 1.00 g of glucose, $C_6H_{12}O_6$, by photosynthesis in the reaction $6\ CO_2(g) + 6\ H_2O(l) \longrightarrow C_6H_{12}O_6(s) + 6\ O_2(g)$.

[*Answer:* 0.81 L]

Self-Test 4.12B The reaction of H_2 and O_2 gases to produce liquid H_2O is used in fuel cells on the space shuttles to provide electricity. What mass of water can be produced in the reaction of 100.0 L of oxygen stored at 25°C and 1.00 atm?

There may be more than a thousandfold increase in volume when liquids or solids react to form a gas. The molar volumes of gases are close to 25 $L \cdot mol^{-1}$ under normal conditions (room temperature and pressure), whereas liquids and solids occupy only about a few tens of milliliters per mole. The molar volume of liquid water, for instance, is only 18 $mL \cdot mol^{-1}$ at 25°C. In other words, 1 mol of gas molecules at 25°C and 1 atm occupies as much as 1000 times the volume of 1 mol of molecules in a typical liquid or solid.

The increase in volume as gaseous products are formed in a chemical reaction is even larger if several gas molecules are produced from each reactant molecule, such as the formation of CO and CO_2 from a solid fuel (Fig. 4.17). Lead azide, $Pb(N_3)_2$, which is used as a detonator for explosives, suddenly releases a large volume of nitrogen gas when it is struck:

$$Pb(N_3)_2(s) \longrightarrow Pb(s) + 3\ N_2(g)$$

An explosion of the same kind, but using sodium azide, NaN_3, is used in air bags in automobiles (Fig. 4.18). The explosive release of nitrogen is detonated electrically when the vehicle decelerates abruptly in a collision.

The molar volume (at the specified temperature and pressure) is used to convert the amount of a reactant or product in a chemical reaction into a volume of gas.

4.8 Mixtures of Gases

Many of the gases we meet in chemistry—and in everyday life—are mixtures. The atmosphere, for instance, is a mixture of nitrogen, oxygen, argon, carbon dioxide, and many other gases. The air we inhale is one mixture; the air we exhale is another mixture. Many

FIGURE 4.18 The rapid decomposition of sodium azide, NaN_3, results in the formation of a large volume of nitrogen gas. The reaction is triggered electrically in this air bag.

gaseous anesthetics are carefully controlled mixtures. We need to extend the model of a gas that we have been developing to include mixtures of gases.

To extend our model, we should note that, at low pressures at least, all gases respond in the same way to changes in pressure, volume, and temperature. Therefore, for calculations of the type that we are doing in this chapter, it does not matter whether all the molecules in a sample are the same. *A mixture of gases that do not react with one another behaves like a single pure gas*. For instance, we can treat air as a single gas when we want to use the ideal gas law to predict its properties.

John Dalton was the first to see how to calculate the pressure of a mixture of gases. His reasoning was something like this. Imagine that we introduce a certain amount of oxygen into a container and end up with a pressure of 0.60 atm. Then we evacuate the container to empty it of all gas. Now we introduce into the container enough nitrogen gas to give a pressure of 0.40 atm at the same temperature. Dalton wondered what the total pressure would be if these same amounts of the two gases were present in the container simultaneously. From some fairly crude measurements, he concluded that the total pressure resulting from the pressure of both gases in the same container would be 1.00 atm, the sum of the individual pressures.

This is the same Dalton whose contribution to atomic theory we met in Section B.

Dalton summarized his observations in terms of the **partial pressure** of each gas, the pressure that the gas would exert if it occupied the container alone. In our example, the partial pressures of oxygen and nitrogen in the mixture are 0.60 atm and 0.40 atm, respectively, because those are the pressures that the gases exert when each one is in the container alone. Dalton then described the behavior of gaseous mixtures by his **law of partial pressures:**

> The total pressure of a mixture of gases is the sum of the partial pressures of its components.

If we denote the partial pressures of the gases A, B, . . . as P_A, P_B, . . . and the total pressure of the mixture as P, then we can write Dalton's law as follows:

$$P = P_A + P_B + \cdots \qquad \textbf{(11)}^*$$

The law is illustrated in Fig. 4.19. It is exactly true only for gases that behave ideally, but it is a good approximation for nearly all gases under normal conditions.

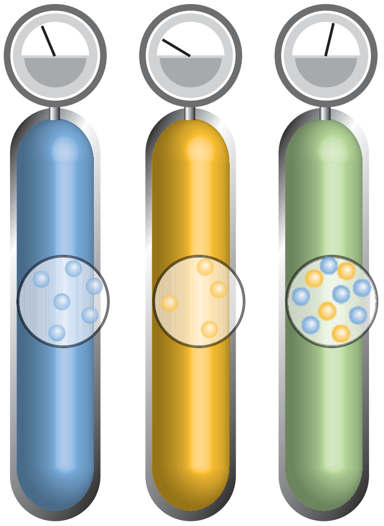


FIGURE 4.19 A representation of the experiment that Dalton performed on a gas mixture. According to Dalton's law, the total pressure, P, of a mixture of gases is the sum of the partial pressures P_A and P_B of gases A and B. Each partial pressure is the pressure that one of the gases would exert if it were the sole gas in the container (at the same temperature).

Dalton's law is consistent with our model of a gas and adds a little more information. The total pressure of a gas arises, as we have seen, from the battering of the molecules on the walls of the container. That battering is due to all the molecules in a mixture. The molecules of gas A exert a pressure, the molecules of gas B do, too, and the total pressure is the sum of these individual pressures. The additional piece of information that we can use to expand our model is that, for the total pressure to be the sum of the individual contributions, the A molecules must be blind to the presence of the B molecules. That is, there are no interactions—neither attractions nor repulsions—between the two kinds of molecules except during their very brief collisions. Later, we shall see that the absence of such interactions is a characteristic feature of an ideal gas.

We use partial pressures to describe the composition of a humid gas. For example, the total pressure of the damp air in our lungs is

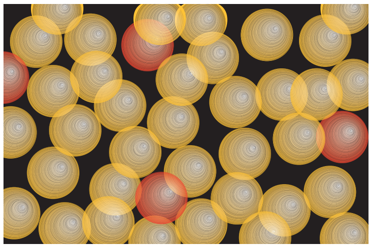
$$P = P_{\text{dry air}} + P_{\text{water vapor}}$$

In a closed container, to which a lung is a good first approximation, water vaporizes until its partial pressure has reached a certain value, called its *vapor pressure*. The vapor pressure of water at normal body temperature is 47 Torr. The partial pressure of the air itself in our lungs is therefore

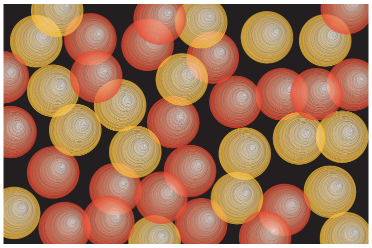
$$P_{\text{dry air}} = P - P_{\text{water vapor}} = P - 47 \text{ Torr}$$

On a typical day, the total pressure at sea level is 760. Torr; so at sea level the pressure in our lungs due to all the gas except the water vapor is 760. − 47 Torr = 713 Torr.

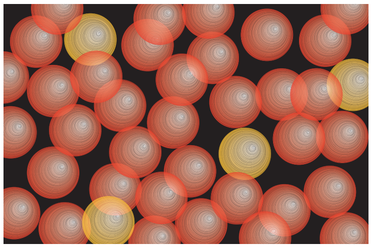
Thinking point: Is damp air more dense or less dense than dry air under the same conditions?



$x_{RED} = 0.1$



$x_{RED} = 0.5$



$x_{RED} = 0.9$

FIGURE 4.20 A mole fraction, x, tells us the fraction of molecules of a particular kind in a mixture of two or more kinds of molecules. In this illustration, the mole fraction of A molecules, which are colored red, is given below each mixture; the B molecules are colored yellow. The mixture can be solid or liquid as well as gaseous.

Self-Test 4.13A As a sample of oxygen was collected over water at 24°C and 745 Torr, it became saturated with water vapor. At this temperature, the vapor pressure of water is 24.38 Torr. What is the partial pressure of the oxygen?

[***Answer:*** 721 Torr]

Self-Test 4.13B Students collecting hydrogen and oxygen gases by electrolysis of water failed to separate the two gases. If the total pressure of the dry mixture is 720. Torr, what is the partial pressure of each gas?

A good way to express the relation between the total pressure of a mixture and the partial pressures of its components is to use the **mole fraction,** x, of each component A, B, . . . , the number of moles of molecules of the gas expressed as a fraction of the total number of moles of molecules in the sample. If the amounts of gas molecules present are n_A, n_B, and so forth, the mole fraction of A is

$$x_A = \frac{n_A}{n} = \frac{n_A}{n_A + n_B + \cdots} \qquad (12)^*$$

and likewise for the mole fractions of the other components. This expression is used to calculate the mole fraction of each component of the mixture. In a binary (two-component) mixture of gases A and B,

$$x_A + x_B = \frac{n_A}{n_A + n_B} + \frac{n_B}{n_A + n_B} = \frac{n_A + n_B}{n_A + n_B} = 1 \qquad (13)$$

When $x_A = 1$, the mixture is pure A; when $x_B = 1$, the mixture is pure B. When $x_A = x_B = 0.50$, half the molecules are A and half are B (Fig. 4.20).

Our task is to find the relation between the partial pressure of a gas and its mole fraction.

HOW DO WE DO THAT?

To find the relation between the partial pressure of a gas in a mixture and its mole fraction, we first express the partial pressure, P_A, of a gas A in terms of the amount of A molecules present, n_A, the volume, V, occupied by the mixture, and the temperature, T:

$$P_A = \frac{n_A RT}{V}$$

Because $n_A = nx_A$ (where n is the total amount of all gases) and $P = nRT/V$,

$$P_A = \frac{nx_A RT}{V} = x_A\frac{nRT}{V} = x_A P$$

The relation that we have derived for the partial pressure of a gas A is

$$P_A = x_A P \qquad (14)^*$$

where P is the total pressure and x_A is the mole fraction of A in the mixture. In modern applications, Eq. 14 is regarded as the definition of the partial pressure of a gas, ideal or real.

EXAMPLE 4.7 Calculating partial pressures

Air is a source of reactants for many chemical processes. To determine how much air is needed for these reactions, it is useful to know the partial pressures of the components. A certain sample of dry air of total mass 1.00 g consists almost entirely of 0.76 g of nitrogen and 0.24 g of oxygen. Calculate the partial pressures of these gases when the total pressure is 0.87 atm.

Anticipate The molar masses of N_2 and O_2 are very similar, so very approximately we should expect the amounts of N_2 and O_2 to be in the ratio of the masses present, which is 0.76:0.24. The partial pressures should be in the same ratio, or about 3:1.

PLAN To use Eq. 14, we need the total pressure (given) and the mole fraction of each component. The first step is to calculate the amount (in moles) of each gas present and the total amount (in moles). Then calculate the mole fractions from Eq. 12. To obtain the partial pressures of the gases, multiply the total pressure by the mole fractions of the gases in the mixture (Eq. 14).

SOLVE

Use their molar masses to find the amounts (in moles) of each gas present.

$$n_{N_2} = \frac{0.76\ \text{g}}{28.02\ \text{g·mol}^{-1}} = \frac{0.76}{28.02}\ \text{mol}\ \ (= 0.027\ \text{mol})$$

$$n_{O_2} = \frac{0.24\ \text{g}}{32.00\ \text{g·mol}^{-1}} = \frac{0.24}{32.00}\ \text{mol}\ (= 0.0075\ \text{mol})$$

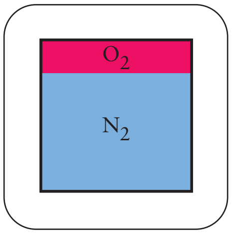
Find the total amount of gas molecules from $n = n_A + n_B$:

$$n_{N_2} + n_{O_2} = \frac{0.76}{28.02} + \frac{0.24}{32.00}\ \text{mol}\ (= 0.035\ \text{mol})$$

Calculate the mole fractions from $x_A = n_A/n$:

$$x_{N_2} = \frac{0.76/28.02}{0.76/28.02 + 0.24/32.00} = 0.78$$

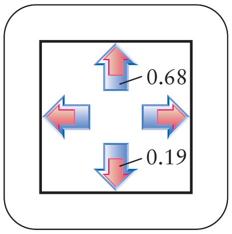
$$x_{O_2} = \frac{0.24/32.02}{0.76/28.02 + 0.24/32.00} = 0.22$$



Multiply each mole fraction by the total pressure, $P_A = x_AP$:

$$P_{N_2} = 0.78 \times (0.87\ \text{atm}) = 0.68\ \text{atm}$$

$$P_{O_2} = 0.22 \times (0.87\ \text{atm}) = 0.19\ \text{atm}$$



Evaluate As expected, P_{N_2} is about three times P_{O_2}. A check of the calculation against given information shows that 0.68 + 0.19 atm = 0.87 atm, as in the data.

Self-Test 4.14A A baby with a severe bronchial infection is in respiratory distress. The anesthetist administers heliox, a mixture of helium and oxygen with 92.3% by mass O_2. What is the partial pressure of oxygen being administered to the baby if atmospheric pressure is 730 Torr?

[*Answer:* 4.4×10^2 Torr]

Self-Test 4.14B Divers exploring a shipwreck and wishing to avoid the narcosis associated with breathing nitrogen under high pressure switch to a neon–oxygen gas mixture containing 141.2 g of oxygen and 335.0 g of neon. The pressure in the gas tanks is 50.0 atm. What is the partial pressure of oxygen in the tanks?

The partial pressure of a gas is the pressure that it would exert if it were alone in the container; the total pressure of a mixture of gases is the sum of the partial pressures of the components; the partial pressure of a gas is related to the total pressure by the mole fraction: $P_A = x_AP$.

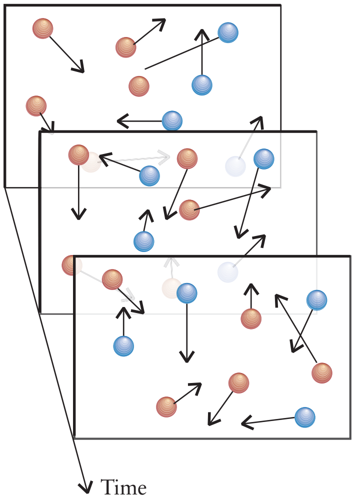


FIGURE 4.21 In diffusion, the molecules of one substance spread into the region occupied by molecules of another in a series of random steps, undergoing collisions as they move.

MOLECULAR MOTION

The empirical results summarized by the gas laws suggest a model of an ideal gas in which widely spaced (most of the time), noninteracting (except during collisions) molecules undergo ceaseless motion, with average speeds that increase with temperature. In the next three sections, we refine our model in two steps. First, we use experimental measurements of the rate at which gases spread from one region to another to gather information about the *average* speeds of molecules. Then we use this information to set up a quantitative version of our model.

4.9 Diffusion and Effusion

Observations of two processes, diffusion and effusion, provide data that show how the average speeds of gas molecules are related to molar mass and temperature. **Diffusion** is the gradual dispersal of one substance through another substance, such as krypton dispersing through a neon atmosphere (Fig. 4.21). Diffusion explains the spread of perfumes and pheromones (chemical signals exchanged by animals) through air. It also helps to keep the composition of the atmosphere approximately uniform. **Effusion** is the escape of a gas through a small hole into a vacuum (Fig. 4.22). Effusion occurs whenever a gas is separated from a vacuum by a porous barrier—a barrier that contains microscopic holes—or even a single pinhole, as in a punctured tire. A gas escapes through a pinhole because there are more "collisions" with the hole on the high-pressure side than on the low-pressure side, and so more molecules pass from the high-pressure region into the low-pressure region than pass in the opposite direction. Effusion is easier to treat than diffusion, so we concentrate on it; but similar remarks apply to diffusion too.

The nineteenth-century Scottish chemist Thomas Graham carried out a series of experiments on the rates of effusion of gases. He found that,

> *At constant temperature, the rate of effusion of a gas is inversely proportional to the square root of its molar mass*:

$$\text{Rate of effusion} \propto \frac{1}{\sqrt{\text{molar mass}}} \quad \text{or} \quad \text{Rate of effusion} \propto \frac{1}{\sqrt{M}} \tag{15a}$$

This observation is now known as **Graham's law of effusion**. The rate of effusion is proportional to the average speed of the molecules in the gas because that speed determines the rate at which molecules approach the hole. Therefore, we can conclude that

$$\text{Average speed} \propto \frac{1}{\sqrt{M}} \tag{15b}$$

This relation is an important clue about the motion of molecules in a gas and we shall use it shortly, but first we look at some practical applications of Graham's law.

If we were to write Graham's law for two gases A and B with molar masses M_A and M_B, and divide one equation by the other, we would obtain

$$\frac{\text{Rate of effusion of A molecules}}{\text{Rate of effusion of B molecules}} = \frac{1/\sqrt{M_A}}{1/\sqrt{M_B}} = \sqrt{\frac{M_B}{M_A}} \tag{16a}^*$$

Because the times it takes for the same amount of two substances to effuse through a small hole are inversely proportional to the rates at which they effuse, an equivalent statement is

$$\frac{\text{Time for A to diffuse}}{\text{Time for B to diffuse}} = \sqrt{\frac{M_A}{M_B}} \tag{16b}$$

This relation can be used to estimate the molar mass of a substance by comparing the time required for a given amount of the unknown substance to effuse with that required for the same amount of a substance with a known molar mass.

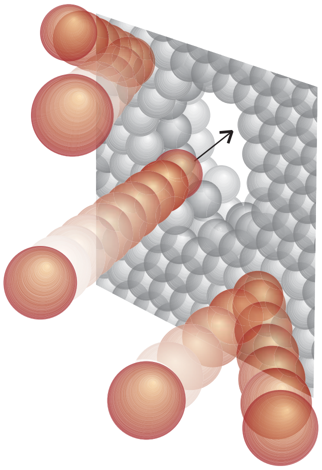

FIGURE 4.22 In effusion, the molecules of one substance escape through a small hole in a barrier into a vacuum or a region of low pressure.

Self-Test 4.15A It takes 30. mL of argon 40. s to effuse through a porous barrier. The same volume of vapor of a volatile compound extracted from Caribbean sponges takes 120. s to effuse through the same barrier under the same conditions. What is the molar mass of this compound?

[*Answer:* $3.6 \times 10^2\ g \cdot mol^{-1}$]

Self-Test 4.15B It takes a certain amount of helium atoms 10. s to effuse through a porous barrier. How long does it take the same amount of methane, CH_4, molecules to effuse through the same barrier under the same conditions?

We have seen that effusion reveals that the average speed of molecules in a gas is inversely proportional to the square root of their molar mass. In effusion experiments at different temperatures, we find that the rate of effusion increases as the temperature is raised. Specifically, for a given gas,

The rate of effusion increases as the square root of the temperature:

$$\frac{\text{Rate of effusion at } T_2}{\text{Rate of effusion at } T_1} = \sqrt{\frac{T_2}{T_1}} \qquad \textbf{(17a)}$$

Because the rate of effusion is proportional to the average speed of the molecules, we can infer that

The average speed of molecules in a gas is proportional to the square root of the temperature:

$$\text{Average speed} \propto \sqrt{T} \qquad \textbf{(17b)}$$

This very important relation begins to reveal the significance of one of the most elusive concepts in science: the nature of temperature. We see that, when referring to a gas, the temperature is an indication of the average speed of the molecules, and the higher the temperature, the higher the average speed of the molecules.

We can combine the two relations that we have found. Because the average speed of molecules in a gas is proportional to the square root of the temperature (Eq. 17b) and inversely proportional to the square root of the molar mass (Eq. 15b), we can write

$$\text{Average speed} \propto \sqrt{\frac{T}{M}} \qquad \textbf{(18)}$$

That is, the higher the temperature and the lower the molar mass, the higher is the average speed of molecules in a gas.

The average speed of molecules in a gas is directly proportional to the square root of the temperature and inversely proportional to the square root of the molar mass.

4.10 The Kinetic Model of Gases

We now have enough information to turn our qualitative ideas about a gas into a quantitative model that can be used to make numerical predictions. The **kinetic model** ("kinetic molecular theory," KMT) of a gas is based on four assumptions (Fig. 4.23):

1 A gas consists of a collection of molecules in continuous random motion.

2 Gas molecules are infinitesimally small points.

3 The molecules move in straight lines until they collide.

4 The molecules do not influence one another except during collisions.

The fourth assumption means that we are proposing, as part of the model, that there are no attractive forces between ideal gas molecules and no repulsive forces between them except during collisions.

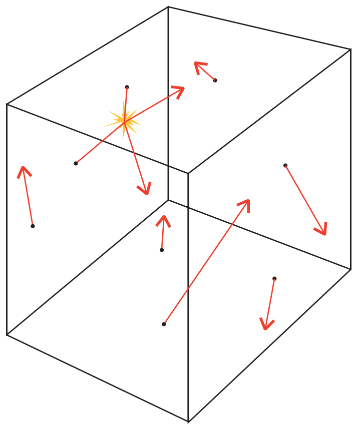

FIGURE 4.23 In the kinetic model of gases, the molecules are regarded as infinitesimal points that travel in straight lines until they undergo instantaneous collisions.

In this context, "molecules" includes all types of particles, whether atoms, ions, or molecules.

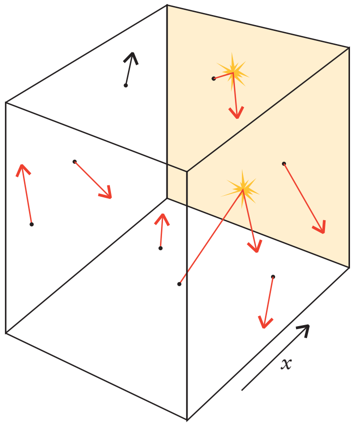

FIGURE 4.24 In the kinetic model of gases, the pressure arises from the force exerted on the walls of the container when the impacting molecules are deflected. We need to know the force of each impact and the number of impacts in a given time interval.

In the kinetic model of gases, we picture the molecules as widely separated for most of the time and in ceaseless random motion. They zoom from place to place, always in straight lines, changing direction only when they collide with a wall of the container or another molecule. The collisions change the speed and direction of the molecules, just like balls in a three-dimensional cosmic game of pool.

In Section 4.4, we used a molecular model of a gas to explain *qualitatively* why the pressure of a gas rises as the temperature is increased: as a gas is heated, its molecules move faster and strike the walls of their container more often. The kinetic model of a gas allows us to derive the *quantitative* relation between pressure and the speeds of the molecules.

HOW DO WE DO THAT?

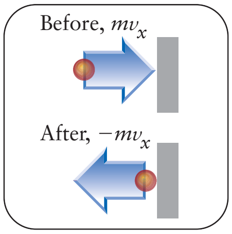
The following calculation of the pressure of a gas based on the kinetic model may seem complicated at first, but it breaks down into a series of small steps, each of which can be interpreted physically.

We begin with the gas sample illustrated in Fig. 4.24 and initially suppose that all the molecules are traveling at the same speed; we remove that constraint later. The molecules strike the wall on the right. If we know how often these impacts occur and what force they exert on the wall, we can calculate the pressure (which is force divided by area) that results.

To calculate the force exerted by a single molecule, we use Newton's second law of motion: force is equal to the rate of change of momentum of a particle (Section A). Momentum is the product of mass and velocity; so, if a molecule of mass m is traveling with a velocity v_x parallel to the side of the box that we are calling x, then its linear momentum before it strikes the wall on the right is mv_x. Immediately after the collision, the momentum of the molecule is $-mv_x$ because the velocity has changed from v_x to $-v_x$. We have assumed that the collision is "elastic," which means that no energy is transferred to the wall and therefore that the speed of the molecule is the same after the collision as it was before.

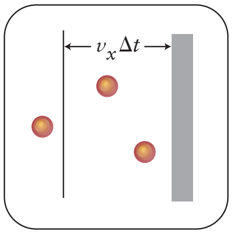
The change in momentum of one molecule:

$$2mv_x$$

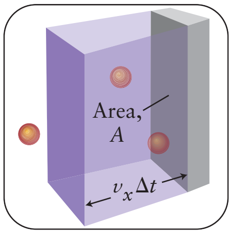


Next, we calculate the number of molecules that can strike the wall in a time interval Δt.

All the molecules within a distance $v_x\Delta t$ of the wall and traveling toward it will strike the wall during the interval Δt.



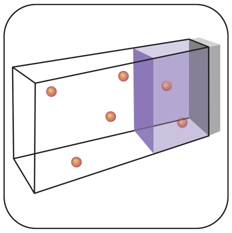
If the wall has area A, all the particles in a volume $Av_x\Delta t$ will reach the wall if they are traveling toward it.



Suppose that the total number of particles in the container is N and that the volume of the container is V. Because a gas fills its container, we know that the molecules are spread evenly throughout the container. Therefore,

The number of molecules in the volume $Av_x\Delta t$ is that fraction of the total volume V, multiplied by the total number of molecules:

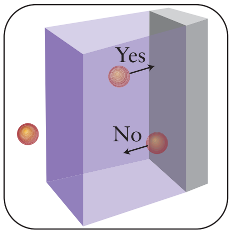
$$\text{Number of molecules} = \frac{Av_x\Delta t}{V} \times N = \frac{NAv_x\Delta t}{V}$$



Half the molecules in the box are moving toward the wall on the right and half are moving away from that wall. Therefore,

The average number of collisions with the wall during the interval Δt is half the number in the volume $Av_x\Delta t$:

$$\text{Number of collisions} = \frac{NAv_x\Delta t}{2V}$$



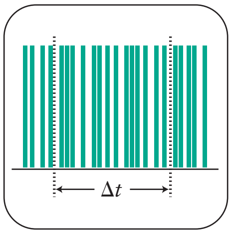
We have calculated the momentum of one molecule and the number of collisions during the interval Δt. Now we bring the parts of the calculation together. The total momentum change of the molecules in that interval is the change $2mv_x$ that an individual molecule undergoes multiplied by the total number of collisions:

$$\text{Total momentum change} = \frac{NAv_x\Delta t}{2V} \times 2mv_x = \frac{NmAv_x^2\Delta t}{V}$$

At this point, we calculate the rate of change of momentum by dividing this total momentum change by the time interval during which it occurs (Δt) and use Newton's second law that the force is equal to the rate of change of momentum:

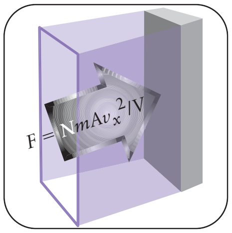
From Rate of change of momentum = (total momentum change)/Δt,

$$\text{Rate of change of momentum} = \frac{NmAv_x^2\Delta t}{V\Delta t} = \frac{NmAv_x^2}{V}$$



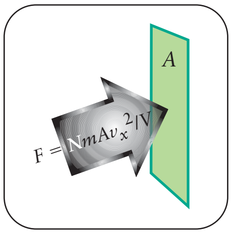
From Newton's second law,

$$\text{Force} = \text{rate of change of momentum} = \frac{NmAv_x^2}{V}$$



From Pressure = force/area,

$$\text{Pressure} = \frac{NmAv_x^2}{VA} = \frac{Nmv_x^2}{V}$$



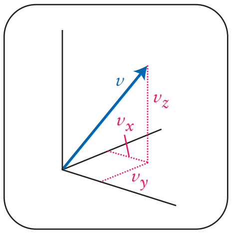
Not all the molecules in the sample are traveling at the same speed. To obtain the detected pressure, P, we need to use the *average* value of v_x^2 in place of v_x^2 for each individual molecule. Averages are commonly denoted by angular brackets; so we write

$$P = \frac{Nm\langle v_x^2\rangle}{V}$$

where $\langle v_x{}^2\rangle$ is the average value of $v_x{}^2$ for all the molecules in the sample. At this stage, we relate $\langle v_x{}^2\rangle$ to the *root mean square speed*, $v_{\text{rms}} = \langle v^2\rangle^{1/2}$, the square root of the average of the squares of the molecular speeds (this quantity is explained in more detail in the text following this derivation). First, we note that the speed, v, of a single molecule is related to the velocity parallel to the x, y, and z directions:

From the Pythagorean theorem,

$$v^2 = v_x{}^2 + v_y{}^2 + v_z{}^2$$



Therefore, the mean square speed is given by

$$v_{\text{rms}}{}^2 = \langle v^2\rangle = \langle v_x{}^2 + v_y{}^2 + v_z{}^2\rangle = \langle v_x{}^2\rangle + \langle v_y{}^2\rangle + \langle v_z{}^2\rangle$$

However, because the particles are moving randomly, the average of $v_x{}^2$ is the same as the average of $v_y{}^2$ and the average of $v_z{}^2$, the analogous quantities in the y and z directions. Because $\langle v_x{}^2\rangle$, $\langle v_y{}^2\rangle$, and $\langle v_z{}^2\rangle$ are all equal, we know that $\langle v^2\rangle = 3\langle v_x{}^2\rangle$; therefore, $\langle v_x^2\rangle = \frac{1}{3}v_{\text{rms}}^2$. It follows that

$$P = \frac{Nmv_{\text{rms}}^2}{3V}$$

The total number of molecules, N, is the product of the amount, n, and Avogadro's constant, N_A ($N = nN_A$) so the last equation becomes

$$P = \frac{nN_A m v_{\text{rms}}^2}{3V} = \frac{nMv_{\text{rms}}^2}{3V}$$

where m is the mass of one molecule and $M = mN_A$ is the molar mass of the molecules.

We have deduced that the pressure of a gas and the volume are related by

$$PV = \tfrac{1}{3}nMv_{\text{rms}}^2 \qquad (19)$$

where n is the amount (in moles) of gas molecules, M is their molar mass, and v_{rms} is the root mean square speed of the molecules. As remarked in the preceding derivation, the **root mean square speed,** v_{rms}, is the square root of the average value of the squares of the molecular speeds. If there are N molecules in the sample and the speeds of these molecules at some instant are $v_1, v_2, \ldots, v_N$, then the root mean square speed is

$$v_{\text{rms}} = \left(\frac{v_1^2 + v_2^2 + \cdots + v_N^2}{N}\right)^{1/2} \qquad (20)$$

The importance of the root mean square speed stems from the fact that v_{rms}^2 is proportional to the average kinetic energy of the molecules, $\langle E_k\rangle = \frac{1}{2}m\langle v^2\rangle = \frac{1}{2}mv_{\text{rms}}^2$.

Thinking point: What is the average *velocity* of the molecules?

We can now use the ideal gas law, derived from observations of the bulk properties of gases, to calculate the root mean square speed of the molecules of a gas. We know that $PV = nRT$ for an ideal gas; therefore, we can set the right-hand side of Eq. 19 equal to nRT and rearrange the resulting expression ($\frac{1}{3}nNv_{\text{rms}}^2 = nRT$) into

$$v_{\text{rms}} = \left(\frac{3RT}{M}\right)^{1/2} \qquad (21a)^*$$

This important result is used to find the root mean square speeds of the gas-phase molecules at any temperature (Fig. 4.25). We can rewrite this equation to emphasize that, for a gas, the temperature is a measure of mean molecular speed. From $v_{\text{rms}}{}^2 = 3RT/M$, it follows that

$$T = \frac{Mv_{\text{rms}}^2}{3R} \qquad (21b)$$

That is,

The temperature is proportional to the mean square speed of the molecules in a gas.

Thinking point: How is the root mean square speed of a molecule related to its molar mass?

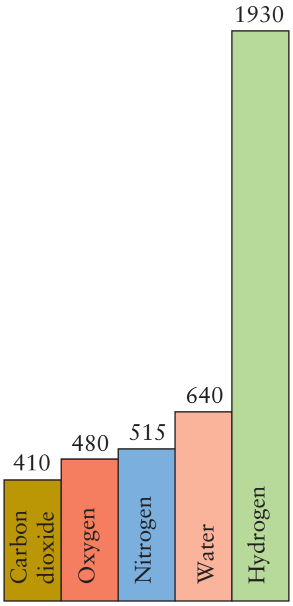


FIGURE 4.25 The root mean square speeds of five gases at 25°C, in meters per second. The gases are some of the components of air; hydrogen is included to show that the root mean square speed of light molecules is much greater than that of heavier molecules.

EXAMPLE 4.8 Calculating the root mean square speed of gas molecules

What is the root mean square speed of nitrogen molecules in air at 20.°C?

Anticipate Because a sound wave is propagated by the movement of molecules, we can suspect that typical speeds are about the same as the speed of sound in air. That is about 300 $m\cdot s^{-1}$.

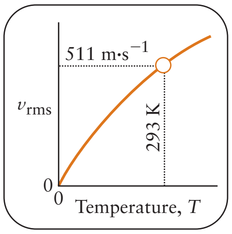
PLAN For the actual calculation, we substitute the data into Eq. 21a. In KMT calculations, use R in SI units and molar masses in SI base units, namely kilograms per mole.

SOLVE The temperature is 293 K and the molar mass of N_2 is 28.02 $g\cdot mol^{-1}$ (corresponding to 2.802×10^{-2} $kg\cdot mol^{-1}$).

From $v_{rms} = (3RT/M)^{1/2}$,

$$v_{rms} = \left(\frac{3 \times (8.3145\ J\cdot K^{-1}\cdot mol^{-1}) \times (293\ K)}{2.802 \times 10^{-2}\ kg\cdot mol^{-1}}\right)^{1/2}$$

$$= 511\ m\cdot s^{-1}$$



Evaluate This result, $v_{rms} = 511\ m\cdot s^{-1}$, is close to the speed of sound in air, as we anticipated. It means that nitrogen molecules are zooming about your head at about 1140 miles per hour.

A note on good practice: We use SI units throughout: R is in its fundamental SI form and the molar mass is in SI base units to be consistent with the choice for R. The cancellation of the units has made use of the relation $1\ J = 1\ kg\cdot m^2\cdot s^{-2}$.

Self-Test 4.16A Estimate the root mean square speed of water molecules in the vapor above boiling water at 100.°C.

[*Answer:* 719 $m\cdot s^{-1}$]

Self-Test 4.16B Estimate the root mean square speed of CH_4 molecules at 25°C.

The kinetic model of gases is consistent with the ideal gas law and provides an expression for the root mean square speed of the molecules. Root mean square speeds of gas molecules are proportional to the square root of the temperature.

4.11 The Maxwell Distribution of Speeds

Useful as it is, Eq. 21a gives only the root mean square speed of gas molecules. Like cars in traffic, individual molecules have speeds that vary over a wide range. Moreover, like a car in a head-on collision, a molecule might be brought almost to a standstill when it collides with another. In the next instant (but now unlike a colliding car), it might be struck by another molecule and move off at the speed of sound. An individual molecule undergoes several billion changes of speed and direction each second.

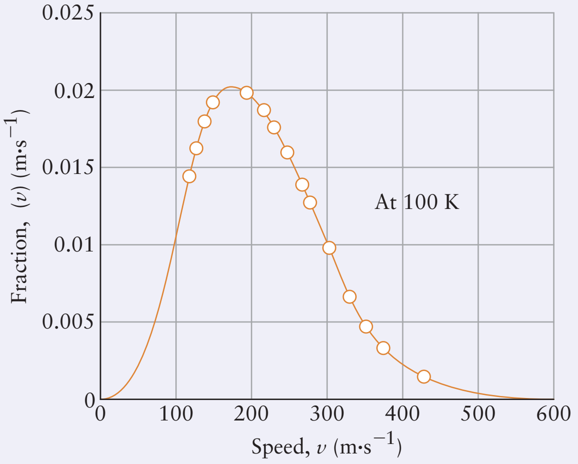
The formula for calculating the fraction of gas molecules having a given speed, v, at any instant was first derived from the kinetic model by the Scottish scientist James Clerk Maxwell. He derived the expression

$$\Delta N = Nf(v)\Delta v \qquad \text{with } f(v) = 4\pi\left(\frac{M}{2\pi RT}\right)^{3/2} v^2 e^{-Mv^2/2RT} \tag{22}$$

BOX 4.1 HOW DO WE KNOW . . . THE DISTRIBUTION OF MOLECULAR SPEEDS?

The distribution of molecular speeds in a gas can be determined experimentally in a molecular beam apparatus. In this technique, the gas is heated to the required temperature in an oven. The molecules then stream out of the oven through a small hole into an evacuated region. To ensure that the molecules form a narrow beam, they may also pass through a series of slits, and the pressure must be kept very low so that collisions within the beam do not cause spreading.

The molecular beam passes through a series of rotating disks (see diagram). Each disk contains a slit that is offset by a certain angle from its neighbor. A molecule that passes through the first slit will pass through the slit in the next disk only if the time that it takes to pass between the disks is the same as the time required for the slit in the second disk to move into the orientation originally occupied by the first disk. The two times must continue to match if the same molecule is to pass through subsequent disks. Therefore, a particular rate of rotation of the disks allows the passage of only those molecules having the speed that carries them through the slits. To determine the distribution of molecular speeds, we would measure the intensity of the beam of molecules arriving at the detector for different rotational rates of the disks. A typical result is shown in the graph, and we see that it is a good match to the theoretical Maxwell expression (see Figs. 4.26 and 4.27).



The points represent a typical result of a molecular speed distribution measurement. They are superimposed on the theoretical curve. To obtain the fraction of molecules with speeds in the range from v to $v + \Delta v$, multiply $f(v)$ by Δv.

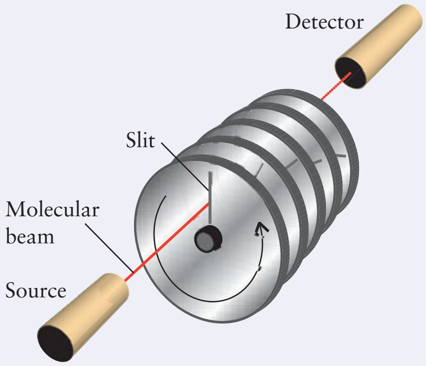


Diagram of the rotating disks that serve as a velocity selector in a molecular beam apparatus.

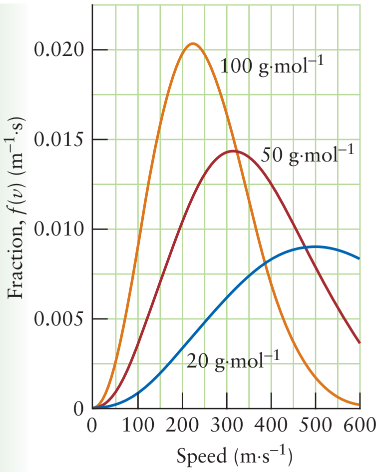

FIGURE 4.26 The range of molecular speeds for three gases, as given by the Maxwell distribution. All the curves correspond to the same temperature (300 K). The greater the molar mass, the lower the average speed and the narrower the spread of speeds. To obtain the fraction of molecules with speeds in the range from v to $v + \Delta v$, multiply $f(v)$ by Δv.

Living Graphs 4.26

where ΔN is the number of molecules with speeds in the narrow range between v and $v + \Delta v$, N is the total number of molecules in the sample, M is the molar mass, and R is the gas constant. This expression for $f(v)$ is the **Maxwell distribution of speeds** (Box 4.1).

What does this equation tell us? The exponential factor (which falls rapidly toward zero as v increases) means that very few molecules have very high speeds. The factor v^2 that multiplies the exponential factor goes to zero as v goes to zero, so it means that very few molecules have very low speeds. The factor $4\pi(M/2\pi RT)^{3/2}$ simply ensures that the total probability of a molecule having a speed between zero and infinity is 1.

Figure 4.26 shows a plot of the Maxwell distribution against speed for several different gases. We see that heavy molecules (of molar mass 100 g·mol^{-1}, for instance) travel with speeds close to their average values. Light molecules (of 20 g·mol^{-1}, for instance) not only have a higher average speed but also a wider range of speeds. Some molecules of gases with low molar masses have such high speeds that they can escape from the gravitational pull of small planets and go off into space. As a consequence, hydrogen molecules and helium atoms, which are both very light, are rare in the Earth's atmosphere, although they are abundant on massive planets such as Jupiter.

A plot of the Maxwell distribution for the same gas at several different temperatures shows that the average speed increases as the temperature is raised (Fig 4.27). We knew that from our observations of gas behavior (Section 4.9); but the curves also show that the spread of speeds widens as the temperature increases. At low temperatures, most molecules of a gas have speeds close to the average speed. At high temperatures, a

high proportion have speeds widely different from their average speed. Because the kinetic energy of a molecule in a gas is proportional to the square of its speed, the distribution of molecular kinetic energies follows the same trends.

Thinking point: Which term in Maxwell's equation causes the broadening of the curve, (the shift of the peak to the right) as the temperature increases?

The molecules of all gases have a wide range of speeds. As the temperature increases, the root mean square speed and the range of speeds both increase. The range of speeds is described by the Maxwell distribution, Eq. 22.

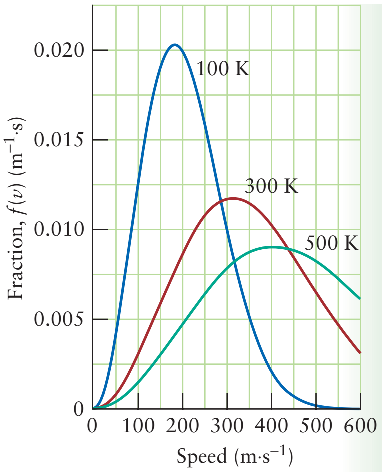

FIGURE 4.27 The Maxwell distribution again, but now the curves correspond to the speeds of a single substance (of molar mass 50 $g\cdot mol^{-1}$) at different temperatures. The higher the temperature, the higher the average speed and the broader the spread of speeds.

Living Graph 4.27

REAL GASES

In industry and in many research laboratories, gases must be used under high pressures, when the ideal gas law is not followed closely. Recall that the ideal gas law is a limiting law, valid only as $P \longrightarrow 0$. All actual gases, which are called **real gases,** have properties that differ from those predicted by the ideal gas law. These differences are significant at high pressures and low temperatures. We first explore the experimental evidence for those differences and then relate the behavior of real gases to the properties of their molecules. We then consider some of the implications of the nonideal behavior of gases and how that behavior can be described mathematically, which brings us to the final, refined version of our model of gases.

4.12 Deviations from Ideality

Two types of observations, one qualitative and the other quantitative, show that our model of a gas must be refined. The qualitative observation is that gases can be condensed to liquids when cooled or compressed. This property strongly suggests that, contrary to the assumptions of the kinetic model, gas molecules do attract one another because otherwise they would not cohere (stick together). In addition, liquids are very difficult to compress. This observation strongly suggests that powerful repulsive forces must prevent molecules from being squashed together into a tiny volume. The presence of attractive and repulsive forces implies that once again the kinetic model must be refined.

We can assess the effect of intermolecular forces quantitatively by comparing the behavior of real gases with that expected of an ideal gas. One of the best ways of exhibiting these deviations is to measure the **compression factor,** Z, the ratio of the actual molar volume of the gas to the molar volume of an ideal gas under the same conditions:

$$Z = \frac{V_m}{V_m^{ideal}} \qquad (23)$$

The compression factor of an ideal gas is 1, and so deviations from $Z = 1$ are a sign of nonideality. Figure 4.28 shows the experimental variation of Z for a number of gases. We see that all gases deviate from $Z = 1$ as the pressure is raised. Our model of gases must account for these deviations.

All deviations from ideal behavior can be explained by the presence of **intermolecular forces,** or attractions and repulsions between molecules. Sections 5.1 through 5.5 describe the origin of intermolecular forces. Here, all we need to know is that all molecules attract one another when they are a few molecular diameters apart but (provided they do not react) repel one another as soon as their electron clouds come into contact. Figure 4.29 shows how the potential energy of a molecule varies with its distance from a second molecule. At moderate separations, its potential energy is lower than when it is infinitely far away: attractions always lower the potential energy of an object. As the molecules come into contact, the potential energy starts to rise, because repulsions always increase the potential energy of an object.

The presence of attractive intermolecular forces accounts for the condensation of gases to liquids when they are compressed or cooled. Compression reduces the average

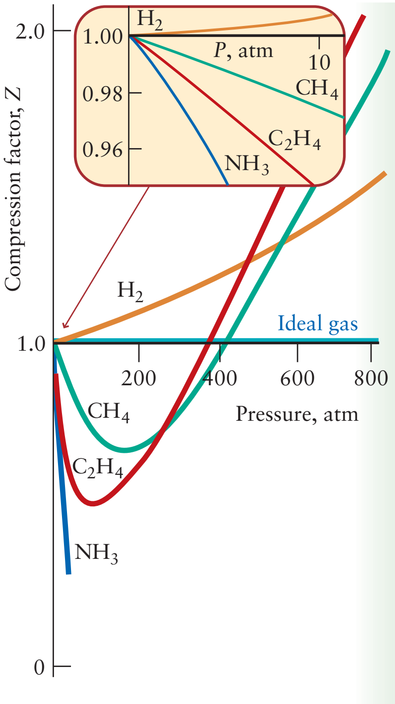

FIGURE 4.28 A plot of the compression factor, Z, as a function of pressure for a variety of gases. An ideal gas has $Z = 1$ for all pressures. For a few real gases with very weak intermolecular attractions, such as H_2, Z is always greater than 1. For most gases, at low pressures the attractive forces are dominant and $Z < 1$ (see inset). At high pressures, repulsive forces become dominant and $Z > 1$ for all gases.

Living Graph 4.28

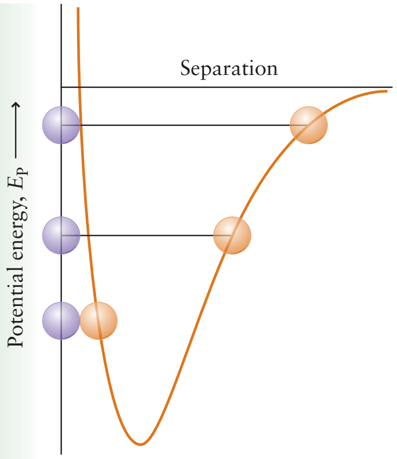

FIGURE 4.29 Variation in the potential energy of a molecule as it approaches another molecule. The potential energy rises sharply once the two molecules come into direct contact.

Living Graph 4.29

separation of the molecules, and neighboring molecules can be captured by one another's attraction, provided that they are traveling slowly enough (that is, the sample is cool enough). The low compressibility of liquids and solids is consistent, as we have seen, with the presence of strong repulsive forces when molecules are pushed together. Another way to describe the repulsive forces between molecules is to say that molecules have definite volumes. When you touch a solid object, you feel its size and shape because your fingers cannot penetrate into it. The resistance to compression offered by the solid is due to the repulsive forces exerted by its atoms on the atoms in your fingers.

The presence of intermolecular forces also accounts for the variation in the compression factor. Thus, for gases under conditions of pressure and temperature such that $Z > 1$, the repulsions are more important than the attractions. Their molar volumes are greater than expected for an ideal gas because repulsions tend to drive the molecules apart. For example, a hydrogen molecule has so few electrons that its molecules are only very weakly attracted to one another. For gases under conditions of pressure and temperature such that $Z < 1$, the attractions are more important than the repulsions, and the molar volume is smaller than for an ideal gas because attractions tend to draw molecules together. To improve our model of a gas, we need to add to it that the molecules of a real gas exert attractive and repulsive forces on one another.

Real gases consist of atoms or molecules with intermolecular attractions and repulsions. Attractions have a longer range than repulsions. The compression factor is a measure of the strength and type of intermolecular forces. When $Z > 1$, intermolecular repulsions are dominant; when $Z < 1$, attractions are dominant.

4.13 The Liquefaction of Gases

As described in Section 4.12, at low temperatures, molecules of a real gas move so slowly that intermolecular attractions may result in one molecule being captured by others and sticking to them instead of moving freely. When the temperature falls below the boiling point of the substance, the gas condenses to a liquid (Fig. 4.30).

Gases can also be liquefied by making use of the relation between temperature and molecular speed. Because lower average speed corresponds to lower temperature, slowing the molecules is equivalent to cooling the gas. The molecules of a real gas can be slowed by making use of the attractions between them and allowing the gas to expand: the molecules have to climb away from one another's attractive forces when a gas expands, rather like a ball rising up above the surface of the Earth against the pull of gravity (Fig. 4.31). Therefore, allowing the gas to occupy a larger volume, and hence increasing the average separation of the molecules, results in the molecules having a lower average speed. In other words, provided attractive effects are dominant, a real gas cools as it expands. This observation is called the **Joule–Thomson effect** in honor of the scientists who first studied it, James Joule and William Thomson (later to become Lord Kelvin), the inventor of the absolute temperature scale.

Exceptions are helium and hydrogen, which have very weak attractive interactions and relatively strong repulsive interactions; at room temperature, they get warmer as they expand.

The Joule–Thomson effect is used in some commercial refrigerators to liquefy gases. The gas to be liquefied is compressed and then allowed to expand through a small hole, called the throttle. The gas cools as it expands, and the cooled gas circulates past the incoming compressed gas (Fig. 4.32). This contact cools the incoming gas before it expands and cools still further. As the gas is continually recompressed and recirculated, its temperature progressively falls until finally it condenses to a liquid. If the gas is a mixture, such as air, then the liquid that it forms can later be distilled to separate its components. This technique is used for harvesting nitrogen, oxygen, neon, argon, krypton, and xenon from the atmosphere.

Many gases can be liquefied by making use of the Joule–Thomson effect, cooling brought about by expansion.

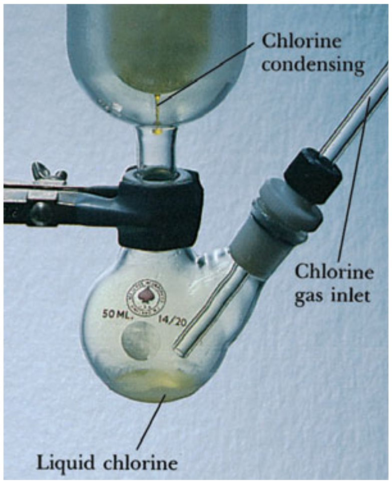

FIGURE 4.30 Chlorine can be condensed to a liquid at atmospheric pressure by cooling it to −35°C or lower. Here chlorine gas is introduced to the lower flask. The upper flask contains a "cold finger," a smaller tube filled with dry ice in acetone at −78°C, on which the chlorine condenses.

4.14 Equations of State of Real Gases

How do we describe the behavior of real gases that do not obey the ideal gas law? A common procedure in chemistry is to suppose that the term on the right-hand side of an equation (such as nRT in $PV = nRT$ of the ideal gas law) is just the leading (and predominant) term of a more complicated expression. Thus, to extend the ideal gas law to real gases, one procedure is to write

$$PV = nRT\left(1 + \frac{B}{V_m} + \frac{C}{V_m^{\,2}} + \cdots\right) \quad (24)$$

This expression is called the **virial equation.** The coefficients B, C, . . . are called the **second virial coefficient, third virial coefficient,** and so on. The virial coefficients, which depend on the temperature, are found by fitting experimental data to the virial equation.

Although the virial equation can be used to make accurate predictions about the properties of a real gas, provided that the virial coefficients are known for the temperature of interest, it is not a source of much insight without a lot of advanced analysis. An equation that is less accurate but easier to interpret was proposed by the Dutch scientist Johannes van der Waals. The **van der Waals equation** is

$$\left(P + a\frac{n^2}{V^2}\right)(V - nb) = nRT \quad (25)$$

The temperature-independent **van der Waals parameters** a and b are unique for each gas and are determined experimentally (Table 4.5). Parameter a represents the role of *attractions*; so it is relatively large for molecules that attract each other strongly and for large molecules with many electrons. Parameter b represents the role of *repulsions*; it can be thought of as representing the volume of an individual molecule (more precisely, the volume per mole of molecules), because it is the repulsive forces between molecules that prevent one molecule from occupying the space already occupied by another molecule.

The roles of the parameters become clearer when we write the compression factor as

$$Z = \frac{V/n}{RT/P} = \frac{PV}{nRT}$$

and substitute the van der Waals' expression for P, which is obtained by dividing each side by $V - nb$ and then subtracting an^2/V^2 from both sides:

$$P = \frac{nRT}{V - nb} - a\frac{n^2}{V^2} \quad (26)$$

We obtain

$$Z = \frac{V}{nRT} \times \left(\frac{nRT}{V - nb} - a\frac{n^2}{V^2}\right) = \frac{V}{V - nb} - \frac{an}{RTV}$$

TABLE 4.5 Van der Waals Parameters

Gas	a ($L^2 \cdot atm \cdot mol^{-2}$)	b (10^{-2} $L \cdot mol^{-1}$)
ammonia	4.169	3.71
argon	1.337	3.20
benzene	18.57	11.93
carbon dioxide	3.610	4.29
chlorine	6.260	5.42
ethane	5.507	6.51
hydrogen	0.2420	2.65
hydrogen sulfide	4.484	4.34
oxygen	1.364	3.19
water	5.464	3.05

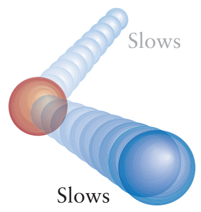

FIGURE 4.31 Cooling by the Joule–Thomson effect can be visualized as a slowing of the molecules (here shown blue) as they climb away from each other (in this case, from the one shown red) against the force of attraction between them.

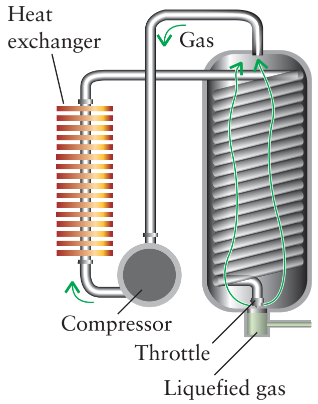

FIGURE 4.32 A Linde refrigerator for liquefying gases. The compressed gas gives up heat to the surroundings in the heat exchanger (left) and passes through the coil (right). The gas is cooled still further by the Joule–Thomson effect as it emerges through the throttle. This gas cools the incoming gas and is recirculated through the system. Eventually, the temperature of the incoming gas is so low that it condenses to a liquid.

The name "virial" comes from the Latin word meaning "force."

When we divide the numerator and denominator of the first term on the right of the final expression by V we obtain

$$Z = \frac{1}{1 - nb/V} - \frac{an}{RTV} \qquad (27)$$

What does this equation tell us? For an ideal gas, a and b are both zero, and $Z = 1$. We see that $Z > 1$ when the attractive contribution (a) is small so the second term on the right can be neglected and the repulsive contribution (b) is appreciable, so the denominator in the first term is less than 1 and the term itself is greater than 1. Conversely, $Z < 1$ when the repulsive contribution is weak (b is small) and the attractive interaction is strong (a is large), so the first term on the right is close to 1 and the second term on the right subtracts significantly from it.

The values of a and b for a gas are found experimentally by fitting this expression for Z to curves like those in Fig. 4.28. Once the parameters have been determined, they can be used in the van der Waals equation to predict the pressure of the gas under the conditions of interest.

EXAMPLE 4.9 Estimating the pressure of a real gas

Investigators are studying the physical properties of a gas to be used as a refrigerant in an air-conditioning unit. A table of van der Waals parameters shows that for this gas $a = 16.2\ \text{L}^2\cdot\text{atm}\cdot\text{mol}^{-2}$ and $b = 8.4 \times 10^{-2}\ \text{L}\cdot\text{mol}^{-1}$. Estimate the pressure of the gas when 1.50 mol occupies 5.00 L at 0°C.

Anticipate In most gases under normal conditions, the attractive interaction dominates the repulsive (the clue is in Fig. 4.28, which shows that the compression factor is less than 1 at low pressures for most gases). So, we should suspect that the pressure we calculate will be less than that based on an ideal gas, but small, because real gases typically show only small deviations from ideal behavior.

PLAN Substitute the data into Eq. 26 after converting the temperature into the Kelvin scale, if necessary. Use R in units that match those given.

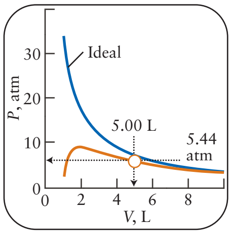
SOLVE

From $P = nRT/(V - nb) - an^2/V^2$,

$$P = \frac{(1.50\ \text{mol}) \times (0.082\,06\ \text{L}\cdot\text{atm}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}) \times (273\ \text{K})}{5.00\ \text{L} - (1.50\ \text{mol}) \times (8.4 \times 10^{-2}\ \text{L}\cdot\text{mol}^{-1})} - (16.2\ \text{L}^2\cdot\text{atm}\cdot\text{mol}^{-2}) \times \frac{(1.50\ \text{mol})^2}{(5.00\ \text{L})^2}$$

$$= \frac{1.50 \times (0.082\,06\ \text{atm}) \times 273}{500 - 1.50 \times 8.4 \times 10^{-2}} - (16.2\ \text{atm}) \times \frac{(1.50)^2}{(5.00)^2}$$

$$= 5.44\ \text{atm}$$



Evaluate An ideal gas under the same circumstances has a pressure of 6.72 atm, so the "real" pressure (at least, as calculated from the van der Waals equation) of 5.44 atm is smaller, as we anticipated.

Self-Test 4.17A A 10.0-L tank containing 25 mol O_2 is stored in a diving supply shop at 25°C. Use the data in Table 4.5 and the van der Waals equation to estimate the pressure in the tank.

[*Answer:* 58 atm]

Self-Test 4.17B The properties of carbon dioxide gas are well known in the bottled beverage industry. In an industrial process, a tank of volume 100. L at 20.°C contains 20. mol CO_2. Use the data in Table 4.5 and the van der Waals equation to estimate the pressure in the tank.

We have arrived at our final model. By drawing on a wide range of experimental information, we now visualize a gas as a large number of molecules in ceaseless, random motion. The average speed—and the spread of speeds—of the molecules increases with temperature and decreases with molar mass. Because the average separation of the molecules is so great, intermolecular forces have only a weak effect on the properties of a gas, and the molecules travel in straight lines until they collide with other molecules or with the walls of the container. However, the intermolecular forces are not completely negligible, and repulsions increase the molar volume (at a given temperature and pressure), whereas attractions decrease the molar volume. Which effect dominates in a real gas depends on the relative strengths of the two kinds of interactions.

The virial equation is a general equation for describing real gases. The van der Waals equation is an approximate equation of state for a real gas; the parameter a represents the role of attractive forces and the parameter b represents the role of repulsive forces.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Calculate the pressure at the foot of a column of liquid (Example 4.1).

❑ 2 Interpret a manometer reading (Self-Test 4.2).

❑ 3 Use the gas laws to calculate P, V, T, or n for given conditions or after a change in conditions (Toolbox 4.1 and Examples 4.2–4.4).

❑ 4 Determine molar mass from gas density and vice versa (Example 4.5).

❑ 5 Calculate the mass or volume of reactant needed to react with a specified volume of gas (Example 4.6).

❑ 6 Calculate the partial pressures of gases in a mixture and the total pressure of the mixture (Example 4.7).

❑ 7 Use Graham's law to account for relative rates of effusion (Self-Test 4.15).

❑ 8 Describe the effect of temperature on average speed (Section 4.9).

❑ 9 List and explain the assumptions of the kinetic model of gases (Section 4.10).

❑ 10 Calculate the root mean square speed of molecules in a sample of gas (Example 4.8).

❑ 11 Describe the effect of molar mass and temperature on the Maxwell distribution of molecular speeds (Section 4.11).

❑ 12 Explain how real gases differ from ideal gases (Sections 4.12–4.14).

❑ 13 Use the van der Waals equation to estimate the pressure of a gas (Example 4.9).

EXERCISES

The Nature of Gases

4.1 The pressure needed to make synthetic diamonds from graphite is 8×10^4 atm. Express this pressure in (a) Pa; (b) kbar; (c) Torr; (d) lb·inch^{-2}.

4.2 The pressure recorded for an argon gas cylinder is 44.0 lb·inch^{-2}. Convert this pressure into (a) kPa; (b) Torr; (c) bar; (d) atm.

4.3 A student attaches a glass bulb containing neon gas to an open-tube manometer (refer to Fig. 4.5) and calculates the pressure of the gas to be 0.890 atm. (a) If the atmospheric pressure is 762 Torr, what height difference between the two sides of the mercury in the manometer did the student find? (b) Which side is higher, the side of the manometer attached to the bulb or the side open to the atmosphere? (c) If the student mistakenly switches the numbers for the sides of the manometer when recording the data in the laboratory notebook, what would be the reported pressure in the gas bulb?

4.4 A reaction is performed in a vessel attached to a closed-tube manometer. Before the reaction, the levels of mercury in the two sides of the manometer were at the same height. As the reaction proceeds, a gas is produced. At the end of the reaction, the height of the mercury column on the vacuum side of the manometer has risen 30.74 cm and the height on the side of the manometer connected to the flask has fallen by the same amount. What is the pressure in the apparatus at the end of the reaction expressed in (a) Torr; (b) atm; (c) Pa; (d) bar?

4.5 Suppose you were marooned on a tropical island and had to use seawater (density 1.10 g·cm^{-3}) to make a primitive barometer. What height would the water reach in your barometer when a mercury barometer would reach 73.5 cm? The density of mercury is 13.6 g·cm^{-3}.

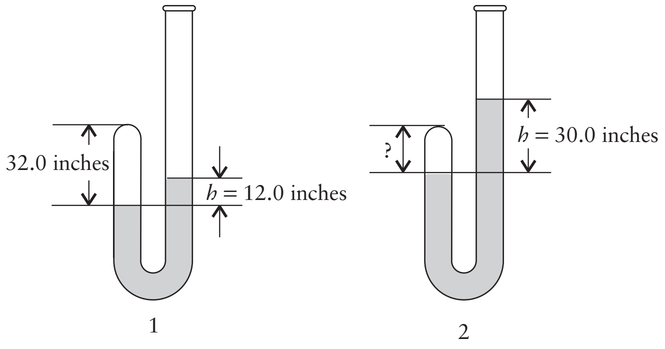
4.6 An unknown liquid is used to fill a closed-tube manometer. The atmosphere is found to produce a height difference of 6.14 m in this manometer at the same time that a mercury manometer gives a displacement of 758.7 mm. What is the density of the unknown liquid?

4.7 Assume that the width of your body (across your shoulders) is 20. inches and the depth of your body (chest to back) is 10. inches. If atmospheric pressure is 14.7 lb·inch^{-2}, what mass of air does your body support when you are in an upright position?

4.8 Low-pressure gauges in research laboratories are occasionally calibrated in inches of water (inH_2O). Given that the density of mercury at 15°C is 13.5 g·cm^{-3} and the density of water at that temperature is 1.0 g·cm^{-3}, what is the pressure (in Torr) inside a gas cylinder that reads 8.9 inH_2O at 15°C?

The Gas Laws

4.9 When Robert Boyle conducted his experiments, he measured pressure in inches of mercury (inHg). On a day when the atmospheric pressure was 29.85 inHg, he trapped some air in the tip of a J-tube (**1**) and measured the difference in height of the mercury in the two arms of the tube (h). When $h = 12.0$ inches, the height of the gas in the tip of the tube was 32.0 in. Boyle then added additional mercury and the level rose in both arms of the tube so that $h = 30.0$ inches (**2**). (a) What was the height of the air space (in inches) in the tip of the tube in (**2**)? (b) What was the pressure of the gas in the tube in (**1**) and in (**2**) in inHg?



4.10 Boyle continued to add mercury to the apparatus in Exercise 4.9 until the height of the trapped air had been reduced to 6.85 inches. Assuming that atmospheric pressure had not changed, what was the pressure of the trapped air at that point (in inHg)?

4.11 The following data were collected for a gas sample consisting of 1.00 mol of molecules in a rigid container. (a) Determine the volume of the sample. (b) Plot the data either by hand or using a computer spreadsheet program. Now suppose you add an additional 1.00 mol of gas molecules into the same volume. Plot the corresponding line for the second sample. (c) At what temperature (in kelvins) would the two lines intersect?

Temperature (°C)	Pressure (atm)
0	1.12
20	1.20
40	1.28
60	1.36
80	1.45

4.12 The following data were collected for a gas sample consisting of 5.00 mol of molecules in a rigid container. (a) Determine the volume of the sample. (b) Plot the data either by hand or using a computer spreadsheet program. Now suppose you add another 5.00 mol of gas molecules into the same volume. Plot the corresponding line for the second sample. (c) At what temperature (in kelvins) would the two lines intersect?

Temperature (°C)	Pressure (atm)
0	4.48
20	4.80
40	5.14
60	5.46
80	5.80

4.13 (a) A 350.0-mL flask contains 0.1500 mol Ar at 24°C. What is the pressure of the gas in kilopascals? (b) You are told that 23.9 mg of bromine trifluoride exerts a pressure of 10.0 Torr at 100.°C. What is the volume of the container in milliliters? (c) A 100.0-mL flask contains sulfur dioxide at 0.77 atm and 30.°C. What mass of gas is present? (d) A storage tank of volume 6.00×10^3 m^3 contains methane at 129 kPa and 14°C. How many moles of CH_4 are present? (e) A 1.0-μL ampoule of helium has a pressure of 2.00 kPa at −115°C. How many He atoms are present?

4.14 (a) A 125-mL flask contains argon at 1.30 atm and 77°C. What amount of Ar is present (in moles)? (b) A 120.-mL flask contains 2.7 μg of O_2 at 17°C. What is the pressure (in Torr)? (c) A 20.0-L flask at 215 K and 20. Torr contains nitrogen. What mass of nitrogen is present (in grams)? (d) A 16.7-g sample of krypton exerts a pressure of 1.00×10^2 mTorr at 44°C. What is the volume of the container (in liters)? (e) A 2.6-μL ampoule of xenon has a pressure of 2.00 Torr at 15°C. How many Xe atoms are present?

4.15 (a) Using the Living Graphs on the Web site for this book, prepare and print a single plot of the pressure against temperature for 1.00 mol of gas molecules, showing the curves at volumes ranging from 0.01 L to 0.05 L in increments of 0.01 L for $T = 0$ to 400 K. (b) What is the expression for the slope of each of these lines? (c) What is each intercept? Give your answers to two decimal places.

4.16 (a) Using the Living Graphs on the Web site for this book, prepare and print a single plot of the volume against temperature graph for 1.00 mol of gas molecules, showing the curves at pressures ranging from 11 000 atm to 15 000 atm in increments of 1000 atm for $T = 0$ to 400 K. (b) What is the expression for the slope of each of these lines? (c) What is each intercept? Give your answers to two decimal places.

4.17 Determine the final pressure when (a) 7.50 mL of krypton at 2.00×10^5 kPa is transferred to a vessel of volume 1.0 L; (b) 54.2 cm^3 of O_2 at 643 Torr is compressed to 7.8 cm^3. Assume constant temperature.

4.18 (a) Suppose that 4.00 L of methane at a pressure of 800. Torr is transferred to a vessel of volume 2.40 L. What is the final pressure of methane if the change occurs at constant temperature? (b) A fluorinated organic gas in a cylinder is compressed from an initial volume of 936 mL at 158 Pa to 468 mL at the same temperature. What is the final pressure?

4.19 A 250.-mL aerosol can at 25°C and 1.10 atm was thrown into an incinerator. When the temperature in the can reached 712°C, it exploded. What was the pressure in the can just before it exploded, assuming it reached the maximum pressure possible at that temperature?

4.20 An outdoor storage vessel for hydrogen gas with a volume of 300. m^3 is at 1.5 atm and 10.°C at 2:00 AM. By 2:00 PM, the temperature has risen to 30.°C. What is the new pressure of the hydrogen in the vessel?

4.21 A helium balloon has a volume of 12.4 L when the pressure is 0.885 atm and the temperature is 22°C. The balloon is cooled at a constant pressure until the temperature is −18°C. What is the volume of the balloon at this stage?

4.22 A chemist prepares a sample of hydrogen bromide and finds that it occupies 250. mL at 65°C and 500. Torr. What volume would it occupy at 0°C at the same pressure?

4.23 A chemist prepares 0.100 mol Ne gas at a certain pressure and temperature in an expandable container. Another 0.010 mol Ne is then added to the same container. How must the volume be changed to keep the pressure and temperature the same?

4.24 A chemist prepares a sample of helium gas at a certain pressure, temperature, and volume and then removes half the gas molecules. How must the temperature be changed to keep the pressure and volume the same?

4.25 A sample of methane gas, CH_4, was slowly heated at a constant pressure of 0.90 bar. The volume of the gas was measured at a series of different temperatures and a plot of volume vs. temperature was constructed. The slope of the line was 2.88×10^{-4} L·K^{-1}. What was the mass of the sample of methane?

4.26 A sample of butane gas, C_4H_{10}, was slowly heated at a constant pressure of 0.80 bar. The volume of the gas was measured at a series of different temperatures and a plot of volume vs. temperature was constructed. The slope of the line was 0.0208 L·K^{-1}. What was the mass of the sample of butane?

4.27 You are told that 35.5 mL of xenon exerts a pressure of 0.255 atm at −45°C. (a) What volume does the sample occupy at 1.00 atm and 298 K? (b) What pressure would it exert if it were transferred to a flask of volume 12.0 mL at 20.°C? (c) Calculate the temperature needed for the xenon to exert a pressure of 5.00×10^2 Torr in the flask.

4.28 A lungful of air (355 cm^3) is exhaled into a machine that measures lung capacity. If the air is exhaled from the lungs at a pressure of 1.08 atm at 37°C but the machine is at ambient conditions of 0.958 atm and 23°C, what is the volume of air measured by the machine?

4.29 What is the molar volume of an ideal gas at 1.00 atm and (a) 500.°C; (b) at the normal boiling point of liquid nitrogen (−196°C)?

4.30 What is the molar volume of an ideal gas at 1.00 atm and (a) 212°F; (b) at the normal sublimation point of dry ice (−78.5°C)?

4.31 Originally at −20.°C and 759 Torr, a 1.00-L sample of air is heated to 235°C. Next, the pressure is increased to 765 Torr. Then it is heated to 1250.°C, and finally the pressure is decreased to 252 Torr. What is the final volume of the air?

4.32 A domestic water-carbonating kit uses steel cylinders of carbon dioxide, each with a volume of 250. mL. Each weighs 1.04 kg when full and 0.74 kg when empty. What is the pressure of gas (in bar) in a full cylinder at 20.°C?

4.33 The effect of high pressure on organisms, including humans, is studied to gain information about deep-sea diving and anesthesia. A sample of air occupied 1.00 L at 25°C and 1.00 atm. What pressure (in atm) is needed to compress it to 239 cm^3 at this temperature?

4.34 To what temperature must a sample of helium gas be cooled from 127.0°C to reduce its volume from 4.60 L to 0.115 L at constant pressure?

4.35 The "air" in the space suit of astronauts is actually pure oxygen supplied at a pressure of 0.30 bar. The two tanks on a space suit each have a volume of 3980. cm^3 and have an initial pressure of 5860. kPa. Assuming a tank temperature of 16°C, what mass of oxygen is contained in the two tanks?

4.36 A balloon vendor has a 20.0 L helium tank under 150 atm pressure at 25°C. How many balloons of 2.50 L each can be filled at 1.0 atm by the helium in this tank?

4.37 Nitrogen monoxide, NO, has been found to act as a neurotransmitter. To prepare to study its effect, a sample was collected in a container of volume 250.0 mL. At 19.5°C, its pressure in this container is found to be 24.5 kPa. What amount (in moles) of NO has been collected?

4.38 Hot-air balloons gain their lift from the reduction in the density of air that occurs when the air in the envelope is heated. To what temperature should you heat a sample of air, initially at 340. K, to increase its volume by 14%?

4.39 At sea level, where the pressure was 104 kPa and the temperature 21.1°C, a certain mass of air occupied 2.0 m^3. To what volume will the air mass expand when it has risen to an altitude where the pressure and temperature are (a) 52 kPa, −5.0°C; (b) 880. Pa, −52.0°C?

4.40 A meteorological balloon had a radius of 1.0 m when released at sea level at 20.°C. It expanded to a radius of 3.0 m when it had risen to its maximum altitude, where the temperature was −20.°C. What was the pressure inside the balloon at that altitude?

Gas Density

4.41 Order the following gases according to increasing density: CO; CO_2; H_2S. The temperature and pressure are the same for all three samples.

4.42 Order the following gases according to increasing density: N_2; NH_3; NO_2. The temperature and pressure are the same for all three samples.

4.43 A 2.00-mg sample of argon is confined to a 0.0500-L vial at 20.°C; 2.00 mg of krypton is confined to a different 0.0500-L vial. What must the temperature of the krypton be if it is to have the same pressure as the argon?

4.44 What mass of ammonia will exert the same pressure as 12 mg of hydrogen sulfide, H_2S, in the same container under the same conditions?

4.45 What is the density (in g·L^{-1}) of chloroform, $CHCl_3$, vapor at (a) 2.00×10^2 Torr and 298 K; (b) 100.°C and 1.00 atm?

4.46 What is the density (in g·L^{-1}) of hydrogen sulfide, H_2S, at (a) 1.00 atm and 298 K; (b) 45.0°C and 0.876 atm?

4.47 A gaseous fluorinated methane compound has a density of 8.0 g·L^{-1} at 2.81 atm and 300. K. (a) What is the molar mass of the compound? (b) What is the formula of the compound if it is composed solely of C, H, and F? (c) What is the density of the gas at 1.00 atm and 298 K?

4.48 The density of a gaseous compound of phosphorus is 0.943 g·L^{-1} at 420. K when its pressure is 727 Torr. (a) What is the molar mass of the compound? (b) If the compound remains gaseous, what would be its density at 1.00 atm and 298 K?

4.49 A compound used in the manufacture of Saran is 24.7% C, 2.1% H, and 73.2% Cl by mass. The storage of 3.557 g of the gaseous compound in a 755-mL vessel at 0°C results in a pressure of 1.10 atm. What is the molecular formula of the compound?

4.50 The analysis of a hydrocarbon revealed that it was 85.7% C and 14.3% H by mass. When 1.77 g of the gas was stored in a

1.500-L flask at 17°C, it exerted a pressure of 508 Torr. What is the molecular formula of the hydrocarbon?

4.51 The density of a gaseous compound was found to be $0.943\ g{\cdot}L^{-1}$ at 298 K and 53.1 kPa. What is the molar mass of the compound?

4.52 A 115-mg sample of eugenol, the compound responsible for the odor of cloves, was placed in an evacuated flask with a volume of 500.0 mL at 280.0°C. The pressure that eugenol exerted in the flask under those conditions was found to be 48.3 Torr. In a combustion experiment, 18.8 mg of eugenol burned to give 50.0 mg of carbon dioxide and 12.4 mg of water. What is the molecular formula of eugenol?

The Stoichiometry of Reacting Gases

4.53 The Haber process for the synthesis of ammonia is one of the most significant industrial processes for the well-being of humanity. It is used extensively in the production of fertilizers as well as polymers and other products. (a) What volume of hydrogen at 15.00 atm and 350.°C must be supplied to produce 1.0 tonne ($1\ t = 10^3\ kg$) of NH_3? (b) What volume of hydrogen is needed in part (a) if it is supplied at 376 atm and 250.°C?

4.54 Nitroglycerin is a shock-sensitive liquid that detonates by the reaction

$$4\ C_3H_5(NO_3)_3(l) \longrightarrow 6\ N_2(g) + 10\ H_2O(g) + 12\ CO_2(g) + O_2(g)$$

Calculate the total volume of product gases at 215 kPa and 275°C from the detonation of 1.00 lb (454 g) of nitroglycerin.

4.55 Which starting condition would produce the larger volume of carbon dioxide by combustion of $CH_4(g)$ with an excess of oxygen gas to produce carbon dioxide and water: (a) 2.00 L of $CH_4(g)$; (b) 2.00 g of $CH_4(g)$? Justify your answer. The system is maintained at a temperature of 75°C and 1.00 atm.

4.56 Which starting condition would produce the larger volume of carbon dioxide by combustion of $C_2H_4(g)$ with an excess of oxygen gas to produce carbon dioxide and water: (a) 1.00 L of $C_2H_4(g)$; (b) 1.20 g of $C_2H_4(g)$? Justify your answer. The system is maintained at a temperature of 45°C and 2.00 atm.

4.57 Through a series of enzymatic steps, carbon dioxide and water undergo photosynthesis to produce glucose and oxygen according to the equation

$$6\ CO_2(g) + 6\ H_2O(l) \longrightarrow C_6H_{12}O_6(s) + 6\ O_2(g)$$

Given that the partial pressure of carbon dioxide in the troposphere is 0.26 Torr and that the temperature is 25°C, calculate the volume of air needed to produce 10.0 g of glucose.

4.58 The naturally occurring compound urea, $CO(NH_2)_2$, was first synthesized by Friedrich Wöhler in Germany in 1828 by heating ammonium cyanate. This synthesis was a significant event because it was the first time that an organic compound had been produced from an inorganic substance. Urea may also be made by the reaction of carbon dioxide and ammonia:

$$CO_2(g) + 2\ NH_3(g) \longrightarrow CO(NH_2)_2(s) + H_2O(g)$$

What volumes of CO_2 and NH_3 at 200. atm and 450.°C are needed to produce 2.50 kg of urea, assuming the reaction goes to completion?

4.59 A 15.0-mL sample of ammonia gas at 1.00×10^2 Torr and 30.°C is mixed with 25.0 mL of hydrogen chloride gas at 1.50×10^2 Torr and 25°C, and the following reaction takes place:

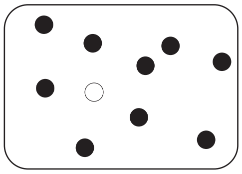
$$NH_3(g) + HCl(g) \longrightarrow NH_4Cl(s)$$

(a) Calculate the mass of NH_4Cl that forms. (b) Identify the gas in excess and determine the pressure of the excess gas at 27°C after the reaction is complete (in the combined volume of the original two flasks).

4.60 A sample of ethene gas, C_2H_4, of volume 1.00 L at 1.00 atm and 298 K is burned in 4.00 L of oxygen gas to form carbon dioxide gas and liquid water at the same pressure and temperature. Ignore the volume of water, and determine the final volume of the reaction mixture (including any excess reactant) at 1.00 atm and 298 K if the reaction goes to completion.

Mixtures of Gases

4.61 A sample of hydrogen chloride gas, HCl, is being collected by bubbling it through liquid benzene into a graduated cylinder. Assume that the molecules pictured as spheres show a representative sample of the mixture of HCl and benzene vapor (● represents an HCl molecule and ○ a benzene molecule). (a) Use the figure to determine the mole fractions of HCl and benzene vapor in the gas inside the container. (b) What are the partial pressures of HCl and benzene in the container when the total pressure inside the container is 0.80 atm?



4.62 A piece of lithium metal was added to a flask of water on a day when the atmospheric pressure was 757.5 Torr. The lithium reacted completely with the water to produce 250.0 mL of hydrogen gas, collected over the water at 23°C, at which temperature the vapor pressure of water is 21.07 Torr. (a) What is the partial pressure of hydrogen in the collection flask? (b) What mass of lithium metal reacted?

4.63 A vessel of volume 22.4 L contains 2.0 mol $H_2(g)$ and 1.0 mol $N_2(g)$ at 273.15 K. Calculate (a) their partial pressures and (b) the total pressure.

4.64 An apparatus consists of a 4.0-L flask containing nitrogen gas at 25°C and 803 kPa, joined by a valve to a 10.0-L flask containing argon gas at 25°C and 47.2 kPa. The valve is opened and the gases mix. (a) What is the partial pressure of each gas after mixing? (b) What is the total pressure of the gas mixture?

4.65 A 1.00-L flask contains nitrogen gas at a temperature of 15°C and a pressure of 0.50 bar. 0.10 mol $O_2(g)$ is added to the flask and allowed to mix. Then a stopcock is opened to allow 0.020 mol of molecules to escape. What is the partial pressure of oxygen in the final mixture?

4.66 A gas mixture being used to simulate the atmosphere of another planet consists of 320. mg of methane, 175 mg of argon, and 225 mg of nitrogen. The partial pressure of nitrogen at 300. K is 15.2 kPa. Calculate (a) the total pressure of the mixture and (b) the volume.

4.67 In the course of the electrolysis of water, hydrogen gas was collected at one electrode over water at 20.°C when the external pressure was 756.7 Torr. The vapor pressure of water at 20.°C is 17.54 Torr. The volume of the gas was measured to be 0.220 L. (a) What is the partial pressure of hydrogen? (b) The other product of the electrolysis of water is oxygen gas. Write a balanced equation for the electrolysis of water into H_2 and O_2. (c) What mass of oxygen was also produced in the reaction?

4.68 Dinitrogen oxide, N_2O, gas was generated from the thermal decomposition of ammonium nitrate and collected over water. The wet gas occupied 126 mL at 21°C when the atmospheric pressure was 755 Torr. What volume would the same amount of *dry* dinitrogen oxide have occupied if collected at 755 Torr and 21°C? The vapor pressure of water is 18.65 Torr at 21°C.

Molecular Motion

4.69 Do all the molecules of a gas strike the walls of their container with the same force? Justify your answer on the basis of the kinetic model of gases.

4.70 How does the frequency of collisions of the molecules of a gas with the walls of the container change as the volume of the gas is decreased at constant temperature? Justify your answer on the basis of the kinetic model of gases.

4.71 What is the molecular formula of a compound of empirical formula CH that diffuses 1.24 times more slowly than krypton at the same temperature and pressure?

4.72 What is the molar mass of a compound that takes 2.7 times as long to effuse through a porous plug as it did for the same amount of XeF_2 at the same temperature and pressure?

4.73 A sample of argon gas effuses through a porous plug in 147 s. Calculate the time required for the same amount of (a) CO_2, (b) C_2H_4, (c) H_2, and (d) SO_2 to effuse under the same conditions of pressure and temperature.

4.74 A sample of neon gas effuses through a porous plug in 85.3 s. Calculate the time required for the same amount of (a) CH_2O, (b) C_3H_8, (c) He, and (d) NO_2 to effuse under the same conditions of pressure and temperature.

4.75 A hydrocarbon of empirical formula C_2H_3 takes 349 s to effuse through a porous plug; under the same conditions of temperature and pressure, it took 210. s for the same number of molecules of argon to effuse. What is the molar mass and molecular formula of the hydrocarbon?

4.76 The composition of a compound used to make polyvinyl chloride (PVC) is 38.4% C, 4.82% H, and 56.8% Cl by mass. It took 7.73 min for a given volume of the compound to effuse through a porous plug, but it took only 6.18 min for the same amount of Ar to diffuse at the same temperature and pressure. What is the molecular formula of the compound?

4.77 Calculate the molar kinetic energy (in joules per mole) of Kr(g) at (a) 55.85°C and (b) 54.85°C. (c) The difference between the answers to parts (a) and (b) is the energy per mole that it takes to raise the temperature of Kr(g) by 1.00°C. The quantity is known as the molar heat capacity. What is its value?

4.78 Calculate the molar kinetic energy (in joules per mole) of a sample of Ne(g) at (a) 25.00°C and (b) 26.00°C. (c) The difference between the answers to parts (a) and (b) is the energy per mole that it takes to raise the temperature of Ne(g) by 1°C. The quantity is known as the molar heat capacity. What is its value?

4.79 Calculate the root mean square speeds of (a) methane, (b) ethane, and (c) propane molecules, all at −20.°C.

4.80 Calculate the root mean square speed of (a) fluorine gas, (b) chlorine gas, and (c) bromine gas molecules, all at 350.°C.

4.81 The root mean square speed of gaseous methane molecules, CH_4, at a certain temperature was found to be 550. $m\cdot s^{-1}$. What is the root mean square speed of krypton atoms at the same temperature?

4.82 In an experiment on gases, you are studying a 1.00-L sample of hydrogen gas at 20°C and 2.40 atm. You heat the gas until the root mean square speed of the molecules of the sample has been doubled. What will be the final pressure of the gas?

4.83 A bottle contains 1.0 mol He(g) and a second bottle contains 1.0 mol Ar(g) at the same temperature. At that temperature, the root mean square speed of He is 1477 $m\cdot s^{-1}$ and that of Ar is 467 $m\cdot s^{-1}$. What is the ratio of the number of He atoms in the first bottle to the number of Ar atoms in the second bottle having these speeds? Assume that both gases behave ideally.

C 4.84 The number of molecules in a gas sample that have the most probable speed (v_{mp}) at a temperature T is one-half the number of the same type of molecules that have the most probable speed at 300. K. What is the temperature?

4.85 (a) From the graph of Maxwell distribution of speeds in Fig. 4.27, find the location that represents the most probable speed of the molecules at each temperature. (b) What happens to the percentage of molecules having the most probable speed as the temperature increases?

4.86 A scientist is investigating a sample of 1.00 mol He(g) in a large cylinder at 200. K. Calculate by what factor each of the following variables would change the pressure of the gas and its root mean square speed: (a) The gas is compressed into a third of its original volume. (b) The temperature is reduced to 100. K. (c) The helium is replaced by the same amount of xenon.

Real Gases

4.87 The pressure of a sample of hydrogen fluoride is lower than expected and, as the temperature is increased, rises more quickly than the ideal gas law predicts. Suggest an explanation.

4.88 Under what conditions would you expect a real gas to be (a) more compressible than an ideal gas; (b) less compressible than an ideal gas?

4.89 Two identical flasks are each filled with a gas at 20°C and 100 atm. One flask contains 1 mol NH_3 and the other 1 mol H_2. (a) In which flask do the molecules have the greater root mean square speed? (b) In which flask are the attractions between the molecules the stronger? Explain your reasoning.

4.90 Two identical flasks are each filled with a gas at 20°C and 100 atm. One flask contains 1 mol NH_3 and the other 1 mol H_2. (a) In which flask do the molecules have more collisions per second with the walls of the container? (b) For each flask predict whether the pressure will be higher or lower than predicted by the ideal gas law. Explain your reasoning.

4.91 Using the ideal gas equation, calculate the pressure at 298 K exerted by 1.00 mol CO_2(g) when confined in a volume of (a) 15.0 L; (b) 0.500 L; (c) 50.0 mL. Repeat these calculations with the use of the van der Waals equation. What do these calculations indicate about how the reliability of the ideal gas law depends on the pressure?

4.92 Using the ideal gas equation, calculate the pressure at 298 K exerted by 1.00 mol H_2(g) when confined in a volume of (a) 30.0 L; (b) 1.00 L; (c) 50.0 mL. Repeat these calculations with the use of the van der Waals equation. What do these calculations indicate about how the reliability of the ideal gas law depends on the pressure?

4.93 The following table lists the van der Waals *a* parameters for CO_2, CH_3CN, Ne, and CH_4. Use your knowledge of the factors governing the magnitudes of *a* to assign each of these four gases to its *a* value.

a ($L^2 \cdot atm \cdot mol^{-2}$)	Substance
17.58	________
3.392	________
2.253	________
0.2107	________

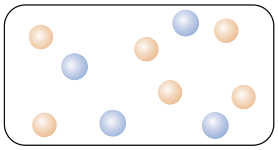
4.94 Calculate the pressure exerted by 1.00 mol C_2H_6(g) behaving as (a) an ideal gas; (b) a van der Waals gas when it is confined under the following conditions: (1) at 273.15 K in 22.414 L; (2) at 1.00×10^3 K in 0.100 L.

4.95 Plot pressure against volume for 1 mol of (a) an ideal gas, (b) ammonia, and (c) oxygen gas, for the range $V = 0.05$ L to 1.0 L at 298 K. Use the van der Waals equation to calculate the pressures of the two real gases. Use a spreadsheet or the graphical plotter on the Web site for this book. Compare the plots and explain the origin of any differences you find.

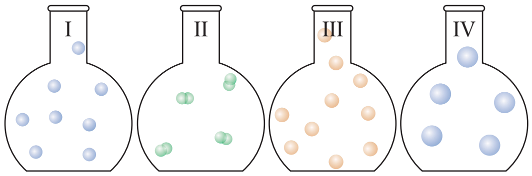
4.96 Plot pressure against volume for 1 mol of (a) an ideal gas, (b) carbon dioxide, (c) ammonia, and (d) benzene for the range $V = 0.1$ L to 1.0 L at 298 K. Use the van der Waals equation to determine the pressures of the real gases. Use a spreadsheet or the graphical plotter on the Web site for this book. Compare the shapes of the curves and explain the differences.

Integrated Exercises

4.97 The drawing below shows a tiny section of a flask containing two gases. The orange spheres represent atoms of neon and the blue spheres represent atoms of argon. (a) If the partial pressure of neon in this mixture is 420. Torr, what is the partial pressure of argon? (b) What is the total pressure?



4.98 The four flasks below were prepared with the same volume and temperature. Flask I contains He atoms, Flask II contains Cl_2 molecules, Flask III contains Ar atoms, and Flask IV contains NH_3 molecules. Which flask has (a) the largest number of atoms; (b) the highest pressure; (c) the greatest density; (d) the highest root mean square speed; (e) the highest molar kinetic energy?



4.99 The interhalogen compounds can be prepared by direct reaction of the elements. The following syntheses were carried out at 298 K and 1.00 atm. In each case, give the volume of product at the same temperature and pressure that can be produced from 2.00 mol F_2 and an excess of Cl_2: (a) $Cl_2(g) + F_2(g) \longrightarrow 2\ ClF(g)$; (b) $Cl_2(g) + 3\ F_2(g) \longrightarrow 2\ ClF_3(g)$; (c) $Cl_2(g) + 5\ F_2(g) \longrightarrow 2\ ClF_5(g)$.

4.100 Roommates fill ten balloons for a party, five with hydrogen and five with helium. After the party they notice that the hydrogen balloons have lost 1/4 of their hydrogen due to diffusion through the walls of the balloons. What fraction of helium will the other balloons have lost at that same time?

4.101 Photochemical smog is formed, in part, by the action of light on nitrogen dioxide. The wavelength of the radiation absorbed by NO_2 in this reaction is 197 nm.

$$NO_2 \xrightarrow{h\nu} NO + O$$

(a) Draw the Lewis structure for NO_2 and sketch its π molecular orbitals. (b) When 1.07 mJ of energy is absorbed by 2.5 L of air at 20.°C and 0.85 atm, all the NO_2 molecules in this sample are dissociated by the reaction just shown. Assume that each photon absorbed results in the dissociation (into NO and O) of one NO_2 molecule. What is the proportion, in parts per million, of NO_2 molecules in this sample? Assume that the sample is behaving ideally.

4.102 The reaction of solid dimethylhydrazine, $(CH_3)_2N_2H_2$, and liquefied dinitrogen tetroxide, N_2O_4, has been investigated as a rocket fuel; the reaction produces gaseous carbon dioxide (CO_2), nitrogen (N_2), and water vapor (H_2O), which are ejected as exhaust gases. In a controlled experiment, solid dimethylhydrazine reacted with excess nitrogen tetroxide and the gases were collected in a closed vessel until a pressure of 2.50 atm and a temperature of 400.0 K were reached. What are the partial pressures of CO_2, N_2, and H_2O?

4.103 Suppose that 200. mL of hydrogen chloride at 690. Torr and 20.°C is dissolved in 100. mL of water. The solution was titrated to the stoichiometric point with 15.7 mL of a sodium hydroxide solution. What is the molar concentration of the NaOH solution used for the titration?

4.104 Suppose that 2.00 L of propane gas, C_3H_8, at 1.00 atm and 298 K is mixed with 5.00 L of oxygen gas at the same pressure and temperature and burned to form carbon dioxide gas and liquid water. Ignore the volume of water formed, and determine the final volume of the reaction mixture (including products and excess reactant) at 1.00 atm and 298 K if reaction goes to completion.

4.105 A flask of volume 5.00 L is evacuated and 43.78 g of solid dinitrogen tetroxide, N_2O_4, is introduced at −196°C. The sample is then warmed to 25°C, during which time the N_2O_4 vaporizes and some of it dissociates to form brown NO_2 gas. The pressure slowly increases until it stabilizes at 2.96 atm. (a) Write a balanced equation for the reaction. (b) If the gas in the flask at 25°C were all N_2O_4, what would the pressure be? (c) If all the gas in the flask converted into NO_2, what would the pressure be? (d) What are the

mole fractions of N_2O_4 and NO_2 once the pressure stabilizes at 2.96 atm?

4.106 When 0.40 g of impure zinc reacted with an excess of hydrochloric acid, 127 mL of hydrogen was collected over water at 10.°C. The external pressure was 737.7 Torr. (a) What volume would the dry hydrogen occupy at 1.00 atm and 298 K? (b) What amount (in moles) of H_2 was collected? (c) What is the percentage purity of the zinc, assuming that all the zinc present reacted completely with HCl and that the impurities did not react with HCl to produce hydrogen? The vapor pressure of water at 10.°C is 9.21 Torr.

4.107 Suppose that 0.473 g of an unknown gas that occupies 200. mL at 1.81 atm and 25°C was analyzed and found to contain 0.414 g of nitrogen and 0.0591 g of hydrogen. (a) What is the molecular formula of the compound? (b) Draw the Lewis structure of the molecule. (c) If 0.35 mmol NH_3 effuses through a small opening in a glass apparatus in 15.0 min at 200.°C, what amount of the gas being studied will effuse through the same opening in 25.0 min at 200.°C?

4.108 When 2.36 g of phosphorus was burned in chlorine, the product was 10.5 g of a phosphorus chloride. Its vapor took 1.77 times as long to effuse as the same amount of CO_2 under the same conditions of temperature and pressure. What is the molar mass and molecular formula of the phosphorus chloride?

4.109 Determine the ratio of the number of molecules in a gas having a speed ten times as great as the root mean square speed to the number having a speed equal to the root mean square speed. Is this ratio independent of temperature? Explain your reasoning.

4.110 Air bags in automobiles contain crystals of sodium azide, NaN_3, which during a collision decomposes rapidly to give nitrogen gas and sodium metal. The nitrogen gas liberated by this process instantly inflates the air bag. Assume that the nitrogen gas liberated behaves as an ideal gas and that any solid produced has a negligible volume (which may be ignored). (a) Calculate the mass (in grams) of sodium azide required to generate enough nitrogen gas to fill a 57.0-L air bag at 1.37 atm and 25.0°C. (b) What is the root mean square speed of the N_2 gas molecules generated?

4.111 The spreading of smells through still air is due to the diffusion of the gas molecules. In a room that is 5 m long, a vial of ethyl octanoate is opened at the north end of the room, and simultaneously a second vial containing *p*-anisaldehyde is opened at the south end of the room (5 m away). Ethyl octanoate ($C_{10}H_{20}O_2$) has a fruity smell, and *p*-anisaldehyde ($C_8H_8O_2$) has a minty smell. How far (in meters) from the north end of the room must a person stand to smell first a minty smell?

4.112 You are told that 2.55 g of a gaseous hydrocarbon occupies a vessel of volume 3.00 L at 0.950 atm and 82.0°C. Draw the Lewis structure of this hydrocarbon.

4.113 A finely powdered solid sample of an osmium oxide (which melts at 40.°C and boils at 130.°C) with a mass of 1.509 g is placed into a cylinder with a movable piston that can expand against the atmospheric pressure of 745 Torr. Assume that the amount of residual air initially present in the cylinder is negligible. When the sample is heated to 200.°C, it is completely vaporized and the volume of the cylinder expands by 235 mL. What is the molar mass of the oxide? Assuming that the oxide is OsO_x, find the value of x.

4.114 How does the root mean square speed of gas molecules vary with temperature? Illustrate this relationship by plotting the root mean square speed of N_2 as a function of temperature from $T = 100$ K to $T = 300$ K.

4.115 A group of chemistry students have injected 46.2 g of a gas into an evacuated, constant-volume container at 27°C and atmospheric pressure. Now the students want to heat the gas at constant pressure by allowing some of the gas to escape during the heating. What mass of gas must be released if the temperature is raised to 327°C?

4.116 The root mean square speed, v_{rms}, of gas molecules was derived in Section 4.10. Using the Maxwell distribution of speeds, we can also calculate the mean speed and most probable (mp) speed of a collection of molecules. The equations used to calculate these two quantities are $v_{mean} = (8RT/\pi M)^{1/2}$ and $v_{mp} = (2RT/M)^{1/2}$. These values have a fixed relation to one another. (a) Place these three quantities in order of increasing magnitude. (b) Show that the relative magnitudes are independent of the molar mass of the gas. (c) Using the smallest speed as the reference point, rank them by magnitude and determine the ratios of the larger values to the smallest.

4.117 (a) The van der Waals parameters for helium are $a = 3.41 \times 10^{-2}\ L^2\cdot atm\cdot mol^{-2}$ and $b = 2.38 \times 10^{-2}\ L\cdot mol^{-1}$. Calculate the apparent volume (in pm^3) and radius (in pm) of a helium atom as determined from the van der Waals parameters. (b) Estimate the volume of a helium atom on the basis of its atomic radius. (c) How do these quantities compare? Should they be same? Discuss.

4.118 Show that the van der Waals parameter b is related to the molecular volume V_{mol} by $b = 4N_A V_{mol}$. Treat the molecules as spheres of radius r, so that $V_{mol} = \frac{4}{3}\pi r^3$. The closest that the centers of two molecules can approach is $2r$.

4.119 A 1.00-L sample of chlorine gas at 1.00 atm and 298 K reacts completely with 1.00 L of nitrogen gas and 2.00 L of oxygen gas at the same temperature and pressure. There is a single gaseous product, which fills a 2.00-L flask at 1.00 atm and 298 K. Use this information to determine the following characteristics of the product: (a) its empirical formula; (b) its molecular formula; (c) the most favorable Lewis structure based on formal charge arguments (the central atom is an N atom); (d) the molecular shape.

4.120 A sample of gaseous arsine, AsH_3, in a 500.0-mL flask at 300. Torr and 223 K is heated to 473 K, at which temperature arsine decomposes to solid arsenic and hydrogen gas. The flask is then cooled to 273 K, at which temperature the pressure in the flask is 508 Torr. Has all the arsine decomposed? Calculate the percentage of arsine molecules that have decomposed.

4.121 The van der Waals equation can be arranged into the following cubic equation:

$$V^3 + n\left(\frac{RT + bP}{P}\right)V^2 + \left(\frac{n^2a}{P}\right)V - \frac{n^3ab}{P} = 0$$

(a) Using this equation, calculate the volume occupied by 0.505 mol $NH_3(g)$ at 25°C and 95.0 atm. The van der Waals parameters for NH_3 are $a = 4.169\ L^2\cdot atm\cdot mol^{-2}$ and $b = 3.71\ L\cdot mol^{-1}$. (b) Do the attractive or the repulsive forces dominate at this temperature and pressure?

Chemistry Connections

4.122 Iron pyrite, FeS_2, is the form in which much of the sulfur exists in coal. In the combustion of coal, oxygen reacts with iron pyrite to produce iron(III) oxide and sulfur dioxide, which is a major source of air pollution and a substantial contributor to acid rain.

(a) Write a balanced equation for the burning of FeS_2 in air to produce iron(III) oxide and sulfur dioxide.

(b) Calculate the mass of Fe_2O_3 that is produced from the reaction of 75.0 L of oxygen at 2.33 atm and 150.°C with an excess of iron pyrite.

(c) If the sulfur dioxide that is generated in part (b) is dissolved to form 5.00 L of aqueous solution, what is the molar concentration of H_2SO_3 in the resulting solution?

(d) What mass of SO_2 is produced in the burning of 1.00 tonne ($1\ t = 10^3$ kg) of high-sulfur coal, if the coal is 5% pyrite by mass?

(e) What is the volume of the SO_2 gas generated in part (d) at 1.00 atm and 25°C?

(f) One way to remove SO_2 from exhaust gases is to remove it in the reaction $CaO(s) + SO_2(g) \longrightarrow CaSO_3(s)$. In a test of this reaction, a mixture of sulfur dioxide and nitrogen gases is prepared at 25°C in a vessel of volume 500. mL at 1.09 atm. The mixture is passed over warm calcium oxide powder, which removes the sulfur dioxide, and is then transferred to a vessel of volume 150. mL, where the pressure is 1.09 atm at 50.°C. (i) What was the partial pressure of the SO_2 in the initial mixture? (ii) What mass of SO_2 was present in the initial mixture?

(g) The van der Waals parameters for SO_2 are $a = 6.865\ L^2{\cdot}atm{\cdot}mol^{-1}$ and $b = 0.0568\ L{\cdot}mol^{-1}$. For $SO_2(g)$ confined in a 1.00-L vessel at 27°C, calculate the pressure of the gas by using the ideal gas law and the van der Waals equation for 0.100 mol to 0.500 mol SO_2 at 0.100-mol increments.

(h) Calculate the percentage deviation of the ideal value from the value calculated from the van der Waals equation at each point in part (g).

(i) Under the conditions in part (g), which term has the larger effect on the pressure of SO_2, the intermolecular attractions or the repulsions?

(j) If we consider to be ideal those gases for which the observed pressure differs by no more than 5% from the ideal value, at what pressure does SO_2 become a “real” gas?

What Are the Key Ideas? The condensed phases of matter result from attractive intermolecular forces. When atoms, ions, and molecules do not have enough energy to escape from their neighbors they form solids with their atoms in characteristic arrangements. They form liquids when they have enough energy to move past their neighbors but not enough to escape from them entirely.

Why Do We Need to Know This Material? This chapter shows how atomic and molecular properties are related to the structure and properties of bulk solids and liquids, continuing the process begun in Chapter 4 for gases. Because scientists design new materials by considering how the properties and interactions of individual particles give rise to bulk properties, formulating the materials of tomorrow will require an understanding of these relationships, as we shall see in greater detail in Chapter 6.

What Do We Need to Know Already? This chapter uses the concepts of potential energy (Section A), coulombic interactions (Section 2.4), polar molecules and dipoles (Section 3.3), and intermolecular forces in gases (Section 4.12).

Molecules attract one another. From that simple fact spring fundamentally important consequences. Rivers, lakes, and oceans exist because water molecules attract one another and form a liquid. Without that liquid, there would be no life. Without forces between molecules, our flesh would drip off our bones and the oceans would be gas. Less dramatically, the forces between molecules govern the physical properties of bulk matter and help to account for the differences in the substances around us. They explain why carbon dioxide is a gas that we exhale, why wood is a solid that we can stand on, and why ice floats on water.

Molecules also repel one another. When pressed together, molecules resist further compression. As a result, we do not sink into the floor and solid objects have a specific size and shape. Even in a gas, repulsions are important as they mean that molecules do not simply pass through one another but undergo actual collisions.

In Chapter 4 we considered gases, in which intermolecular forces play only a minor role. Here, we deal with liquids and solids, in which the forces that hold molecules together are of crucial importance for determining the physical properties of bulk samples. Individual water molecules, for instance, are not wet, but bulk water is wet because water molecules are attracted to other substances and spread over their surfaces. Individual water molecules neither freeze nor boil, but bulk water does, because in the process of freezing molecules stick together and form a rigid array and in boiling they separate from one another and form a gas.

We have to refine our atomic and molecular model of matter to see how bulk properties can be interpreted in terms of the properties of individual molecules, such as their size, shape, and polarity. We begin by exploring **intermolecular forces,** the forces between molecules, as distinct from the forces responsible for the formation of chemical bonds between atoms. Then we consider how intermolecular forces determine the physical properties of liquids and the structures and physical properties of solids.

INTERMOLECULAR FORCES

The simplest state of matter is a gas. We can understand many of the bulk properties of a gas—its pressure, for instance—in terms of the kinetic model introduced in Chapter 4, in which the molecules do not interact with one another except during collisions. We have also seen that this model can be improved and used to explain the

properties of real gases, by taking into account the fact that molecules do in fact attract and repel one another. But what is the origin of these attractive and repulsive forces? How does their strength relate to the properties of bulk matter? These are some of the questions addressed in the next six sections.

5.1 The Origin of Intermolecular Forces

Intermolecular forces are responsible for the existence of several different "phases" of matter. A **phase** is a form of matter that is uniform throughout in both chemical composition and physical state. The phases of matter include the three common physical states, solid, liquid, and gas (or vapor), introduced in Section A. Many substances have more than one solid phase, with different arrangements of their atoms or molecules. For instance, carbon has several solid phases; one is the hard, transparent diamond and another is the soft, black graphite we use in common pencil lead. A **condensed phase** means simply a solid or liquid phase. The temperature at which a gas condenses to a liquid or a solid depends on the strength of the attractive forces between its molecules.

All interionic and almost all intermolecular interactions can be traced to the coulombic interaction between charges (Section 2.4), and throughout the discussion of intermolecular interactions we shall build on Eq. 5 from Section A, the expression for the potential energy E_P of two charges Q_1 and Q_2 separated by a distance r:

$$E_P = \frac{Q_1 Q_2}{4\pi\varepsilon_0 r} \qquad (1)^*$$

This expression applies directly to ions, but it underlies all the interactions we shall discuss, including the interactions between neutral molecules.

Figure 5.1 depicts the general features of the distance dependence of this potential energy of the interaction between atoms that form chemical bonds and between atoms or molecules that do not form chemical bonds to one another. In each case, as the separation decreases from large values, their energy is lowered. However, there comes a stage when the potential energy begins to rise. The repulsions rapidly become dominant, and the potential energy rises sharply to high values. The shapes of the two curves are similar, but the depth of the minimum is very much less for intermolecular interactions than when bonds form and the minima occur at greater distances. In this chapter we focus on intermolecular interactions; the different types of interactions are summarized in Table 5.1.

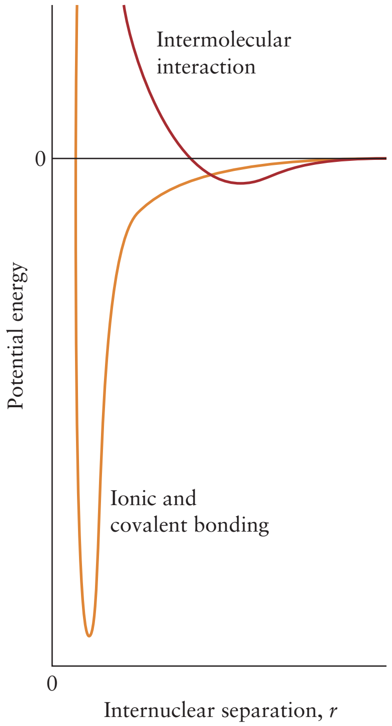

FIGURE 5.1 The distance dependence of the potential energy of the interaction between atoms or ions that form a bond (orange, lower line) and those that do not form bonds (brown, upper line). Notice the deep energy well that is a sign of bond formation. The dip in the upper line is an indication that even when atoms or molecules do not form a bond, attractive forces lower the energies of the particles.

Condensed phases form when attractive forces between molecules pull them together; repulsions dominate at short separations.

5.2 Ion–Dipole Forces

Ionic solids dissolve in water when a number of water molecules become attached to each ion and separate it from the other ions. The attachment of water molecules to solute

TABLE 5.1 Interionic and Intermolecular Interactions*

Type of interaction	Typical energy ($kJ \cdot mol^{-1}$)	Interacting species
ion–ion	250	ions only
ion–dipole	15	ions and polar molecules
dipole–dipole	2	stationary polar molecules
	0.3	rotating polar molecules
dipole–induced-dipole	2	at least one molecule must be polar

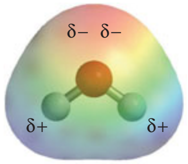
hydrogen bonding	20	molecules containing an N—H, O—H, or F—H bond; a shared H atom links the molecules

*The total interaction experienced by a species is the sum of all the interactions in which it can participate.
†Also known as the induced-dipole–induced-dipole interaction.

particles, particularly but not only ions, is called **hydration.** Hydration of ions is due to the polar character of the H_2O molecule (**1**). The partial negative charge on the O atom is attracted to the cation, and the partial positive charges of the H atoms are repelled by it. Therefore, the water molecules can be expected to cluster around the cation with a lone pair of electrons on each O atom pointing inward and the H atoms pointing outward (Fig. 5.2, left). We expect the reverse arrangement around an anion: the H atoms have partial positive charges, and so they are attracted to the anion's negative charge (Fig. 5.2, right). Because hydration arises from the interaction between the ion and the partial charges on the polar water molecules, it is an example of an **ion–dipole interaction.** Neutron diffraction studies of dilute aqueous solutions of LiCl and NaCl verify that the H atoms on the water molecules are attracted to the anions in a linear hydrogen bond-like arrangement while the partial negative charges on the O atoms are attracted to the cations.



1

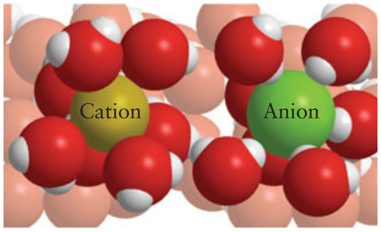


FIGURE 5.2 In water, ions are hydrated. On the left, a cation is surrounded by water molecules, oriented with their partially negatively charged oxygen atoms facing the ion. On the right, an anion is surrounded by water molecules that direct their partially positively charged hydrogen atoms toward the ion.

The potential energy of the interaction between the full charge of an ion and the two partial charges of a polar molecule is

$$E_p \propto -\frac{|z|\mu}{r^2} \tag{2}$$

Here z is the charge number of the ion and μ is the electric dipole moment of the polar molecule.

> ***What does this equation tell us?*** The negative sign means that the potential energy of the ion is *lowered* by its interaction with the polar solvent. The dependence on $1/r^2$ means that the interaction between an ion and a dipole depends more strongly on distance than does the interaction between two ions, which is proportional to $1/r$, as seen in Eq. 1 (Fig. 5.3); therefore, it acts over a shorter range.

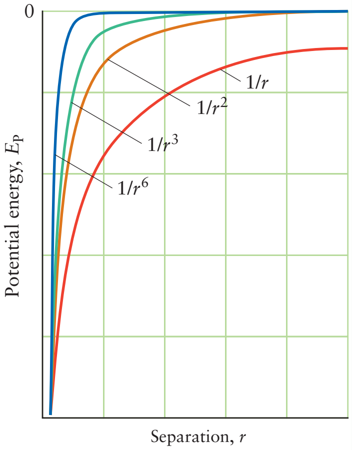

FIGURE 5.3 The distance dependence of the potential energy of the interaction between ions (red, lowest line), ions and dipoles (brown), stationary dipoles (green), and rotating dipoles (blue, uppermost line).

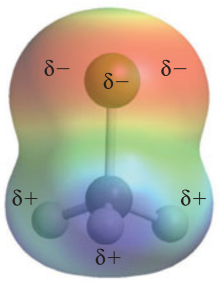
Living Graph 5.3

Because of the short range of the interaction, polar molecules need to be very close to an ion—almost in contact—before the interaction is significant. Even when the molecule and ion are very close, the ion–dipole forces are still smaller than the attraction between two ions, because the dipole moment of a polar molecule arises from only partial charges. In addition, an ion attracted to the partial charge at one end of a polar molecule is repelled by the charge at the other end and the two effects partly cancel. At large distances, the two partial charges are at almost the same distance from the ion, and the cancellation is nearly complete: that is why the potential energy of interaction between a point charge and a dipole falls off more quickly with distance (as $1/r^2$) than the interaction of two point charges does (as $1/r$).

When salts crystallize from an aqueous solution, the ions may retain some of the hydrating water molecules and form solid hydrates such as $Na_2CO_3{\cdot}10H_2O$ and $CuSO_4{\cdot}5H_2O$. Both the size of the ion and its charge control the extent of hydration. The strength of the ion–dipole interaction is greater the smaller the value of r in Eq. 2 (that is, the closer the dipole can come to the center of the ion). Because of their stronger ion–dipole interactions, small cations attract the polar H_2O molecules more strongly than large cations do. As a result, small cations are more extensively hydrated than large cations. In fact, lithium and sodium commonly form hydrated salts, whereas the heavier Group 1 elements (potassium, rubidium, and cesium), which have bigger cations, do not. Solid ammonium salts are usually **anhydrous,** or water free, for a similar reason: an NH_4^+ ion has about the same radius (151 pm) as an Rb^+ ion (152 pm).

For ions of similar size we should expect hydration to be more important the higher the charge. We can see the effect of charge on the extent of hydration by comparing barium and potassium cations, which have similar radii (135 pm for Ba^{2+} and 138 pm for K^+). In the solid state potassium salts are not hydrated to any appreciable extent, but barium salts are often hydrated. For example, barium chloride is found as $BaCl_2{\cdot}2H_2O$, but potassium chloride is anhydrous. The difference can be traced to the barium ion's higher charge. Lanthanum, barium's neighbor has an ion that is both smaller (122 pm) and more highly charged (La^{3+}); so we can expect it to have strong ion–dipole interactions and its compounds to be extensively hydrated. In fact, its salts include $La(NO_3)_3{\cdot}6H_2O$ and $La_2(SO_4)_3{\cdot}9H_2O$.

Ion–dipole interactions are strong for small, highly charged ions; one consequence is that small, highly charged cations are often hydrated in compounds.



2

5.3 Dipole–Dipole Forces

What would we see if we could observe a polar molecule surrounded by other polar molecules in a solid? An example of a polar molecule is chloromethane, CH_3Cl, with the partial negative charge on the Cl atom and the partial positive charge spread over the H atoms (**2**). The arrangement of molecules has a low energy if the partial negative charge of a Cl atom on one molecule is closer to the partial positive charge on the H atoms on a neighboring molecule than it is to the partial negative charge. So we would expect to see the surrounding molecules lined up with opposite partial charges on neighboring molecules as close together as possible (Fig. 5.4). The interaction between dipoles is called the **dipole–dipole interaction,** and the resulting potential energy is

$$E_p \propto -\frac{\mu_1\mu_2}{r^3} \quad (3)$$

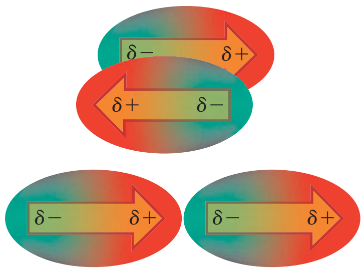


FIGURE 5.4 Polar molecules attract each other by the interaction between the partial charges of their electric dipoles (represented by the arrows). Both the relative orientations shown (end to end or side by side) result in a lower energy.

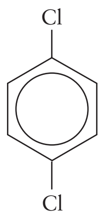
It takes about 1 ps for a small molecule to make a complete revolution in the gas phase.

Here, μ_1 and μ_2 are the dipole moments of two interacting molecules (for a solid composed of identical molecules, $\mu_1 = \mu_2$). The greater the polarity of the molecules, the stronger are the interactions. Equation 3 also shows that doubling the distance between the molecules reduces the strength of their interaction by a factor of $2^3 = 8$. The strong dependence on distance means that the potential energy falls off eight times as fast as the energies of ion–ion interactions and twice as fast as ion–dipole interactions (see Fig. 5.3). The reason for this more rapid falling off is that the opposite partial charges on *each* molecule seem to cancel and merge as the distance between the molecules increases, whereas in the interaction between a point charge and a dipole, only the partial charges on the dipole seem to merge.

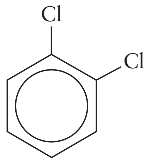
Now imagine that we can observe the same chloromethane molecule in a gas. The molecule and its neighbors are all rotating rapidly (Fig. 5.5). For perfectly free rotation, the attractions between opposite partial charges and the repulsions between like partial charges cancel and there is no net interaction. However, in reality the rotating neighbors linger slightly in energetically favorable orientations (their oppositely charged ends adjacent), and so the attractive interactions between opposite partial charges slightly outweigh the repulsive interactions between like partial charges. As a result, there is a weak net attraction between rotating polar molecules in the gas phase. It turns out that the potential energy varies as the *sixth* power of the distance between the molecules (see Fig. 5.3):

$$E_p \propto -\frac{\mu_1\mu_2}{r^6} \quad (4)$$

Doubling the separation of polar molecules reduces the strength of the interaction by a factor of $2^6 = 64$, and so dipole–dipole interactions between rotating molecules have a significant effect only when the molecules are very close. We can now start to understand why the kinetic model accounts for the properties of gases so well: gas molecules rotate and are far apart for most of the time, so any interactions between their molecules are very weak. Equation 4 also describes attractions between rotating molecules in a liquid. However, in the liquid phase, molecules are closer than in the gas phase and therefore the dipole–dipole interactions are much stronger. Because a lot of energy is required to separate molecules with strong attractions to one another, substances with strong intermolecular forces boil only at high temperatures. We say that they have high boiling points.



3 *p*-Dichlorobenzene



4 *o*-Dichlorobenzene

EXAMPLE 5.1 Predicting relative boiling points on the basis of dipole–dipole interactions

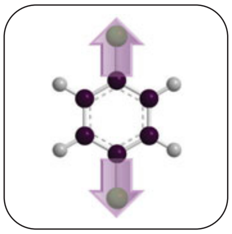
Which would you expect to have the higher boiling point, *p*-dichlorobenzene (**3**) or *o*-dichlorobenzene (**4**)?

PLAN The substance with the stronger intermolecular forces will have the higher boiling point. When two compounds have different dipole moments but are otherwise very similar, we expect the molecules with the larger electric dipole moment to interact more strongly. Therefore, assign the higher boiling point to the more strongly polar compound. To decide

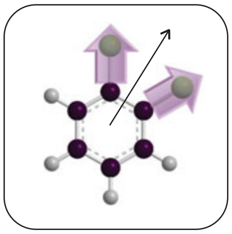
whether a molecule is polar, determine whether the dipole moments of the bonds cancel each other, as explained in Section 3.3. The polarity of C—H bonds is sufficiently low that those bonds have little effect on the molecular polarity and can be ignored.

SOLVE

The two C—Cl bonds in *p*-dichlorobenzene lie directly across the ring and their dipole moments cancel, thereby producing a nonpolar molecule.



An *o*-dichlorobenzene molecule is polar because the two C—Cl bond dipoles do not cancel. We therefore predict that *o*-dichlorobenzene will have a higher boiling point than that of *p*-dichlorobenzene.



Evaluate The experimental values are found to be 180°C for *o*-dichlorobenzene and 174°C for *p*-dichlorobenzene.

Self-Test 5.1A Which will have the higher boiling point, *cis*-dichloroethene (**5**) or *trans*-dichloroethene (**6**)?

[***Answer:*** *cis*-Dichloroethene]

Self-Test 5.1B Which will have the higher boiling point, 1,1-dichloroethene (**7**) or *trans*-dichloroethene?

Polar molecules take part in dipole–dipole interactions, the attraction between the partial charges of their molecules. Dipole–dipole interactions are weaker than forces between ions and fall off rapidly with distance, especially in the liquid and gas phases, where the molecules rotate.

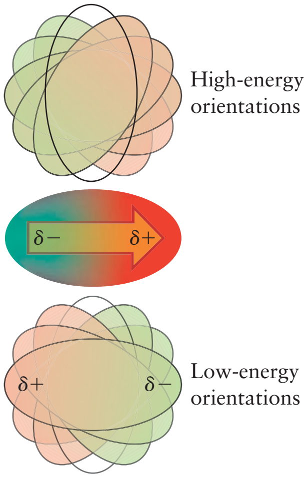


FIGURE 5.5 A polar molecule rotating near another polar molecule spends more time in the low-energy orientations (bottom) that maximize attractions, and so the net interaction is attractive, but not as strong as it would be if the molecules were not rotating.

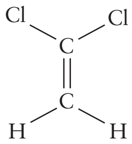
6 *trans*-Dichloroethene



7 1,1-Dichloroethene

5.4 London Forces

Attractive interactions are found even between nonpolar molecules. The evidence for these interactions includes the fact that the noble gases—which, because they are monatomic, are necessarily nonpolar—can be liquefied, and many nonpolar compounds, such as the hydrocarbons that make up gasoline, are liquids.

At first sight, there seems to be no means by which two nonpolar molecules could attract each other. To find the explanation, we must refine our model of the electron distribution in a molecule. First, recall that all the representations of electron distributions and charge distributions in the computer graphics that we have seen (for example, structures **1** and **2**) are *average* values. In a nonpolar molecule or a single atom, the electrons appear to be symmetrically distributed. In fact, at any instant, the electron clouds of atoms and molecules are not uniform. If we could take a snapshot of a molecule at a given instant, the electron distribution would look like a swirling fog. Electrons may accumulate somewhere in a molecule, leaving a nucleus elsewhere partly exposed. As a result, one region of the molecule will have a fleeting partial negative charge and another region will have a fleeting partial positive charge; in the next moment—about 10^{-16} s later—the charges may be reversed or in other locations. Even a nonpolar molecule may have an *instantaneous*, fleeting dipole moment (Fig. 5.6).

An instantaneous dipole moment on one molecule distorts the electron cloud on a neighboring molecule and gives rise to a dipole moment on that molecule: the two

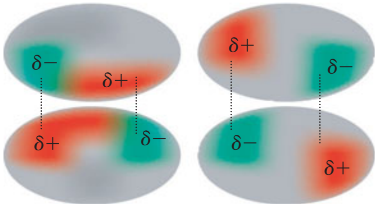


FIGURE 5.6 The rapid fluctuations in the electron distribution in two neighboring molecules result in two instantaneous electric dipole moments that attract each other. The fluctuations flicker into different positions, but each new arrangement in one molecule induces an arrangement in the other that results in mutual attraction.

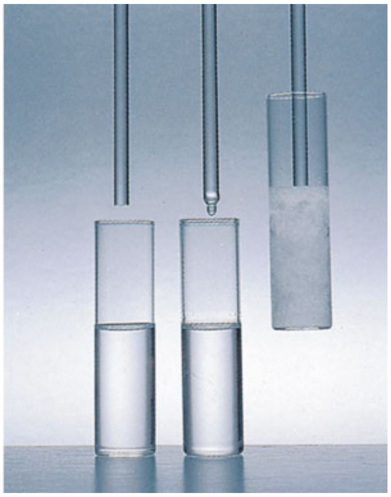

FIGURE 5.7 These hydrocarbons show how London forces increase in strength with molar mass. Pentane is a mobile liquid (left); pentadecane, $C_{15}H_{32}$, a viscous liquid (middle); and octadecane, $C_{18}H_{38}$, a waxy solid (right). To some extent, the effect of increasing intermolecular forces is enhanced by the ability of long-chain molecules to tangle with one another.

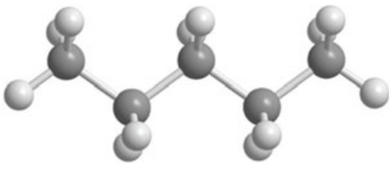
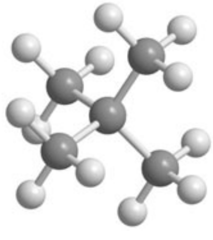


8 Pentane, C_5H_{12}



9 2,2-Dimethylpropane, $C(CH_3)_4$

instantaneous dipoles attract each other. An instant later, the swirling electron cloud of the first molecule will give rise to a dipole moment in a different direction, but that new dipole moment induces a dipole moment in the second molecule, and still the two molecules attract each other. That is, although there is a constant flickering of the dipole moment of one molecule from one orientation to another, the induced dipole moment of the second molecule follows it faithfully, and there is a net attraction between the two molecules. This attractive interaction is called the **London interaction.** It acts between *all* molecules and is the only interaction between nonpolar molecules.

The strength of the London interaction depends on the **polarizability,** α (alpha), of the molecules, the ease with which their electron clouds can be distorted. Highly polarizable molecules are those in which the nuclear charges have little control over the surrounding electrons, perhaps because the atoms are large and the distance between electrons and the nuclei is great or because the valence electrons are well shielded by the inner electrons. There can then be big fluctuations in electron density, and hence highly polarizable molecules can have large instantaneous dipole moments and strong London interactions. Detailed calculations show that the potential energy of the London interaction varies as the inverse sixth power of the separation of two molecules:

$$E_p \propto -\frac{\alpha_1\alpha_2}{r^6} \qquad (5)$$

Like the potential energy of dipole–dipole interactions between rotating polar molecules, the potential energy of the London interaction decreases very rapidly with distance (as $1/r^6$; see Fig. 5.3). The strength of the interaction increases with the polarizability of the interacting molecules. Because a large molecule with many electrons is typically more polarizable than a small molecule with only a few electrons, a large molecule is likely to have stronger London interactions than a smaller one (Fig. 5.7).

We can now see why the halogens range from gases (F_2 and Cl_2), through a liquid (Br_2), to a solid (I_2) at room temperature: the molecules have an increasing number of electrons, so their polarizabilities and hence their London interactions increase going down the group. The increase in strength of London forces is striking when heavier atoms are substituted for hydrogen atoms. Methane boils at −161°C, but tetrachloromethane (carbon tetrachloride, CCl_4) has many more electrons and is a liquid that boils at 77°C (Table 5.2). Tetrabromomethane, CBr_4, has even more electrons: it is a solid at room temperature.

The effectiveness of London forces also depends on the shapes of molecules. Both pentane (8) and 2,2-dimethylpropane (9), for instance, have the molecular formula C_5H_{12}, and so they each have the same number of electrons. However, they have different boiling points (36° and 10°C, respectively). Molecules of pentane are relatively long and rod shaped. The instantaneous partial charges on adjacent rod-shaped molecules can be in contact at several points, leading to strong interactions. In contrast, the instantaneous partial charges on more spherical molecules such as 2,2-dimethylpropane cannot get so close to one another, because only a small region of each molecule can be in contact (Fig. 5.8). As a result of the strong dependence on distance ($1/r^6$ in Eq. 5), the London interactions between rod-shaped molecules are more effective than those between spherical molecules with the same number of electrons.

Closely related to the London interaction is the **dipole–induced-dipole interaction,** in which a polar molecule interacts with a nonpolar molecule (for example, when oxygen dissolves in water). Like the London interaction, the dipole–induced-dipole interaction arises from the ability of one molecule to induce a dipole moment in the other. However, in this case, the molecule that induces the dipole moment has a permanent dipole moment. The potential energy of the interaction is

$$E_p \propto -\frac{\mu_1^{\,2}\alpha_2}{r^6} \qquad (6)$$

Once again, the potential energy is inversely proportional to the sixth power of the separation. Notice that the potential energies of the dipole–dipole interaction of rotating

polar molecules in the gas phase, the London interaction, and the dipole–induced-dipole interaction all have the form

$$E_p \propto -\frac{C}{r^6} \qquad (7)^*$$

with C depending on the molecules and the type of interaction. Intermolecular interactions that depend on the inverse sixth power of the separation are known collectively as **van der Waals interactions,** after Johannes van der Waals, the Dutch scientist who studied them extensively.

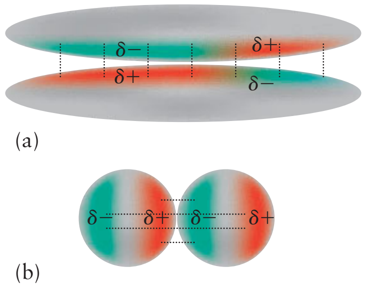

FIGURE 5.8 (a) The instantaneous dipole moments in two neighboring rod-shaped molecules tend to be close together and interact strongly over a relatively broad region of the molecule, as indicated by the vertical lines. (b) Those on neighboring spherical molecules tend to be farther apart and interact weakly over only a small region of the molecule.

EXAMPLE 5.2 Accounting for a trend in boiling points

Explain the trend in the boiling points of the hydrogen halides: HCl, –85°C; HBr, –67°C; HI, –35°C.

PLAN Stronger intermolecular forces result in higher boiling points. The dipole moments, and therefore the strength of the dipole–dipole interactions, increase with the polarity of the H—X bond and therefore with the difference in electronegativity between the hydrogen and the halogen atoms. The strength of London forces increases with the number of electrons. Use the data to decide which is the dominant effect.

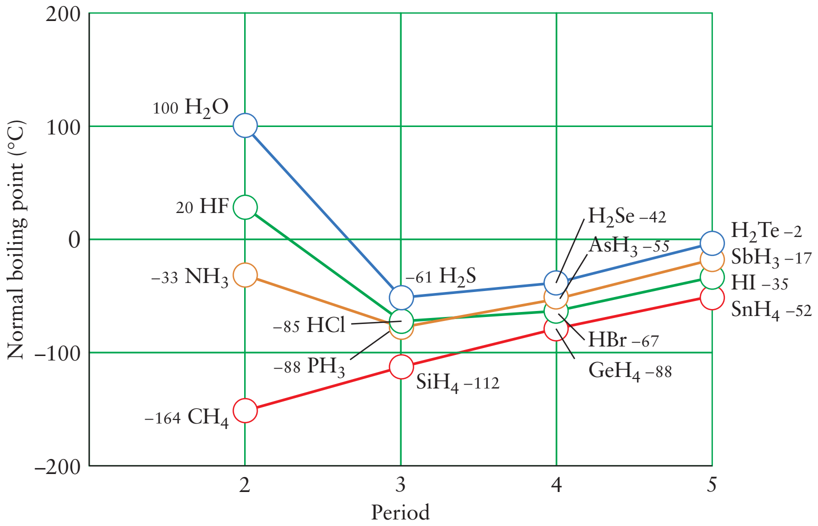
SOLVE The data in Fig. 2.12 show that electronegativity differences decrease from HCl to HI, and so the dipole moments decrease as well. Therefore, dipole–dipole forces decrease, too, a trend suggesting that the boiling points should decrease from HCl to HI. This prediction conflicts with the data; so we examine the London forces. The number of electrons in a molecule increases from HCl to HI, and so the strength of the London interaction increases, too. Therefore, the boiling points should increase from HCl to HI, in accord with the data. This analysis suggests that London forces dominate dipole–dipole interactions for these molecules.

Self-Test 5.2A Account for the trend in boiling points of the noble gases, which increase from helium to xenon.

[*Answer:* The strength of the London interaction increases as the number of electrons increases.]

Self-Test 5.2B Suggest a reason why trifluoromethane, CHF_3, has a higher boiling point than tetrafluoromethane, CF_4.

FIGURE 5.9 The boiling points of most of the molecular hydrides of the p-block elements show a smooth increase with molar mass in each group. However, the boiling points of three compounds—ammonia, water, and hydrogen fluoride—are strikingly out of line.

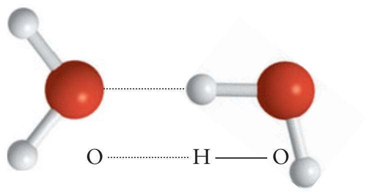


The London interaction arises from the attraction between instantaneous electric dipoles on neighboring molecules and acts between all types of molecules; its strength increases with the number of electrons and occurs in addition to any dipole–dipole interactions. Polar molecules also attract nonpolar molecules by weak dipole–induced-dipole interactions.

5.5 Hydrogen Bonding

The London interaction is "universal" in the sense that it applies to all molecules regardless of their chemical identity. Similarly, the dipole–dipole interaction depends only on the polarity of the molecule, regardless of its chemical identity. However, there is another very strong interaction between molecules that is specific to molecules with certain types of atoms.

We might suspect the existence of a special interaction when we plot the boiling points of the common binary hydrogen compounds of the elements in Groups 14/IV to 17/VII (Fig. 5.9). The trend in Group 14/IV is what we expect for similar compounds that differ in their number of electrons—the boiling points increase down the group because the strength of the London interaction increases. However, ammonia, water, and hydrogen fluoride all show anomalous behavior. Their exceptionally high boiling points suggest that there are unusually strong attractive forces between their molecules.



10 Hydrogen bond (in water)

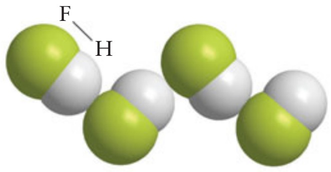
The strong interaction responsible for the high boiling points of these substances and certain others is the **hydrogen bond,** an intermolecular attraction in which a hydrogen atom bonded to a small, strongly electronegative atom, specifically N, O, or F, is attracted to a lone pair of electrons on another N, O, or F atom (**10**). To understand how it forms, let's imagine what happens when one water molecule comes close to another. Each O—H bond is polar. The electronegative O atom exerts a strong pull on the electrons in the bond, and the proton of the H atom is almost completely unshielded. Because it is so small, the hydrogen atom, with its partial positive charge, can get very close to one of the lone pairs of electrons on the O atom of another water molecule. The lone pair and the partial positive charge attract each other strongly and form a hydrogen bond. Hydrogen bonding is strongest when the hydrogen atom is on a straight line between the two oxygen atoms. A hydrogen bond is denoted by a dotted line, so the hydrogen bond between two O atoms is denoted O—H···O. The O—H bond length is 101 pm and the H···O distance is somewhat longer; in ice it is 175 pm.

Self-Test 5.3A Which of the following intermolecular links can be made by hydrogen bonds: (a) CH_3NH_2 to CH_3NH_2; (b) CH_3OCH_3 to CH_3OCH_3; (c) HBr to HBr?

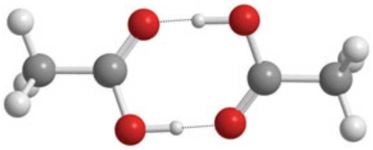
[***Answer:*** Only in (a) is H bonded directly to N, O, or F.]

Self-Test 5.3B Which of the following molecules can take part in hydrogen bonding with other molecules of the same compound: (a) CH_3OH; (b) PH_3; (c) HClO (which has the structure Cl—O—H)?

When it can form, a hydrogen bond is so strong—about 10% of a typical covalent bond strength—that it dominates all the other types of intermolecular interactions. Hydrogen bonding is strong enough to survive even in the vapor of some substances. Liquid hydrogen fluoride, for instance, contains zigzag chains of HF molecules (**11**), and the vapor contains short fragments of the chains and $(HF)_6$ rings. The vapor of acetic acid, CH_3COOH, contains **dimers,** pairs of molecules, linked by two hydrogen bonds (**12**).



11 Hydrogen fluoride, $(HF)_n$



12 Acetic acid dimer

Hydrogen bonds play a vital role in maintaining the shapes of biological molecules. The shape of a protein molecule is governed largely by hydrogen bonds; once the bonds are broken, the delicately organized protein molecule loses its function. When we cook an egg, the clear albumen becomes milky white, because the heat breaks the hydrogen bonds in its protein molecules, which collapse into a random jumble. Trees are held upright by hydrogen bonds (Fig. 5.10). Cellulose molecules (which have many —OH groups) can form many hydrogen bonds with one another, and the strength of wood is due in large part to the strength of the hydrogen bonds between neighboring ribbonlike cellulose molecules. Hydrogen bonding also binds the two chains of a DNA molecule together, and so hydrogen bonding is a key to understanding reproduction (see Section 19.15). The hydrogen bonds are strong enough to keep the two chains of a DNA molecule together but so much weaker than typical covalent bonds that they readily give way in cell division without affecting the covalent bonds within the strands of the DNA.

Hydrogen bonding, which occurs when hydrogen atoms are bonded to oxygen, nitrogen, or fluorine atoms, is the strongest type of intermolecular interaction.

FIGURE 5.10 Vegetation, even huge trees such as these, is held upright by the powerful intermolecular hydrogen bonds that exist between the ribbonlike cellulose molecules that form much of its bulk. Without hydrogen bonding, these trees would collapse.

5.6 Repulsions

As we have remarked, when molecules (or atoms that do not form bonds) are very close together, they repel one another, as was shown on the left of Fig. 5.1. This repulsion can be traced to the Pauli exclusion principle. To see why this is so, think about two He atoms approaching each other. At short separations, their 1s atomic orbitals overlap and form a bonding and an antibonding molecular orbital. Two of the four electrons supplied by the two atoms occupy the lower, bonding orbital; the Pauli exclusion principle then requires the remaining two electrons to occupy the antibonding orbital. As we remarked in Section 3.9, an antibonding orbital is more antibonding than a bonding orbital is bonding, so the net effect is an increase in energy as the two atoms merge into each other. The effect increases sharply as the distance decreases because the overlap between the atomic orbitals increases very rapidly as they approach. The same effect arises for all molecules in which the atoms have filled shells, even though the details of the bonding and antibonding orbitals they form may be much more complicated, and all molecules repel each other when they come into contact and their orbitals overlap.

The electron density in all atomic orbitals and the molecular orbitals they form decreases exponentially toward zero at large distances from the nucleus, so we can expect the overlap between orbitals on neighboring molecules also to depend exponentially on their separation. As a result, the repulsions between molecules depend, typically, exponentially on their separation, and are effective only when the two molecules are very close together, but once they are close, increase sharply. This sharp dependence on separation is the underlying reason why the objects around us have definite, well defined shapes.

Intermolecular repulsions arise from the overlap of orbitals on neighboring molecules and the requirements of the Pauli exclusion principle.

LIQUID STRUCTURE

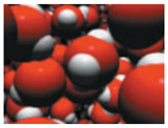
The molecules in a liquid are held in close contact with their neighbors by intermolecular forces, but they have enough energy to move past and tumble over one another (Fig. 5.11). When we imagine a liquid, we can think of a jostling crowd of molecules, each one constantly changing places with its neighbors. A liquid at rest is like a crowd of people milling about in a stadium; a flowing liquid is like a crowd of people leaving a stadium.

5.7 Order in Liquids

The liquid phase of matter is the most difficult to visualize. We have seen that a gas-phase molecule moves with almost complete freedom. The intermolecular forces from other molecules are minimal, and movement is highly disordered. In the solid phase, a molecule is locked in place by intermolecular forces and can only oscillate around an average location. The liquid phase lies between the extremes of the gas and solid phases. The molecules are mobile, but they cannot escape from one another completely.

A crystalline solid has **long-range order.** In other words, its atoms or molecules lie in an orderly arrangement that is repeated over long distances. When the crystal melts, that long-range order is lost. In the liquid, the kinetic energy of the molecules can partly overcome the intermolecular forces, and so the molecules are able to move past one another. However, the molecules still experience strong attractions to one another. In water, for instance, only about 10% of the hydrogen bonds are broken on melting. The rest are continually broken and re-formed with different water molecules. At any given moment, the immediate vicinity of a molecule in the liquid is like that in the solid, but the ordering does not extend very far past the nearest neighbors. This local ordering is called **short-range order.** In water, each molecule is surrounded by an approximately tetrahedral arrangement of other molecules as a result of hydrogen bonds. These interactions are ceaselessly changing from one moment to the next, but are strong enough to affect the local structure of molecules up to the boiling point.

In the liquid phase, molecules have short-range order but not long-range order.



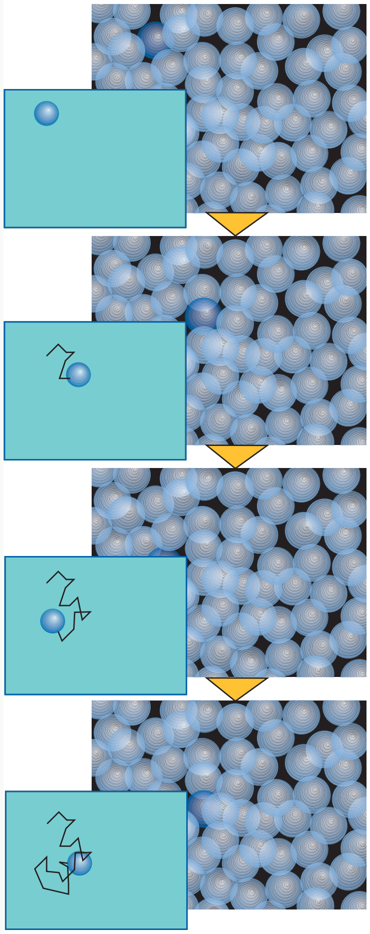


FIGURE 5.11 The structure of a liquid. Although the molecules (represented by the spheres in this series of diagrams) remain in contact with their neighbors, they can move away from one another and have enough energy to push through to a new neighborhood. Consequently, the entire substance is fluid. One sphere is slightly darker so that you can follow its motion. Its path is shown in the insets.

Animation 5.11

5.8 Viscosity and Surface Tension

The **viscosity** of a liquid is its resistance to flow: the higher the viscosity of the liquid, the more sluggish the flow. A liquid with a high viscosity, such as molasses at room temperature or molten glass, is said to be "viscous." The viscosity of a liquid is an indication of the strength of the forces between its molecules: strong intermolecular forces hold molecules together and do not let them move past one another easily (Fig. 5.12). However, the prediction of viscosity is very difficult because it depends not only on the strength with which molecules interact with one another but the ease with which they can take up new positions as the fluid flows. The strong hydrogen bonds in water give it a viscosity greater than that of benzene: benzene molecules can easily slip past one another in the liquid but, for water molecules to move, hydrogen bonds have to be wrenched apart. Nevertheless, the viscosity of water is not very high because an H_2O molecule can quickly readjust the pattern of hydrogen bonds that it forms with its neighbors. On the other hand, glycerol, $HOCH_2CH(OH)CH_2OH$, is much more viscous not only because it forms numerous hydrogen bonds but also because the bulky molecule is less agile at forming hydrogen bonds as the fluid flows. Another factor is the entanglement of long hydrocarbon chains. The molecules of hydrocarbon oils and greases are nonpolar and so participate only in London forces. However, they have long chains that tangle together like cooked spaghetti (Fig. 5.13), and the molecules move past one another only with difficulty.

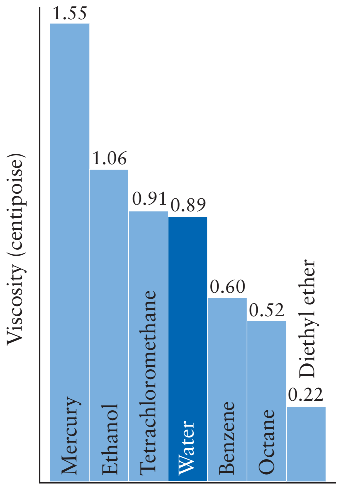

FIGURE 5.12 The viscosities of several liquids. Liquids composed of molecules that cannot form hydrogen bonds are generally less viscous than those that can form hydrogen bonds. Mercury is an exception: its atoms stick together by a kind of metallic bonding, and its viscosity is very high. The centipoise (cP) is the unit commonly used to report viscosity (1 cP = 10^{-3} kg·m·s^{-1}).

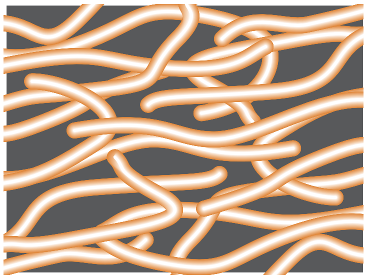

FIGURE 5.13 The long threadlike molecules of heavy hydrocarbon oils tend to get tangled together like a plate of cooked spaghetti. As a result, the molecules do not move past one another very readily and the liquid is very viscous.

Viscosity usually decreases as the temperature rises. Molecules have more energy at high temperatures and can wriggle past their neighbors more readily. The viscosity of water at 100°C, for instance, is only one-sixth of its value at 0°C, and so the same amount of water flows through a tube six times as fast at the higher temperature.

Another property of a liquid that arises from intermolecular forces is **surface tension.** The surface of a liquid is smooth because intermolecular forces tend to pull the molecules together and inward (Fig. 5.14); the surface tension is the net inward pull. Once again, we can expect liquids composed of molecules with strong intermolecular forces to have high surface tensions, because the inward pull at the surface will be strong. Indeed, the surface tension of water is about three times as high as that of most other common liquids, because of its strong hydrogen bonds (Table 5.3). The surface tension of mercury is higher still—more than six times that of water. Its high surface tension suggests that the bonds between mercury atoms in the liquid are very strong: in fact, they are partially covalent in character.

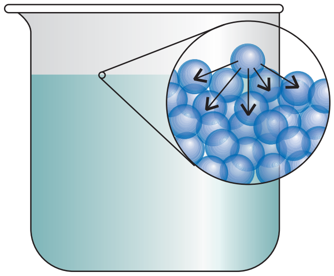

FIGURE 5.14 Surface tension arises from the attractive forces acting on the molecules at the surface. The inset shows that a molecule within the liquid experiences attractive forces from all directions, but a molecule at the surface experiences a net inward force.

TABLE 5.3 Surface Tensions of Liquids at 25°C

Liquid	Surface tension, γ (mN·m^{-1})
benzene	28.88
carbon tetrachloride	27.0
ethanol	22.8
hexane	18.4
mercury	472
methanol	22.6
water	72.75
	58.0 at 100°C

Surface tension accounts for a number of everyday phenomena. For example, a droplet of liquid suspended in air or on a waxy surface is spherical because the surface tension pulls the molecules into the most compact shape, a sphere (Fig. 5.15). The attractive forces between water molecules are greater than those between water and wax, which is largely hydrocarbon. Surface tension decreases as the temperature rises and the interactions between molecules are overcome by the increased molecular motion.

Water has strong interactions with paper, wood, and cloth because it can form hydrogen bonds with the molecules in their surfaces. As a result, water maximizes its contact with these materials by spreading over them; in other words, water *wets* them. We now see that water is wet because of the hydrogen bonds that its molecules can form.

Capillary action, the rise of liquids up narrow tubes, occurs when there are favorable attractions between the molecules of the liquid and the tube's inner surface. These attractions are forces of **adhesion,** forces that bind a substance to a surface, as distinct from the forces of **cohesion,** the forces that bind the molecules of a substance together to form a bulk material. An indication of the relative strengths of adhesion and cohesion is the formation of a **meniscus,** the curved surface of a liquid, in a narrow tube (Fig. 5.16). The meniscus of water in a glass capillary is curved upward at the edges (forming a concave shape) because the adhesive forces between water molecules and the oxygen atoms and —OH groups that are present on a typical glass surface are comparable in strength to the cohesive forces between water molecules. The water therefore tends to spread over the greatest possible area of glass. In contrast, the meniscus of mercury curves downward in glass (forming a convex shape). This shape is a sign that the cohesive forces between mercury atoms are stronger than the forces between mercury atoms and the glass, and so the liquid tends to reduce its contact with the glass.

FIGURE 5.15 The nearly spherical shapes of these beads of water on the waxy surface of a leaf arise from the effect of surface tension.

FIGURE 5.16 When the adhesive forces between a liquid and glass are stronger than the cohesive forces within the liquid, the liquid curves up to maximize contact with the glass, forming the meniscus shown here for water in glass (left). When the cohesive forces are stronger than the adhesive forces (as they are for mercury in glass), the edges of the surface curve downward to minimize contact with the glass (right).

The greater the viscosity of a liquid, the more slowly it flows. Viscosity usually decreases with increasing temperature. Surface tension arises from the imbalance of intermolecular forces at the surface of a liquid. Capillary action arises from the imbalance of adhesive and cohesive forces.

SOLID STRUCTURES

When the temperature is so low that the molecules of a substance do not have enough energy to escape even partially from their neighbors, the substance solidifies. The nature of the solid depends on the types of forces that hold the atoms, ions, or molecules together. An understanding of solids in terms of the properties of their atoms will help us to understand why, for instance, metals can be pounded into different shapes but salt crystals shatter, and why diamonds are so hard.

5.9 Classification of Solids

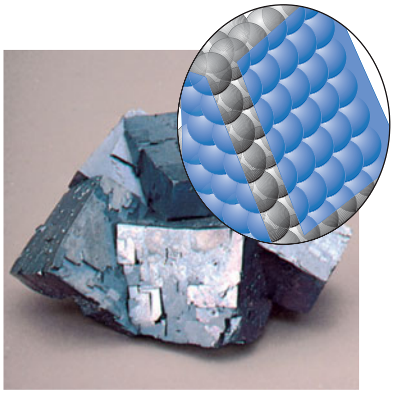

FIGURE 5.17 Crystalline solids have well-defined faces and an orderly internal structure. Each face of the crystal is formed by the top plane of an orderly stack of atoms, molecules, or ions.

A **crystalline solid** is a solid in which the atoms, ions, or molecules lie in an orderly array (Fig. 5.17). A crystalline solid has long-range order. An **amorphous solid** is one in which the atoms, ions, or molecules lie in a random jumble, as in butter, rubber, and glass (Fig. 5.18). An amorphous solid has a structure like that of a frozen instant in the life of a liquid, with only short-range order. Crystalline solids typically have flat, well-defined planar surfaces called **crystal faces,** which lie at definite angles to one another. These faces are formed by orderly layers of atoms (Box 5.1). Amorphous solids do not have well-defined faces unless they have been molded or cut.

The arrangement of atoms, ions, and molecules within a crystal is determined by x-ray diffraction (Major Technique 3, which follows this chapter), one of the most useful techniques for determining the structures of solids.

We classify crystalline solids according to the bonds that hold their atoms, ions, or molecules in place:

Molecular solids are assemblies of discrete molecules held in place by intermolecular forces.
Network solids consist of atoms covalently bonded to their neighbors throughout the extent of the solid.
Metallic solids, also called simply *metals*, consist of cations held together by a sea of electrons.
Ionic solids are built from the mutual attractions of cations and anions.

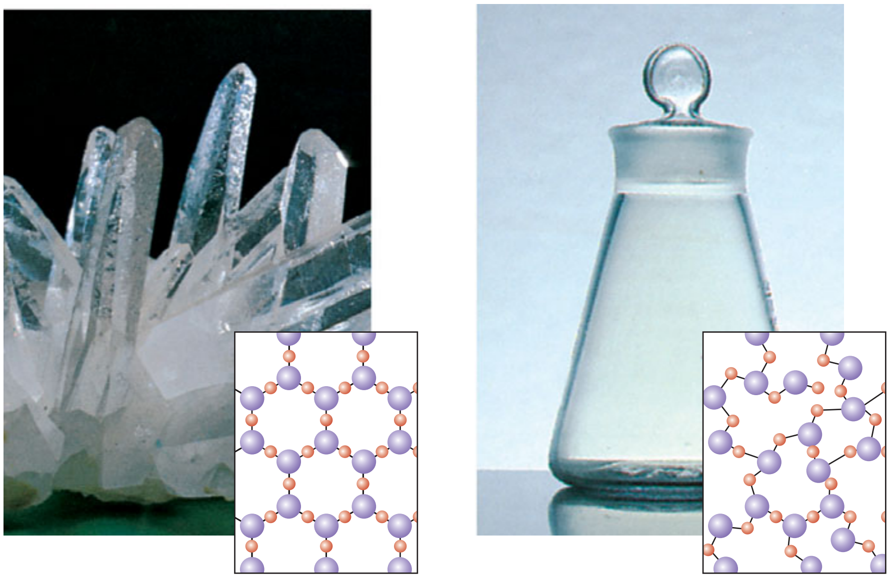

FIGURE 5.18 (Left) Quartz is a crystalline form of silica, SiO_2, with the atoms in an orderly network, represented here in two dimensions. (Right) When molten silica solidifies in an amorphous arrangement, it becomes glass. Now the atoms form a disorderly network.

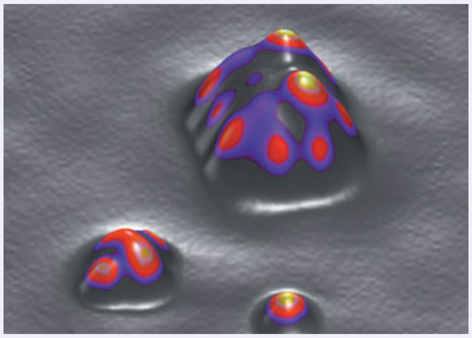
BOX 5.1 HOW DO WE KNOW . . . WHAT A SURFACE LOOKS LIKE?

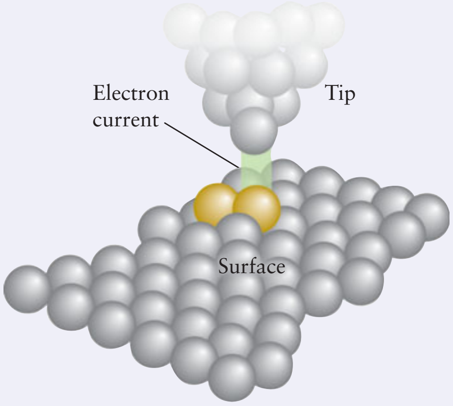
Even the most powerful optical microscopes cannot reveal the individual atoms of a solid surface. However, the new field of *nanotechnology*, the development and study of devices only nanometers in size, requires the ability to resolve surfaces on an atomic scale. A new technique that allows individual atoms to be visualized, *scanning tunneling microscopy* (STM), is an important tool for nanotechnology. The technique produces images like those on this page. The first figure shows a tiny sodium iodide crystal lying on a copper surface.



An experimenter attempted to create a two-dimensional sodium iodide crystal on a copper surface, but the ions spontaneously rearranged themselves into a tiny three-dimensional crystal.

The key idea behind STM is that, because electrons have wavelike properties (Section 1.5), they can penetrate into and through regions where classical mechanics would forbid them to be. This penetration is called *tunneling*. The effect is used in STM (hence the "tunneling" in the name) by bringing a fine tip up to a surface and monitoring the current that flows through the gap between the tip and the surface. The magnitude of the current, like the tunneling itself, is very sensitive to the separation of the tip and the surface, and even atomic-scale variations affect it.

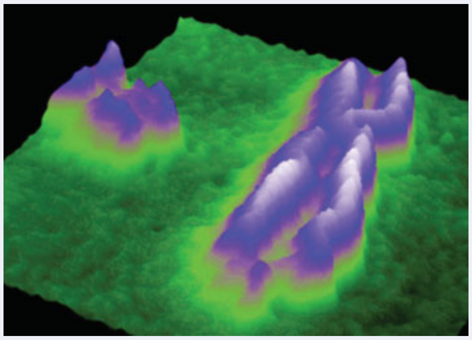
To obtain an STM image, a fine tip is moved back and forth across the surface in a series of closely spaced lines (hence the "scanning" in the name). The tip ends in a single atom (see the second figure). As the tip moves across the surface at a constant height, the tunneling ebbs and flows, and the current varies correspondingly through the circuit. The image is a portrayal of the current measured on each scan.



The tip of a scanning tunneling microscope above a surface. Because the tip is too close to the surface for other molecules to interfere, STM devices can be used in a gaseous atmosphere or even in liquids.

In a modification, the current is maintained at a constant level by varying and monitoring the height of the tip above the surface. That height is controlled by using a *piezoelectric* substance to support the tip, a substance that changes dimensions according to the electrical potential difference applied to it. By measuring the potential difference that must be applied to the piezoelectric support to maintain a constant current through the tip, the height of the tip can be inferred and plotted on a computer screen.

Yet another modification is *atomic force microscopy* (AFM), in which a fine tip attached to a tiny flexible beam is scanned across the surface. The atom at the end of the tip experiences a force that pulls it toward or pushes it away from the atoms on the surface. The deflection of the beam, which shows the shape of the surface, can be monitored by using light from a laser. An advantage of AFM is that it can image biological surfaces that cannot conduct an electrical current. For example AFM can be used to study the shapes of human chromosomes and how carcinogenic (cancer-causing) substances promote the development of tumors by interfering with the reproduction of the DNA molecule. An AFM image of the human X chromosome is shown in the third figure.



This AFM image shows the X chromosome that determines the gender of a person. It includes about 5% of a person's DNA. Females have two X chromosomes, males have one X and one Y chromosome. Because AFM spectroscopy does not require chemical modification of the substance being studied, it can reveal important details of chromosome structure.

The images in this box are computer-generated representations, not true photographs. However, they have opened our eyes to the appearance of surfaces in the most extraordinary ways.

The 1986 Nobel Prize in Physics was awarded to Ernst Ruska and Gerd Binnig of Germany and Heinrich Rohrer of Switzerland for their invention of the scanning tunneling microscope.

TABLE 5.4 Typical Characteristics of Solids

Class	Examples	Characteristics
metallic	s- and d-block elements	malleable, ductile, lustrous, electrically and thermally conducting
ionic	NaCl, KNO_3, $CuSO_4 \cdot 5H_2O$	hard, rigid, brittle; high melting and boiling points; those soluble in water give conducting solutions
network	B, C, black P, BN, SiO_2	hard, rigid, brittle; very high melting points; insoluble in water
molecular	$BeCl_2$, S_8, P_4, I_2, ice, glucose, naphthalene	relatively low melting and boiling points; brittle if pure

Table 5.4 lists examples of each type of solid and their typical characteristics. Solids are dense forms of matter because their atoms, ions, and molecules are packed closely together. Metals are often denser than other kinds of solids because their atoms are packed even more closely. The metallic bond is relatively strong. As a result, most metals have high melting points and serve as tough, strong materials for construction. Ionic solids have higher melting points than molecular solids because interionic forces are much stronger than intermolecular forces. Network solids (such as diamond) have very high melting points because they do not melt until the covalent bonds between their atoms have been overcome.

In this part of the chapter, we begin with molecular solids and distinguish them from network solids. Then we examine metallic solids, which, if consisting of a single element, are built from identical atoms stacked together in orderly arrays. The structures of ionic solids are based on the same kinds of arrays but are complicated by the need to take into account the presence of ions of opposite charges and different sizes.

Crystalline solids have a regular internal arrangement of atoms or ions; amorphous solids do not. Solids are classified as molecular, network, metallic, or ionic.

5.10 Molecular Solids

Molecular solids consist of molecules held together by intermolecular forces and their physical properties depend on the strengths of those forces. Amorphous molecular solids may be as soft as paraffin wax, which is a mixture of long-chain hydrocarbons. These molecules lie together in a disorderly way, and the forces between them are so weak that they can be pushed past one another very easily. Many other molecular solids have crystalline structures and strong intermolecular forces that make them brittle and hard. For example, sucrose molecules, $C_{12}H_{22}O_{11}$, are held together by hydrogen bonds between their numerous —OH groups. Hydrogen bonding between sucrose molecules is so strong that, by the time the melting point has been reached (at 184°C), the molecules themselves have started to decompose. The mixture of partly decomposed products, called caramel, is used to add flavor and color to food. Some molecular solids are very tough. For example, "ultrahigh-density polyethylene" consists of long hydrocarbon chains that lie densely together like close-packed cylinders: the resulting material is so smooth yet tough that it is used to make bullet-proof vests and joint replacements for the human body.

Because molecules have such diverse shapes, they stack together in a wide variety of different ways. In ice, for example, each O atom is surrounded by four H atoms in a

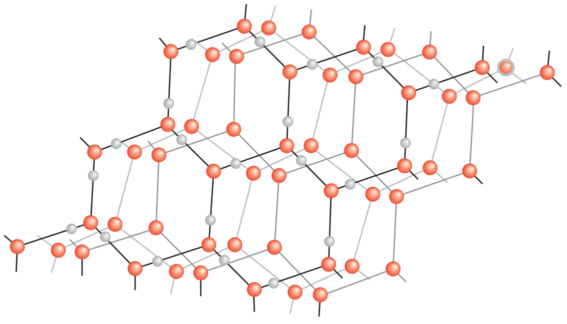


FIGURE 5.19 Ice is made up of water molecules that are held together by hydrogen bonds in an open structure. Each O atom is surrounded tetrahedrally by four hydrogen atoms, two of which are σ-bonded to it and two of which are hydrogen-bonded to it. To show the structure more clearly, only the hydrogen atoms in the front layer are shown.

Animation 5.19

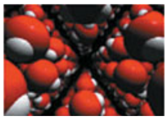

FIGURE 5.20 As a result of its open structure, ice is less dense than liquid water and floats in it (left). Solid benzene is denser than liquid benzene and "benzenebergs" sink in liquid benzene (right).

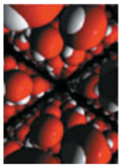

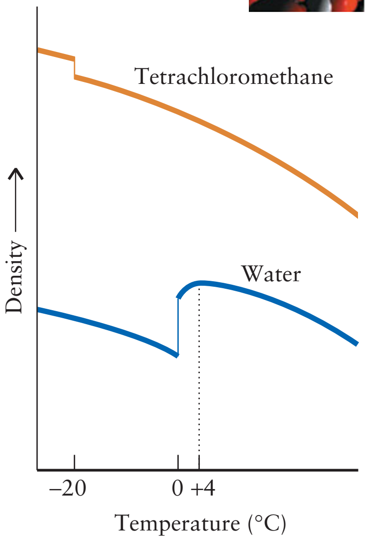

FIGURE 5.21 Variation in the densities of water and tetrachloromethane with temperature. Note that ice is less dense than liquid water at its freezing point and that water has its maximum density at 4°C.

Animation 5.21

tetrahedral arrangement. Two of these H atoms are linked covalently to the O atom through σ-bonds. The other two belong to neighboring H_2O molecules and are linked to the O atom by hydrogen bonds. As a result, the structure of ice is an open network of H_2O molecules held in place by hydrogen bonds (Fig. 5.19). Some of the hydrogen bonds break when ice melts; and, as the orderly arrangement collapses, the molecules pack less uniformly but more densely (Fig. 5.20). The openness of the network in ice compared with the closer arrangement of molecules in the liquid explains why it has a lower density than liquid water (0.92 $g\cdot cm^{-3}$ and 1.00 $g\cdot cm^{-3}$, respectively, at 0°C). Solid benzene and solid tetrachloromethane, in contrast, have higher densities than their liquids (Fig. 5.21). Their molecules are held in place by London forces, which are much less directional than hydrogen bonds, and so they can pack together more closely in the solid than in the liquid.

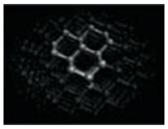
Molecular solids are relatively soft and typically melt at relatively low temperatures.

5.11 Network Solids

Whereas molecular solids consist of molecules held together by relatively weak intermolecular forces, the atoms in network solids are joined to their neighbors by strong covalent bonds that form a framework extending throughout the crystal. In order to break apart a crystal of a network solid, covalent bonds, which are much stronger than intermolecular forces, must be broken. Therefore, network solids are very hard, rigid materials with high melting and boiling points.

Diamond and graphite are elemental network solids. These two forms of carbon are **allotropes,** meaning forms of an element that differ in the way in which the atoms are linked. Each C atom in diamond is covalently bonded to four neighbors through sp^3 hybrid σ-bonds (Fig. 5.22). The tetrahedral framework extends throughout the solid like the steel framework of a large building. This structure accounts for the great hardness of the solid.

Graphite, the most important component of the "lead" of pencils, is a black, lustrous, electrically conducting solid that vaporizes at 3700°C. It consists of flat sheets of sp^2 hybridized carbon atoms bonded covalently into hexagons like chicken wire (Fig. 5.23). There are also weak bonds between the sheets.



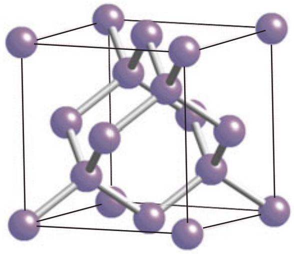


FIGURE 5.22 The structure of diamond. Each sphere represents the location of the center of a carbon atom. Each atom is at the center of a tetrahedron formed by the sp^3 hybrid covalent bonds to each of its four neighbors.

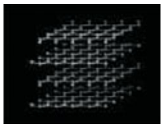
Animation 5.22



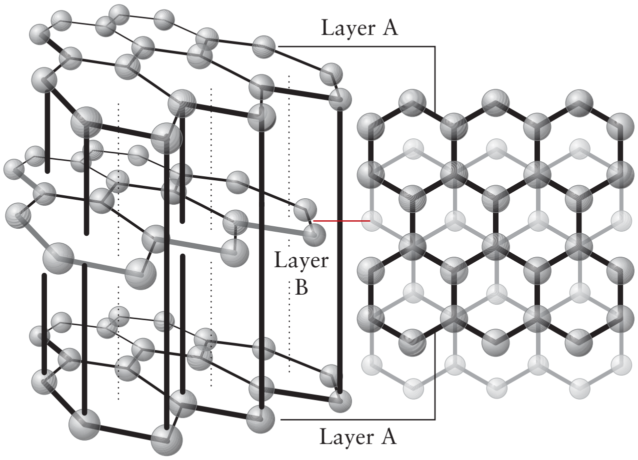


FIGURE 5.23 Graphite consists of layers of hexagonal rings of sp^2 hybridized carbon atoms. The slipperiness of graphite results from the ease with which the layers can slide over one another when there are impurity atoms lying between the planes.

Animation 5.23

Ceramic materials are typically noncrystalline inorganic oxides with a network structure that is produced by heat treatment of a powder. They include many silicate minerals, such as quartz (silicon dioxide, which has the empirical formula SiO_2), and high-temperature superconductors (Section 6.14). Ceramic materials have great strength and stability, because covalent bonds must be broken to cause any deformation in the crystal. As a result, ceramic materials under physical stress tend to shatter rather than bend. Section 6.11 contains further information on the properties of ceramic materials.

Network solids are typically hard and rigid; they have high melting and boiling points. Ceramic materials are commonly network solids.

5.12 Metallic Solids

FIGURE 5.24 The close-packed stacks of apples, oranges, and other produce in a grocery display illustrate how atoms stack together in metals to form crystals with flat faces.

The cations in a metal are bound together by their interaction with the sea formed by the electrons that they have lost (recall Fig. 1.53). For instance, metallic sodium consists of Na^+ ions held together by electrons that spread throughout the solid, with one electron for each cation. Because the interaction between the ions and the electrons is the same in any direction, the arrangement of the cations can be modeled as hard spheres stacked together. It turns out that we can explain the structures and properties of many metals if we suppose that the spheres representing the cations adopt a **close-packed structure,** in which the spheres stack together with the least waste of space, like oranges in a display (Fig. 5.24).

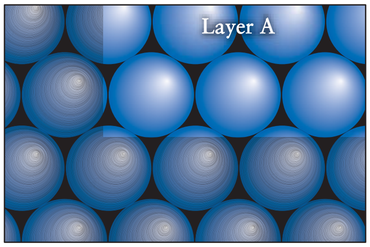

FIGURE 5.25 A close-packed structure can be built up in stages. The first layer (A) is laid down with minimum waste of space.

To see how to stack identical spheres together to give a close-packed structure, look at Fig. 5.25. In the first layer (A) each sphere lies at the center of a hexagon of other spheres. The spheres of the second (upper) layer (B) lie in the dips of the first layer (Fig. 5.26). The third layer of spheres will lie in the dips of the second layer, with the pattern repeating over and over again.

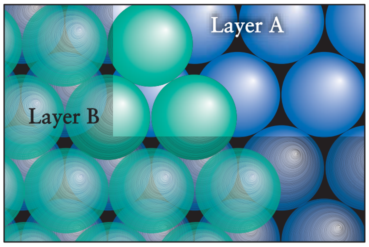

FIGURE 5.26 The second layer (B) lies in the dips—the depressions—between the spheres of the first layer. Each sphere is touching six other spheres in its layer, as well as three in the layer below and three in the layer above.

The third layer of spheres may be added in either of two ways. In the first arrangement, the spheres lie in the dips that are directly above the spheres of the first layer (Fig. 5.27). The third layer then duplicates layer A, the next layer duplicates B, and so on. This procedure results in an ABABAB . . . pattern of layers called a **hexagonal close-packed structure** (hcp). The hexagonal pattern in the arrangement of atoms can be seen in Fig. 5.28. Magnesium and zinc are examples of metals that crystallize in this way. As can be seen from Fig. 5.28, each sphere has three nearest neighbors in the plane below, six in its own plane, and three in the plane above, giving twelve in all. This arrangement is reported by saying that the **coordination number,** the number of nearest neighbors of each atom, in the solid is 12. It is impossible to pack identical spheres together with a coordination number greater than 12.

In the second arrangement, the spheres of the third layer lie in the dips of the second layer that do *not* lie directly over the atoms of the first layer (Fig. 5.29). If we call this third layer C, the resulting structure has an ABCABC . . . pattern of layers to give a **cubic close-packed structure** (ccp, Fig. 5.30), because the atoms form cubes when viewed at an angle to the layers. A ccp structure can be thought of as many of these tiny cubes repeating over and over again in all directions. The coordination number is also 12: each sphere has three nearest neighbors in the layer below, six in its own layer, and three in the layer above. Aluminum, copper, silver, and gold are examples of metals that crystallize in this way.

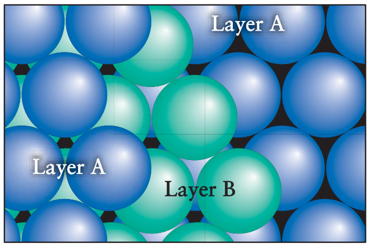

FIGURE 5.27 When the spheres in the third layer lie directly above the spheres of the first layer, an ABABAB . . . structure is formed.

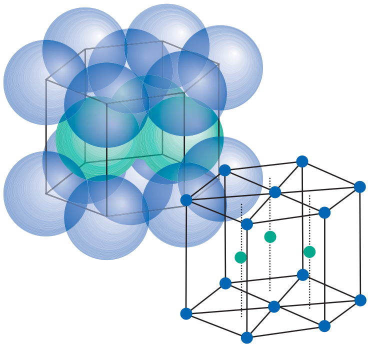

FIGURE 5.28 A fragment of the structure formed as described in Fig. 5.27 shows the hexagonal symmetry of the arrangement—and the origin of its name, "hexagonal close-packed."

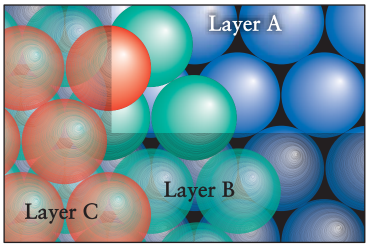

FIGURE 5.29 In an alternative to the scheme shown in Fig. 5.27, the spheres of the third layer can lie in the dips in the second layer that are directly above the dips in the first layer, to give an ABCABC . . . arrangement of layers.

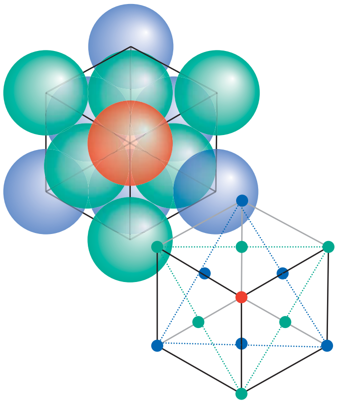

FIGURE 5.30 A fragment of the structure constructed as described in Fig. 5.29. This fragment shows the origin of the names "cubic close-packed" or "face-centered cubic" for this arrangement. The layers A, B, and C can be seen along the diagonals of the faces of the cube and are indicated by the different colors of the atoms.

Even in a close-packed structure, hard spheres do not fill all the space in a crystal. The gaps—the interstices—between the atoms are called "holes." To determine just how much space is occupied, we need to calculate the fraction of the total volume occupied by the spheres.

HOW DO WE DO THAT?

To calculate the fraction of occupied space in a close-packed structure, we consider a ccp structure. We can use the radius of the atoms to find the volume of the cube and how much of that volume is taken up by atoms. First, we look at how the cube is built from the atoms. In Fig. 5.31, we see that the corners of the cubes are at the centers of eight atoms. Only 1/8 of each corner atom projects into the cube, so the corner atoms collectively contribute $8 \times 1/8 = 1$ atom to the cube. There is half an atom on each of the six faces, so the atoms on each face contribute $6 \times 1/2 = 3$ atoms, giving four atoms in all within the cube. The length of the diagonal of the face of the cube shown in Fig. 5.31 is $4r$, where r is the atomic radius. Each of the two corner atoms contributes r and the atom at the center of the face contributes $2r$. From the Pythagorean theorem, we know that the length of the side of the face, a, is related to the diagonal by $a^2 + a^2 = (4r)^2$, or $2a^2 = 16r^2$, and so $a = 8^{1/2}r$. The volume of the cube is therefore $a^3 = 8^{3/2}r^3$. The volume of each atom is $\frac{4}{3}\pi r^3$; so the total volume of the atoms inside the cube is $4 \times \frac{4}{3}\pi r^3 = \frac{16}{3}\pi r^3$. The ratio of this occupied volume to the total volume of the cube is therefore

$$\frac{\text{Total volume of spheres}}{\text{Total volume of cube}} = \frac{(16/3)\pi r^3}{8^{3/2}r^3} = \frac{16\pi}{3 \times 8^{3/2}} = 0.74$$

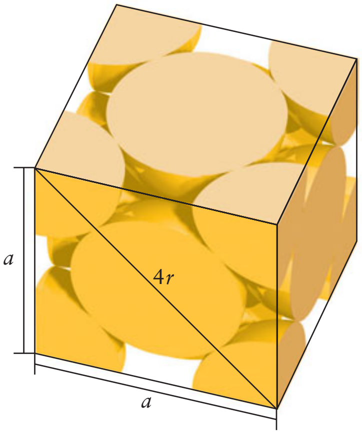

FIGURE 5.31 The relation of the dimensions of a face-centered cubic unit cell to the radius, r, of the spheres. The spheres are in contact along the face diagonals.

The Pythagorean theorem states that the square of the hypotenuse of a right-angled triangle is equal to the sums of the squares of the other two sides. That is, if the hypotenuse is c and the other two sides are a and b, then $a^2 + b^2 = c^2$.

We have shown that 74% of the crystal's space is occupied by atoms and 26% is considered to be empty. Because the hcp structure has the same coordination number of 12, we know that it is packed as densely and must have the same fraction of occupied space.

The holes in the close-packed structure of a metal can be filled with smaller atoms to form alloys (alloys are described in more detail in Sections 6.1–6.4). If a dip between three atoms is directly covered by another atom, we obtain a **tetrahedral hole,** because it is formed by four atoms at the corners of a regular tetrahedron (Fig. 5.32). There are two tetrahedral holes per atom in a close-packed lattice. When a dip in a layer coincides with a dip in the next layer, we obtain an **octahedral hole,** because it is formed by six atoms at the corners of a regular octahedron, as shown in Fig. 5.32. There is one octahedral hole for each atom in the lattice. Note that, because holes are formed by two adjacent layers and because neighboring close-packed layers have identical arrangements in hcp and ccp, the numbers of holes are the same for both close-packed structures.

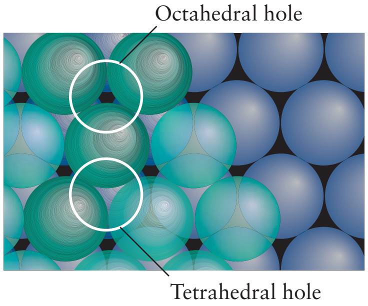

FIGURE 5.32 The locations of octahedral and tetrahedral holes. There are twice as many tetrahedral holes as octahedral holes. Note that both types of holes are defined by two neighboring close-packed layers, so they are present with equal abundance in both hcp and ccp structures.

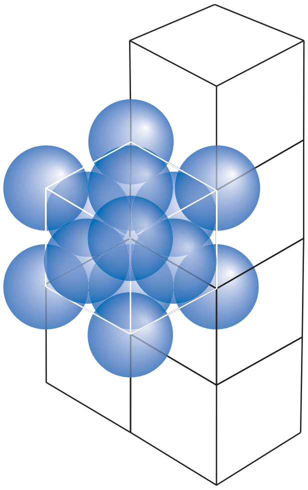

FIGURE 5.33 The entire crystal structure is constructed from a single type of unit cell by stacking the cells together without any gaps.

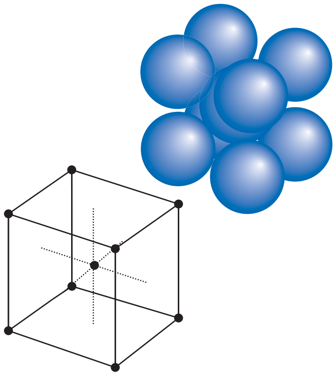

FIGURE 5.34 The body-centered cubic (bcc) structure. This structure is not packed as closely as the face-centered cubic and hexagonal close-packed structures. It is less common among metals than close-packed structures. Some ionic structures are based on this model.

Which close-packed structure—if either—is adopted by a metal depends on which has the lower energy, and that in turn depends on details of its electronic structure. In fact, some elements achieve a lower energy by adopting a different arrangement altogether, as we see in the next section.

Many metals have close-packed structures, with the atoms stacked in either a hexagonal or a cubic arrangement; close-packed atoms have a coordination number of 12. Close-packed structures have one octahedral and two tetrahedral holes per atom.

5.13 Unit Cells

We do not have to draw the complete crystal lattice every time we want to convey the structure of a solid. Instead, we can focus our attention on a small region of the crystal that is representative of the entire crystal. The small group illustrated in Fig. 5.30 is an example of a **unit cell,** the smallest unit that, when stacked together repeatedly without any gaps and without rotations, can reproduce the entire crystal (Fig. 5.33). A cubic close-packed unit cell like that illustrated in Fig. 5.33 has an atom at the center of each face of the unit cell; for this reason, it is also called a **face-centered cubic structure** (fcc). In a **body-centered cubic structure** (bcc), a single atom lies at the center of a cube formed by eight other atoms (Fig. 5.34). This structure is not close packed, and metals that have a body-centered cubic structure can often be forced under pressure into a close-packed form. Iron, sodium, and potassium are examples of metals that crystallize with bcc structures. A **primitive cubic structure** has an atom at each corner of a cube. The atoms touch along the edges (Fig. 5.35). This structure is known for only one element, polonium: covalent forces are so strong in this metalloid that they overcome the tendency toward close packing characteristic of metallic bonding. Unit cells are drawn by representing each atom by a dot that marks the location of the atom's center (Fig. 5.36).

All crystal structures can be expressed in terms of only 14 basic patterns of unit cell called **Bravais lattices** (Fig. 5.37). We can begin to understand why the number of types of unit cells is limited to such a small number by recognizing that regular pentagonal shapes are absent from the Bravais lattices: regular pentagons cannot cover space without gaps (Fig. 5.38). Similarly, regular heptagonal (seven-sided) and higher polygonal shapes cannot be stacked together to cover all space; hence they do not occur among the Bravais lattices.

The number of atoms in a unit cell is counted by noting how they are shared between neighboring cells. For example, an atom at the center of a cell belongs entirely to that cell, but one on a face is shared between two cells and counts as one-half an atom. As noted earlier, for an fcc structure, the eight corner atoms contribute $8 \times 1/8 = 1$ atom to the cell. The six atoms at the centers of faces contribute $6 \times 1/2 = 3$ atoms (Fig. 5.39). The total number of atoms in an fcc unit cell is therefore $1 + 3 = 4$, and the mass of the unit cell is four times the mass of one atom. For a bcc unit cell (like

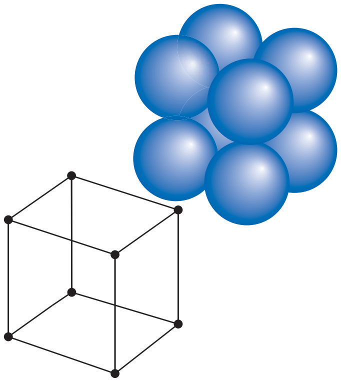

FIGURE 5.35 A primitive cubic unit cell has an atom at each corner. It is rarely found in metals.

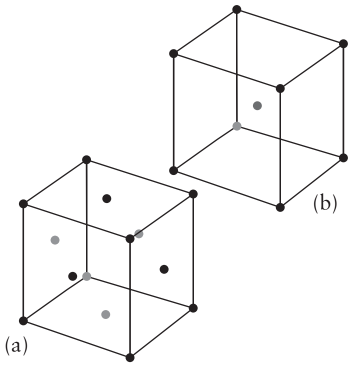

FIGURE 5.36 The unit cells of the (a) ccp (fcc) and (b) bcc structures in which the locations of the centers of the spheres are marked by dots.

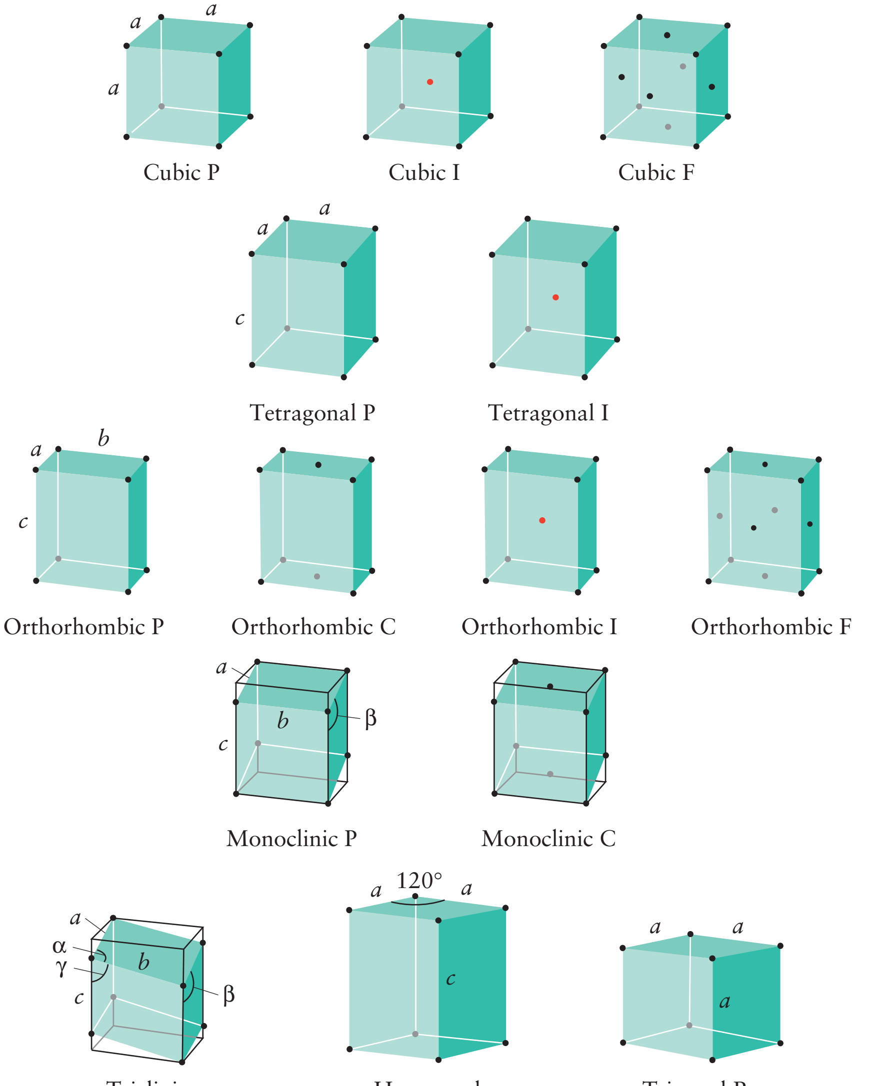

FIGURE 5.37 The 14 Bravais lattices. P denotes primitive; I, body-centered; F, face-centered; C, with a lattice point on two opposite faces; and R, rhombohedral (a rhomb is an oblique equilateral parallelogram).

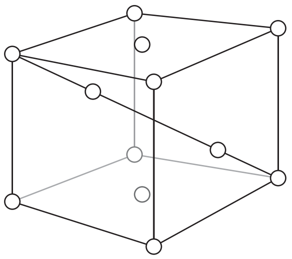
that in Fig. 5.36b), we count 1 for the atom at the center and 1/8 for each of the eight atoms at the vertices, giving $1 + (8 \times 1/8) = 2$ overall.

Self-Test 5.4A How many atoms are there in a primitive cubic cell (see Fig. 5.35)?

[*Answer:* 1]

Self-Test 5.4B How many atoms are there in the structure made up of unit cells like the one shown in (**13**), which has an atom at each corner, two on opposite faces, and two inside the cell on a diagonal?



13

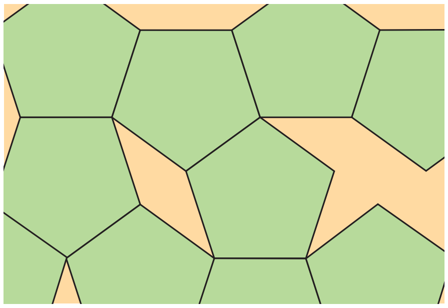


FIGURE 5.38 A plane surface cannot be covered by regular pentagons without leaving gaps. The same is true of regular heptagons.

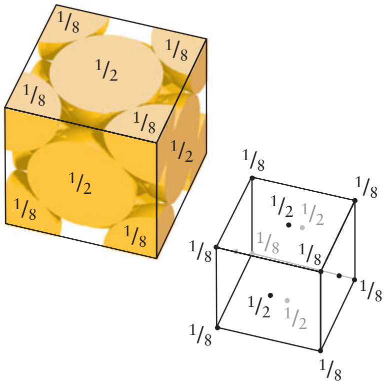

FIGURE 5.39 The calculation of the net number of atoms in a face-centered cubic cell.

The best way to determine the type of unit cell adopted by a metal is x-ray diffraction, which gives a characteristic diffraction pattern for each type of unit cell (see Major Technique 3 following this chapter). However, a simpler procedure that can be used to distinguish between close-packed and other structures is to measure the density of the metal; we then calculate the densities of the candidate unit cells and decide which structure accounts for the observed density. Density is an intensive property, which means that it does not depend on the size of the sample (Section A). Therefore, it is the same for a unit cell and a bulk sample. Hexagonal and cubic close packing cannot be distinguished in this way, because they have the same coordination numbers and therefore the same densities (for a given element).

EXAMPLE 5.3 Deducing the structure of a metal from its density

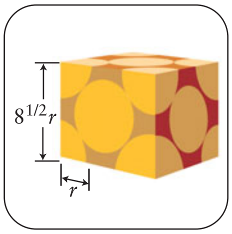
The density of copper is 8.93 $g \cdot cm^{-3}$ and its atomic radius is 128 pm. Is the metal (a) close-packed or (b) body-centered cubic?

PLAN We calculate the density of the metal by assuming first that its structure is ccp (fcc) and then that it is bcc. The structure with the density closer to the experimental value is more likely to be the actual structure. The mass of a unit cell is the sum of the masses of the atoms that it contains. The mass of each atom is equal to the molar mass of the element divided by Avogadro's constant. The volume of a cubic unit cell is the cube of the length of one of its sides. That length is obtained from the radius of the metal atom, the Pythagorean theorem, and the geometry of the cell.

SOLVE (a) We established in Section 5.12 that the length, a, of the side of an fcc unit cell composed of spheres of radius r is $a = 8^{1/2}r$. The volume of the unit cell is a^3 (Fig. 5.40c). Because there are four atoms in the cell, the mass, m, of one unit cell is four times the mass of one atom (M/N_A). The density, d, is therefore

From $d = m/a^3$, $m = 4M/N_A$, and $a = 8^{1/2}r$,

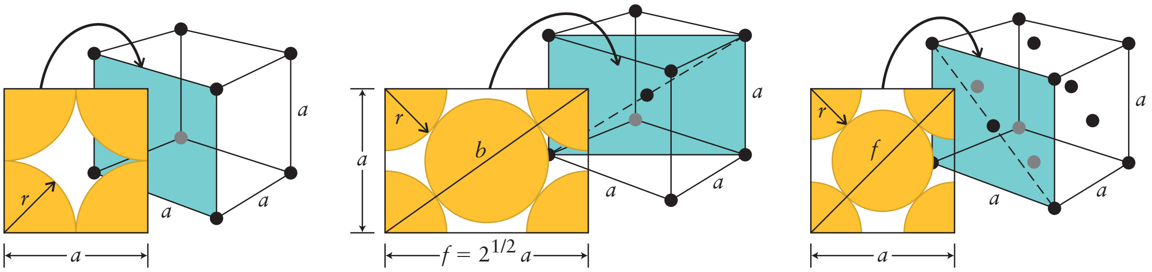
$$d = \frac{4M/N_A}{(8^{1/2}r)^3} = \frac{4M}{8^{3/2}N_A r^3}$$



A radius of 128 pm corresponds to 1.28×10^{-8} cm, and the molar mass of copper (from the periodic table on the inside front cover) is 63.55 $g \cdot mol^{-1}$. The predicted density is therefore

From $d = 4M/(8^{3/2}N_A r^3)$,

$$d = \frac{4 \times (63.55\ g \cdot mol^{-1})}{8^{3/2} \times (6.022 \times 10^{23}\ mol^{-1}) \times (1.28 \times 10^{-8}\ cm)^3} = 8.90\ g \cdot cm^{-3}$$



(a) Primitive cubic (b) Body-centered cubic (c) Face-centered cubic (ccp)

FIGURE 5.40 The geometries of three cubic unit cells, showing the relation of the dimensions of each cell to the radius, r, of a sphere representing an atom or ion. The side of a cell is a, the diagonal of the body of a cell b, and the diagonal of a face f.

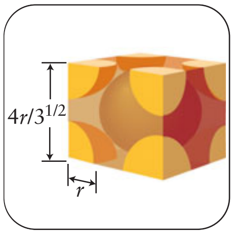
(b) To calculate the density of a bcc unit cell, we let the length of the diagonal of a face of the cell be f and the length of the diagonal through the body of the cell be b. Then, from Fig. 5.40b and the Pythagorean theorem, $a^2 + f^2 = b^2 = (4r)^2$. The Pythagorean theorem also tells us that $f^2 = 2a^2$, and so

$$a^2 + f^2 = a^2 + 2a^2 = 3a^2$$

It follows that $3a^2 = (4r)^2$ and therefore that $a = 4r/3^{1/2}$. Each unit cell contains one sphere at each of the eight corners and one sphere at the center: $8 \times 1/8 + 1 = 2$ spheres; so the total mass of a body-centered cubic unit cell is $2M/N_A$. Therefore,

From $d = m/a^3$, $m = 2M/N_A$, and $a = 4r/3^{1/2}$,

$$d = \frac{2M/N_A}{(4r/3^{1/2})^3} = \frac{3^{3/2}M}{32N_A r^3}$$



When we insert numerical values, we obtain

From $d = 3^{3/2}M/(32N_A r^3)$,

$$d = \frac{3^{3/2} \times (63.55\ \text{g}\cdot\text{mol}^{-1})}{32 \times (6.022 \times 10^{23}\ \text{mol}^{-1}) \times (1.28 \times 10^{-8}\ \text{cm})^3} = 8.17\ \text{g}\cdot\text{cm}^{-3}$$

The value for a body-centered structure is farther from 8.93 $\text{g}\cdot\text{cm}^{-3}$, the experimental value, than that for a close-packed structure, 8.90 $\text{g}\cdot\text{cm}^{-3}$, and so we conclude that copper has a close-packed structure. In fact, x-ray diffraction shows that copper is cubic close-packed at room temperature.

Self-Test 5.5A The atomic radius of silver is 144 pm and its density is 10.5 $\text{g}\cdot\text{cm}^{-3}$. Is the structure close-packed or body-centered cubic?

[***Answer:*** Close-packed cubic]

Self-Test 5.5B The atomic radius of iron is 124 pm and its density is 7.87 $\text{g}\cdot\text{cm}^{-3}$. Is this density consistent with a close-packed or a body-centered cubic structure?

All crystal structures are derived from the 14 Bravais lattices. The atoms in a unit cell are counted by determining what fraction of each atom resides within the cell. The type of unit cell adopted by a metal can be determined by measuring its density.

5.14 Ionic Structures

As we have seen, we can model elemental metals by spheres of the same radius. However, to model ionic solids, we need to pack together spheres of different radii and opposite charges. Sodium chloride, for instance, is modeled by stacking together positively charged spheres of radius 102 pm, representing the Na^+ ions, and negatively charged spheres of radius 181 pm, representing the Cl^- ions. Because the crystal is electrically neutral overall, each unit cell must reflect the stoichiometry of the compound and itself be electrically neutral.

A helpful starting point is one of the close-packed structures we have already considered. Because anions are usually larger than the accompanying cations, we think of the anions as forming a slightly expanded version of a close-packed structure with the smaller cations occupying some of the enlarged holes in the expanded lattice. A slightly enlarged tetrahedral hole is still relatively small and can accommodate only small cations. Octahedral holes are larger and can accommodate somewhat bigger cations.

The **rock-salt structure** is a common ionic structure that takes its name from the mineral form of sodium chloride. In it, the Na^+ ions lie at the corners and in the centers of the faces of a cube, forming a face-centered cube (Fig. 5.41). This arrangement

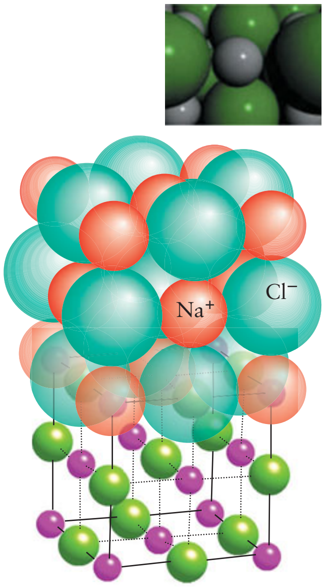


FIGURE 5.41 The arrangement of ions in the rock-salt structure. Above is the unit cell, showing the packing of the individual ions, and below a representation of the same structure by spheres that identify the centers of the ions.

Animation 5.41

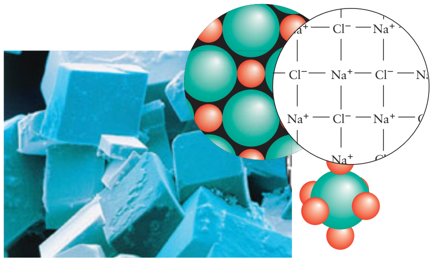

FIGURE 5.42 Billions of unit cells stack together to recreate the smooth faces of the crystal of sodium chloride seen in this micrograph. The first inset shows some of the stacked unit cells. The second inset identifies the individual ions. The third inset (lower right) illustrates the coordination of an anion to its six cation neighbors.

is like an expanded ccp arrangement: the expansion keeps the cations out of contact with one another, thereby reducing their repulsion, and opens up holes that are big enough to accommodate the Cl^- ions. These ions fit into the octahedral holes between the Na^+ ions. There is one octahedral hole for each cation in the close-packed array, and so all the octahedral holes are occupied. If we look carefully at the structure, we can see that each cation is surrounded by six anions and each anion is surrounded by six cations. The pattern repeats over and over, with each ion surrounded by six other ions of the opposite charge (Fig. 5.42). A crystal of sodium chloride is a three-dimensional array of a vast number of these little cubes.

In an ionic solid, the "coordination number" means the number of ions of *opposite* charge immediately surrounding a specific ion. In the rock-salt structure, the coordination numbers of the cations and the anions are both 6, and the structure overall is described as having *(6,6)-coordination*. In this notation, the first number is the cation coordination number and the second is that of the anion. The rock-salt structure is found for a number of other minerals having ions of the same charge number, including KBr, RbI, CaO, and AgCl. It is common whenever the cations and anions have very different radii, in which case the smaller cations can fit into the octahedral holes in a face-centered cubic array of anions. The **radius ratio, ρ** (rho), which is defined as

$$\text{Radius ratio} = \frac{\text{radius of smaller ion}}{\text{radius of larger ion}} \quad \text{or} \quad \rho = \frac{r_{\text{smaller}}}{r_{\text{larger}}} \qquad (8)^*$$

is a guide to the type of structure to expect. Although there are many exceptions, a rock-salt structure can be expected when the radius ratio is in the range from 0.4 to 0.7. For example, the radius of the Mg^{2+} ion is 72 pm and that of the O^{2-} ion is 140. pm. Therefore, for MgO,

$$\rho = \frac{\overbrace{72\text{ pm}}^{\text{radius of } Mg^{2+}}}{\underbrace{140.\text{ pm}}_{\text{radius of } O^{2-}}} = 0.514$$

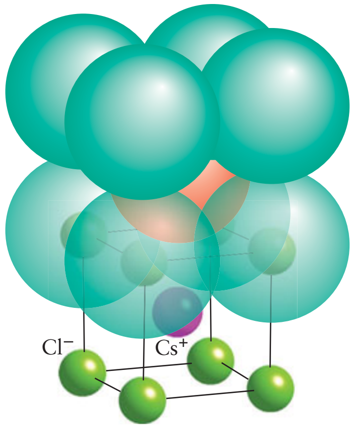

FIGURE 5.43 The cesium chloride structure: above is the unit cell and below a second unit cell showing the location of the centers of the ions.

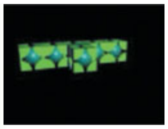
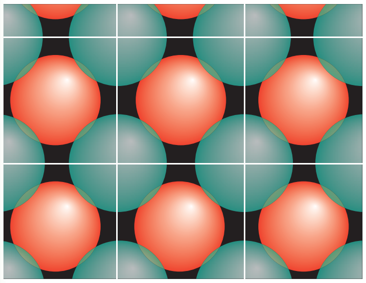
This ratio is consistent with the rock-salt structure, which is indeed the one observed in MgO crystals.

When the radii of the cations and anions are similar and $\rho > 0.7$, more anions can fit around each cation. Now the ions may adopt the **cesium chloride structure** typified by cesium chloride, CsCl (Fig. 5.43). The radius of a Cs^+ ion is 167 pm and that of a Cl^- ion is 181 pm, giving a radius ratio of 0.923; so the two ions are almost the same size. In this structure, the anions form an expanded primitive cubic array, with a Cl^- ion at the eight corners of each cubic unit cell. There is a large "cubic" hole at the center of the cell, and the Cs^+ ion fits into it. Equivalently, each Cl^- ion can be regarded as being at the center of a cubic unit cell with eight Cs^+ ions at its corners, and so overall the crystal can be thought of as built from two interpenetrating primitive cubic lattices (Fig. 5.44). The coordination number of each type of ion is 8, and overall the structure has *(8,8)-coordination*. The cesium chloride structure is much less common than the rock-salt structure, but it is also found for CsBr, CsI, TlCl, and TlBr.





Animation 5.44

FIGURE 5.44 The repetition of the cesium chloride unit cell recreates the entire crystal. This view is from one side of the crystal and shows several unit cells stacked together.

When the radius ratio of an ionic compound is less than about 0.4, corresponding to cations that are significantly smaller than the anion, the small tetrahedral holes may be occupied. An example is the **zinc-blende structure** (which is also called the

sphalerite structure), named after a form of the mineral ZnS (Fig. 5.45). This structure is based on an expanded cubic close-packed lattice of the big S^{2-} anions, with the small Zn^{2+} cations occupying half the tetrahedral holes. Each Zn^{2+} ion is surrounded by four S^{2-} ions, and each S^{2-} ion is surrounded by four Zn^{2+} ions; so the zinc-blende structure has *(4,4)-coordination*.

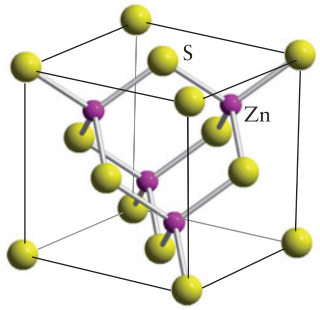


FIGURE 5.45 The zinc-blende (sphalerite) structure. The four zinc ions (purple) form a tetrahedron within a face-centered cubic unit cell composed of sulfide ions (yellow). The zinc ions occupy half the tetrahedral holes between the sulfide ions. Each zinc ion is surrounded by four sulfide ions; each sulfide ion is similarly surrounded by four zinc ions.

Self-Test 5.6A Predict (a) the likely structure and (b) coordination type of solid ammonium chloride. Assume that the ammonium ion can be approximated as a sphere with a radius of 151 pm.

[***Answer:*** (a) cesium chloride structure; (b) (8,8)-coordination]

Self-Test 5.6B Predict (a) the likely structure and (b) coordination type of solid calcium sulfide.

When we discuss the structures of ionic solids, we usually treat ions as spheres of the appropriate radius and stack them together in the arrangement that has the lowest total energy. However, the simple sphere-packing arrangement may break down if the bonding is not purely ionic. In cases where the bonding has a significant degree of covalent character, the ions will lie in specific positions around one another. An example is nickel arsenide, NiAs. In this solid, the small Ni^{3+} cations polarize the big As^{3-} anions, and the bonds have some covalent character. The ions pack together in an arrangement that is quite different from that of a purely ionic, sphere-packing model (Fig. 5.46). Once the structure of an ionic compound is known, its density can be estimated by using an approach similar to that used for metals.

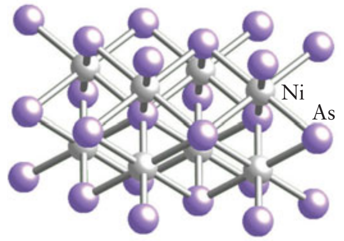

FIGURE 5.46 The structure of nickel arsenide, NiAs. Atypical structures such as this one are often found when the covalent character of the bonding is important and the ions have to take up specific positions relative to one another to maximize their bonding.

EXAMPLE 5.4 Estimating the density of an ionic solid

Estimate the density of cesium chloride from its crystal structure.

Anticipate The densities of ionic compounds are typically a few grams per cubic centimeter.

PLAN As for metals, the density of the bulk solid is the same as that of the unit cell. The volume of the cesium chloride unit cell is the cube of the length of one of its sides, and that length can be worked out from the Pythagorean theorem. The mass of the unit cell is obtained by counting the net number of ions of each kind and using the mass of each ion (its molar mass divided by Avogadro's constant). The density is obtained by dividing the mass by the volume. Assume cations and anions touch either along diagonals (as in cesium chloride) or along edges, as in rock salt.

SOLVE

The radius of the Cs^+ ion is 170 pm and that of the Cl^- is 181 pm. Therefore, the length of the diagonal of the unit cell is, from $r(Cs^+) + 2r(Cl^-) + r(Cs^+)$,

$$b = 170 + 2(181) + 170 \text{ pm} = 702 \text{ pm (Fig. 5.43)},$$

corresponding to 7.02×10^{-8} cm.

The length of the side, a, is related to b by $a = b/3^{1/2}$ (recall Example 5.3).

The volume of the unit cell is therefore $a^3 = (b/3^{1/2})^3$.

Each body-centered unit cell contains one Cs^+ ion (of molar mass 132.91 $g\cdot mol^{-1}$) and one Cl^- ion (of molar mass 35.45 $g\cdot mol^{-1}$). The total mass of the unit cell is the sum of these two masses divided by Avogadro's constant, N_A.

From $d = M/N_A(b/3^{1/2})^3$,

$$d = \frac{(132.91 + 35.45)\ g\cdot mol^{-1}}{(6.022 \times 10^{23}\ mol^{-1}) \times (7.02 \times 10^{-8}\ cm/3^{1/2})^3} = 4.20\ g\cdot cm^{-3}$$

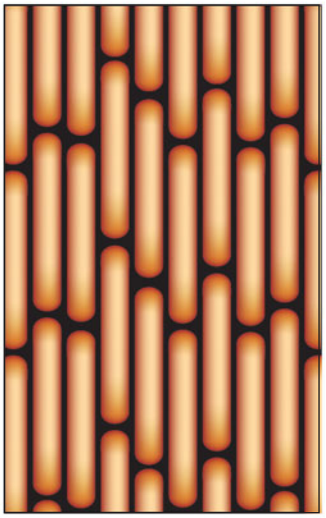

FIGURE 5.47 A representation of the nematic phase of a liquid crystal. The long molecules lie parallel to one another but are staggered along their long axes. In this and the next two illustrations we have not attempted to show the thermal disorder that upsets the regularity of the arrays to some extent.

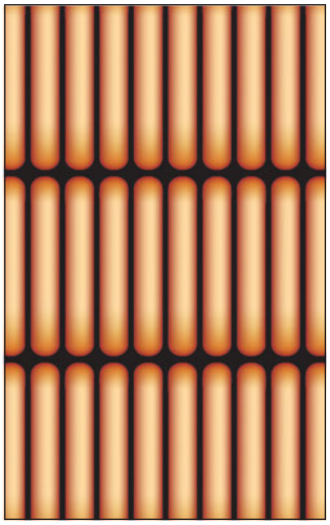

FIGURE 5.48 The smectic phase of a liquid crystal. Not only do the molecules lie parallel to one another, they also line up next to one another to form sheets.

Evaluate The calculated value is in the expected range, but the experimental value is 3.99 $g\cdot cm^{-3}$. The discrepancy is probably due to the assumption that the ions have the radii listed and behave like hard spheres.

Self-Test 5.7A Estimate the density of sodium chloride from its crystal structure.

[*Answer:* 2.14 $g\cdot cm^{-3}$]

Self-Test 5.7B Estimate the density of cesium iodide from its crystal structure.

Ions stack together in the regular crystalline structure corresponding to lowest energy. The structure adopted depends on the radius ratio of cation and anion. Covalent character in an ionic bond imposes a directional character on the bonding.

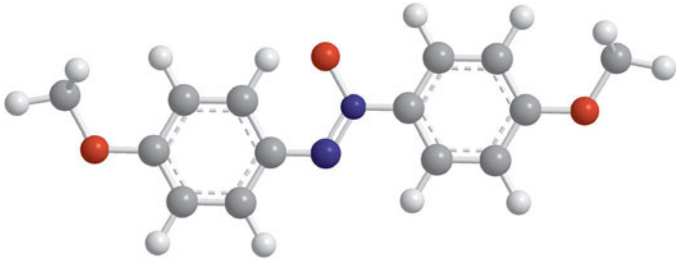
THE IMPACT ON MATERIALS

Some materials do not fall so easily into the categories of solid, liquid, and gas. Others appear to violate the chemical principles we have seen so far in this chapter. Such materials are not rare substances and play a part in our daily lives. In the following sections you will see how a liquid can have some of the properties of a crystal, how some ionic substances can be liquid at room temperature, and how these unusual properties allow such materials to play important roles in modern technology.

5.15 Liquid Crystals

One type of material that has transformed electronic displays is neither a solid nor a liquid, but something intermediate between the two. **Liquid crystals** are substances that flow like viscous liquids, but their molecules lie in a moderately orderly array, like those in a crystal. They are examples of a **mesophase,** an intermediate state of matter with the fluidity of a liquid and some of the molecular order of a solid. Liquid crystalline materials are finding many applications in the electronics industry because they are responsive to changes in temperature and electric fields.

A typical liquid-crystal molecule, such as *p*-azoxyanisole, is long and rodlike (**14**). Their rodlike shape enables the molecules to stack together like dry, uncooked spaghetti: they lie parallel to one another but are free to slide past one another along their long axes. Liquid crystals are anisotropic because of this ordering. **Anisotropic materials** have properties that depend on the direction of measurement. The viscosity of liquid crystals is least in the direction parallel to the long axis of the molecules: it is easier for the long rod-shaped molecules to slip past one another along their axes than to move sideways. **Isotropic materials** have properties that do not depend on the direction of measurement. Ordinary liquids, like water, are isotropic: their viscosities are the same in every direction.



14 *p*-Azoxyanisole

Nematic comes from the Greek word for "thread"; *smectic* comes from the Greek word for "soapy"; *cholesteric* is related to the word cholesterol, which comes from the Greek words for "bile solid."

The three classes of liquid crystals differ in the arrangement of their molecules. In the **nematic phase** the molecules lie together, all in the same direction but staggered, like cars on a busy multilane highway (Fig. 5.47). In the **smectic phase** the molecules line up like soldiers on parade and form layers (Fig. 5.48). Cell membranes are composed mainly of smectic liquid crystals. In the **cholesteric phase** the molecules form

ordered layers, but neighboring layers have molecules at different angles and so the liquid crystal has a helical arrangement of molecules (Fig. 5.49).

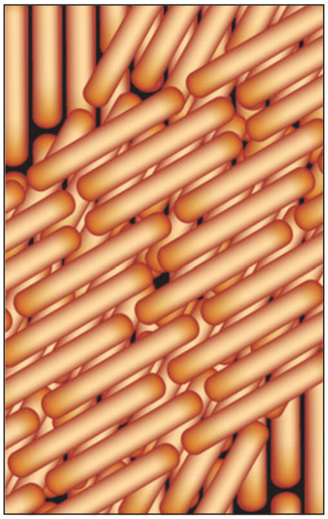


FIGURE 5.49 The cholesteric phase of a liquid crystal. In this phase, sheets of parallel molecules are rotated relative to their neighbors and form a helical structure.

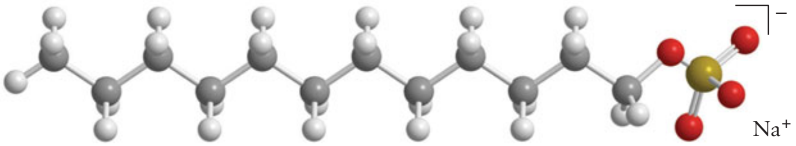
Liquid crystals are also classified by their manner of preparation. **Thermotropic liquid crystals** are made by melting the solid phase. The highly viscous liquid-crystal phase exists over a short temperature range between the solid and liquid states. Thermotropic liquid crystals become isotropic liquids when they are heated above a characteristic temperature, because then the molecules have enough energy to overcome the attractions that restrict their movement. *p*-Azoxyanisole is a thermotropic liquid crystal. Thermotropic liquid crystals are used in applications such as watches, computer screens, and thermometers. **Lyotropic liquid crystals** are layered structures that result from the action of a solvent on a solid or liquid. Examples are cell membranes and aqueous solutions of detergents and lipids (fats). These molecules, like the detergent sodium lauryl sulfate, have long, nonpolar hydrocarbon chains attached to polar heads (**15**). When the lipids that form cell membranes are mixed with water, they spontaneously form sheets in which the molecules are aligned in rows, forming a double layer, with their polar heads facing outward on each side of the sheet. These sheets form the protective membranes of the cells that make up living tissues (see Fig. 9.45).



15 Sodium lauryl sulfate

Electronic displays make use of the anisotropy of the nematic phase and the changes in orientation of liquid-crystal molecules caused by an electric field. In an LCD (liquid-crystal display) television or computer monitor, layers of a liquid crystal in a nematic phase lie between the surfaces of two glass or plastic plates. The long axis of the molecules twists from the orientation governed by grooves in one plate to the perpendicular orientation governed by the grooves in the second plate (Fig. 5.50). The light from the lamp is polarized, and as it passes through the twisted liquid crystal its plane of polarization changes too, and it is able to pass through the second polarizer. However, where a potential difference is applied between the electrodes (the second being in the shape of the characters it is intended to display, in this case, a simple numerical display), the twist is lost, and so too is the change of polarization of the light. As a result, a dark spot forms on the screen. In a "super-twist" LCD screen, the twist of the resting liquid crystal has more than one turn.

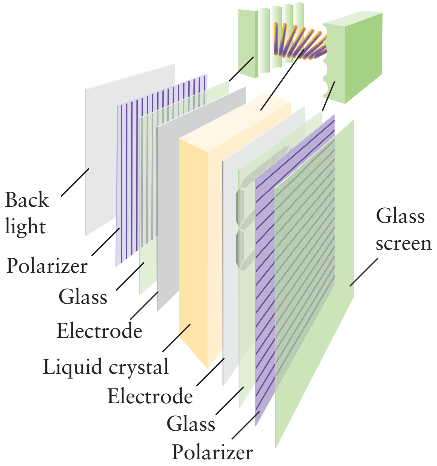


FIGURE 5.50 The structure of a back-lit LCD screen. The inset shows how the liquid crystal molecules twist from one orientation to another as determined by the grooves in the transparent plates. When a potential difference is applied between the electrodes, this twist is lost.

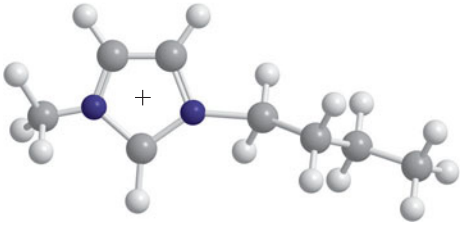
Cholesteric liquid crystals are also of interest because the helical structure unwinds slightly as the temperature is changed. Because the twist of the helical structure affects the optical properties of the liquid crystal, such as its color, these properties change with temperature. The effect is utilized in liquid-crystal thermometers.

Liquid crystals have a degree of order characteristic of solid crystals, but they can flow like viscous liquids. They are mesophases, intermediate between solids and liquids; their properties can be modified by electric fields and changes in temperature.

5.16 Ionic Liquids

We have seen that molecular substances tend to have low melting points, whereas network, ionic, and metallic substances tend to have high melting points. Therefore, with a few exceptions, such as mercury, a substance that is liquid at room temperature is likely to be a molecular substance. Liquid solvents are heavily used in industry to extract substances from natural products and to promote the synthesis of desired compounds. Because many of these solvents have high vapor pressures and so give off hazardous fumes, liquids that have low vapor pressures but dissolve organic compounds have been sought.



16 1-Butyl-3-methylimidazolium ion

A new class of solvents called **ionic liquids** has been developed to meet this need. A typical ionic liquid has a relatively small anion, such as BF_4^-, and a relatively large, organic cation, such as 1-butyl-3-methylimidazolium (**16**). Because the cation has a large nonpolar region and is often asymmetrical, the compound does not crystallize easily and so is liquid at room temperature. It can also dissolve nonpolar organic compounds. However, the attractions between the ions reduce the vapor pressure to about the same as that of an ionic solid, thereby reducing air pollution. Because different cations and anions can be used, solvents can be designed for specific applications. For example, one formulation can dissolve the rubber in old tires so that it can be recycled. Other solvents can be used to extract radioactive waste from groundwater.

Ionic liquids are compounds in which one of the ions is a large, organic ion that prevents the liquid from crystallizing at ordinary temperatures. The low vapor pressures of ionic liquids make them desirable solvents that reduce pollution.

SKILLS YOU SHOULD HAVE MASTERED

- ❑ 1 Predict the relative strengths of ion–dipole interactions (Section 5.2).
- ❑ 2 Explain how London forces arise and how they vary with the polarizability of an atom and the size and shape of a molecule (Section 5.4).
- ❑ 3 Predict the relative order of the boiling points of two substances from the strengths of their intermolecular forces (Examples 5.1 and 5.2).
- ❑ 4 Identify molecules that can take part in hydrogen bonding (Self-Test 5.3).
- ❑ 5 Describe the structure of a liquid and explain how viscosity and surface tension vary with temperature and the strength of intermolecular forces (Sections 5.7 and 5.8).
- ❑ 6 Distinguish metallic solids, ionic solids, network solids, and molecular solids by their structures and by their properties (Sections 5.9–5.12).
- ❑ 7 Determine the fraction of occupied space in a given crystal lattice (Section 5.12).
- ❑ 8 Give the coordination number of an atom or ion in a given crystal lattice (Section 5.12).
- ❑ 9 Find the number of atoms or ions in a given unit cell (Self-Test 5.4).
- ❑ 10 Deduce the crystal structure of a metal from its density (Example 5.3).
- ❑ 11 Describe the structure of ionic solids and liquids (Sections 5.14 and 5.16).
- ❑ 12 Predict the structure of an ionic solid from the relative radii of the ions (Section 5.14).
- ❑ 13 Calculate the density of an ionic solid (Example 5.4).
- ❑ 14 Identify the different types of liquid crystals (Section 5.15).

EXERCISES

Exercises labeled **C** *require calculus*

Intermolecular Forces

5.1 Identify the kinds of intermolecular forces that might arise between molecules of each of the following substances: (a) NH_2OH; (b) CBr_4; (c) H_2SeO_4; (d) SO_2.

5.2 Identify the kinds of intermolecular forces that might arise between molecules of each of the following substances: (a) NF_3; (b) PH_3; (c) HI; (d) HIO (O is the central atom).

5.3 For which of the following molecules will dipole–dipole interactions be important: (a) CH_4; (b) CH_3Cl; (c) CH_2Cl_2; (d) $CHCl_3$; (e) CCl_4?

5.4 For which of the following molecules will dipole–dipole interactions be important: (a) O_2; (b) O_3; (c) CO_2; (d) SO_2?

5.5 Suggest, giving reasons, which substance in each of the following pairs is likely to have the higher normal melting point (Lewis structures may help your arguments): (a) HCl or NaCl; (b) $C_2H_5OC_2H_5$ (diethyl ether) or C_4H_9OH (butanol); (c) CHI_3 or CHF_3; (d) C_2H_4 or CH_3OH.

5.6 Suggest, giving reasons, which substance in each of the following pairs is likely to have the higher normal boiling point: (a) H_2S or H_2O; (b) NH_3 or PH_3; (c) KBr or CH_3Br; (d) CH_4 or SiH_4.

5.7 Using the VSEPR model, predict the shapes of each of the following molecules and identify the member of each pair with the higher boiling point: (a) PBr_3 or PF_3; (b) SO_2 or CO_2; (c) BF_3 or BCl_3.

5.8 Using the VSEPR model, predict the shapes of each of the following molecules and identify the member of each pair with the higher boiling point: (a) BF_3 or ClF_3; (b) SF_4 or CF_4; (c) *cis*-CHCl═CHCl or *trans*-CHCl═CHCl. (See structures **5** and **6**.)

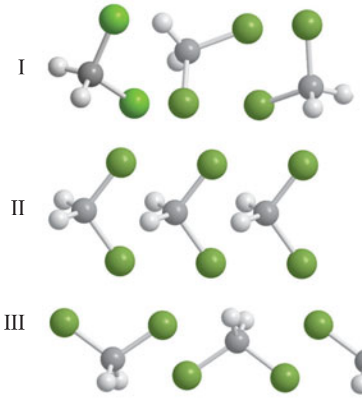
5.9 Place the following types of molecular and ion interactions in order of increasing magnitude: (a) ion–dipole; (b) induced-dipole–induced-dipole; (c) dipole–dipole in the gas phase; (d) ion–ion; (e) dipole–dipole in the solid phase.

5.10 In each pair, indicate which substance has the stronger intermolecular forces and explain your reasoning: (a) Ne, Ar; (b) NF_3, BF_3; (c) SiH_4, GeH_4; (d) NaF, HF.

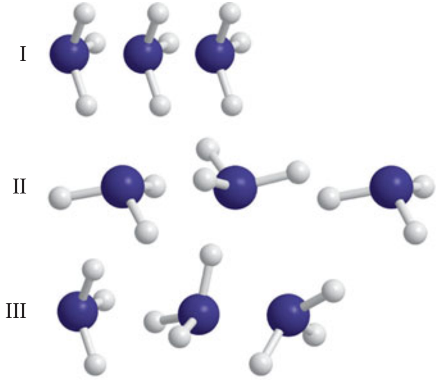
5.11 Which of the following molecules are likely to form hydrogen bonds: (a) PH_3; (b) HBr; (c) C_2H_4; (d) HNO_2?

5.12 Which of the following molecules are likely to form hydrogen bonds: (a) CH_3OCH_3; (b) CH_3COOH; (c) CH_3CH_2OH; (d) CH_3CHO?

5.13 Identify the arrangement (I, II, or III; all molecules are CH_2Cl_2) that should possess the strongest intermolecular attractions, and justify your selection.



5.14 Identify the arrangement (I, II, or III; all molecules are NH_3) that should possess the strongest intermolecular attractions, and justify your selection.



5.15 Calculate the ratio of the potential energies for the interaction of a water molecule with an Al^{3+} ion and with a Be^{2+} ion. Take the center of the dipole to be located at r_{ion} + 100. pm. Which ion will attract a water molecule more strongly?

5.16 Calculate the ratio of the potential energies for the interaction of a water molecule with a Ca^{2+} ion and with an In^{3+} ion. Take the center of the dipole to be located at r_{ion} + 100. pm. Which ion will attract a water molecule more strongly?

5.17 Account for the following observations in terms of the type and strength of intermolecular forces. (a) The melting point of solid xenon is –112°C and that of solid argon is –189°C. (b) The vapor pressure of diethyl ether ($C_2H_5OC_2H_5$) is greater than that of water. (c) The boiling point of pentane, $CH_3(CH_2)_3CH_3$, is 36.1°C, whereas that of 2,2-dimethylpropane (also known as neopentane), $C(CH_3)_4$, is 9.5°C.

5.18 Two students are assigned two pure compounds to investigate. They observe that compound A boils at 37°C and compound B at 126°C. However, they run out of time to make any additional measurements, so make the following guesses about the two compounds. In each case indicate whether the guess can be justified by the data, is in error, or could be either true or false. Justify your answers. (a) Compound B has the higher molar mass. (b) Compound A is the more viscous. (c) Compound B has stronger intermolecular forces. (d) Compound B has the higher surface tension.

5.19 We have been using "intermolecular interaction" and "intermolecular force" almost interchangeably. However, it is important to distinguish the force from the potential energy of interaction. In classical mechanics, the magnitude of the force, F, is related to the distance dependence of the potential energy, E_P, by $F = -dE_P/dr$. How does the intermolecular force depend on separation for a typical intermolecular interaction that varies as $1/r^6$?

5.20 Would you expect the energy of interaction of two rotating polar molecules, as given by Eq. 4, to depend on the temperature? If so, should the interaction increase or decrease as the temperature is raised?

Liquid Structure

5.21 Predict how each of the following properties of a liquid varies as the strength of intermolecular forces increases and explain your reasoning: (a) boiling point; (b) viscosity; (c) surface tension.

5.22 Predict how each of the following properties of a liquid changes as the temperature increases and explain your reasoning: (a) boiling point; (b) viscosity; (c) surface tension.

5.23 Predict which liquid in each of the following pairs has the greater surface tension: (a) *cis*-dichloroethene or *trans*-dichloroethene (see structures **5** and **6**); (b) benzene at 20°C or benzene at 60°C.

5.24 Predict which substance in each of the following pairs has the greater viscosity in its liquid form at 0°C: (a) ethanol, CH_3CH_2OH, or dimethyl ether, CH_3OCH_3; (b) butane, C_4H_{10}, or propanone, CH_3COCH_3.

5.25 Rank the following molecules in order of increasing viscosity at 50°C: C_6H_5SH, C_6H_5OH, C_6H_6.

5.26 Rank the following liquids in order of increasing viscosity at 25°C: C_6H_6, CH_3CH_2OH, $CH_2OHCHOHCH_2OH$, CH_2OHCH_2OH, and H_2O. Explain your ordering.

5.27 The following boiling points correspond to the substances listed. Match the boiling points to the substances by considering the relative strengths of their intermolecular forces. b.p. (°C): −162, −88.5, 28, 36, 64.5, 78.3, 82.5, 140, 205, 290; substance: CH_4, $CH_3CHOHCH_3$, $C_6H_5CH_2OH$ (has a benzene ring), CH_3CH_3, C_5H_9OH (cyclic), $(CH_3)_2CHCH_2CH_3$, CH_3OH, $HOCH_2CHOHCH_2OH$, $CH_3(CH_2)_3CH_3$, CH_3CH_2OH. *Hint*: The boiling point of $(CH_3)_2CHCH_2CH_3$ is 28°C and that of CH_3OH is 64.5°C.

5.28 The following surface tensions (in millinewtons per meter, $mN\cdot m^{-1}$, at 20°C) correspond to the liquids listed. Match the surface tension to the substance. Surface tension: 18.43, 22.75, 27.80, 28.85, 72.75; compound: H_2O, $CH_3(CH_2)_4CH_3$, C_6H_6, CH_3CH_2OH, CH_3COOH.

5.29 Consider Fig. 5.9. (a) Explain the large differences in the boiling points of H_2O and those of the remainder of the series (H_2S to H_2Te). (b) Explain the steady increase in the boiling points in the series CH_4 to SnH_4.

5.30 The surface of glass contains many —OH groups that are bonded to the silicon atoms of SiO_2, which is the major component of glass. If the glass is treated with $Si(CH_3)_3Cl$ (chlorotrimethylsilane), a reaction takes place to eliminate HCl and attach the Si atom to the oxygen atom:

$$\text{(surface of glass)—OH} + Si(CH_3)_3Cl \longrightarrow \text{(surface of glass)—OSi}(CH_3)_3 + HCl$$

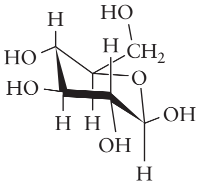
How will this rearrangement affect the interaction of liquids with the glass surface?

5.31 The height, h, of a column of liquid in a capillary tube can be estimated by using $h = 2\gamma/gdr$, where γ is the surface tension, d is the density of the liquid, g is the acceleration of free fall, and r is the radius of the tube. Which will rise higher in a tube that is 0.15 mm in diameter at 25°C, water or ethanol? The density of water is 0.997 $g{\cdot}cm^{-3}$ and that of ethanol is 0.79 $g{\cdot}cm^{-3}$. See Table 5.3.

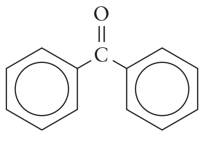
5.32 The expression for the capillary rise in Exercise 5.31 assumes that the tube is vertical. How will the expression be modified when the tube is held at an angle θ (theta) to the vertical?

Classification of Solids

5.33 Glucose, benzophenone ($C_6H_5COC_6H_5$), and methane are examples of compounds that form molecular solids. The structures of glucose and benzophenone are given here. (a) What types of forces hold these molecules in a molecular solid? (b) Place the solids in order of increasing melting point.



Glucose



Benzophenone

5.34 Chloromethane (CH_3Cl), methane, and acetic acid (CH_3COOH) form molecular solids. (a) What types of forces hold these molecules in a molecular solid? (b) Place the solids in order of increasing melting point.

5.35 Classify each of the following solids as ionic, network, metallic, or molecular: (a) quartz, SiO_2; (b) limestone, $CaCO_3$; (c) dry ice, CO_2; (d) sucrose, $C_{12}H_{22}O_{11}$; (e) polyethylene, a polymer with molecules consisting of chains of thousands of repeating $—CH_2CH_2—$ units.

5.36 Classify each of the following solids as ionic, network, metallic, or molecular: (a) iron pyrite (fool's gold), FeS_2; (b) octane (a component of gasoline), C_8H_{18}; (c) cubic boron nitride (a compound with a structure similar to that of diamond, but with alternating boron and nitrogen atoms), BN; (d) calcium sulfate (gypsum), $CaSO_4$; (e) the chromium plating on a motorcycle.

5.37 Three unknown substances were tested in order to classify them. The following table shows the results of the tests. Use Table 5.4 to classify substances A, B, and C as metallic, ionic, network, or molecular solids.

Substance	Appearance	Melting point, °C	Electrical conductivity	Solubility in water
A	hard, white	800	only when dissolved in water	soluble
B	lustrous, malleable	1500	high	insoluble
C	soft, yellow	113	none	insoluble

5.38 Three unknown substances were tested in order to classify them. The following table shows the results of the tests. Use Table 5.4 to classify substances X, Y, and Z as metallic, ionic, network, or molecular solids.

Substance	Appearance	Melting point, °C	Electrical conductivity	Solubility in water
X	brittle, white	146	none	soluble
Y	very hard, colorless	1600	none	insoluble
Z	hard, orange	398	only when dissolved in water	soluble

Solid Metallic Structures

5.39 Iron crystallizes in a bcc structure. The atomic radius of iron is 124 pm. Determine (a) the number of atoms per unit cell; (b) the coordination number of the lattice; (c) the length of the side of the unit cell.

5.40 The metal polonium (which was named by Marie Curie after her homeland, Poland) crystallizes in a primitive cubic structure, with an atom at each corner of a cubic unit cell. The atomic radius of polonium is 167 pm. Sketch the unit cell and determine (a) the number of atoms per unit cell; (b) the coordination number of an atom of polonium; (c) the length of the side of the unit cell.

5.41 Calculate the density of each of the following metals from the data given: (a) aluminum, fcc structure, atomic radius 143 pm; (b) potassium, bcc structure, atomic radius 227 pm.

5.42 Calculate the density of each of the following metals from the data given: (a) strontium, fcc structure, atomic radius 215 pm; (b) europium, bcc structure, atomic radius 204 pm.

5.43 Calculate the atomic radius of each of the following elements from the data given: (a) platinum, fcc structure, density 21.450 $g{\cdot}cm^{-3}$; (b) tantalum, bcc structure, density 16.654 $g{\cdot}cm^{-3}$.

5.44 Calculate the atomic radius of each of the following elements from the data given: (a) silver, fcc structure, density 10.500 $g{\cdot}cm^{-3}$; (b) chromium, bcc structure, density 7.190 $g{\cdot}cm^{-3}$.

5.45 The density of rhodium is 12.42 $g{\cdot}cm^{-3}$ and its atomic radius is 134 pm. Is the metal close-packed or body-centered cubic?

5.46 The density of vanadium is 6.11 $g{\cdot}cm^{-3}$ and its atomic radius is 132 pm. Is the metal close-packed or body-centered cubic?

5.47 One form of silicon has density of 2.33 $g{\cdot}cm^{-3}$ and crystallizes in a cubic lattice with a unit cell edge of 543 pm. (a) What is the mass of each unit cell? (b) How many silicon atoms does one unit cell contain?

5.48 Krypton crystallizes with a face-centered cubic unit cell of edge 559 pm. (a) What is the density of solid krypton? (b) What is

the atomic radius of krypton? (c) What is the volume of one krypton atom? (d) What percentage of the unit cell is empty space if each atom is treated as a hard sphere?

5.49 What percentage of space is occupied by close-packed cylinders of length *l* and radius *r*?

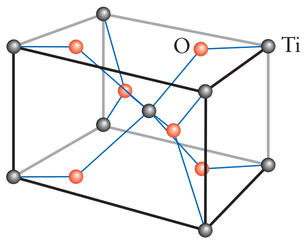
5.50 Calculate the radius of the cavity formed by three circular disks of radius *r* that lie in a close-packed planar arrangement. Check your answer experimentally by using three compact disks and measuring the radius of the cavity that they form.

Nonmetallic Solids

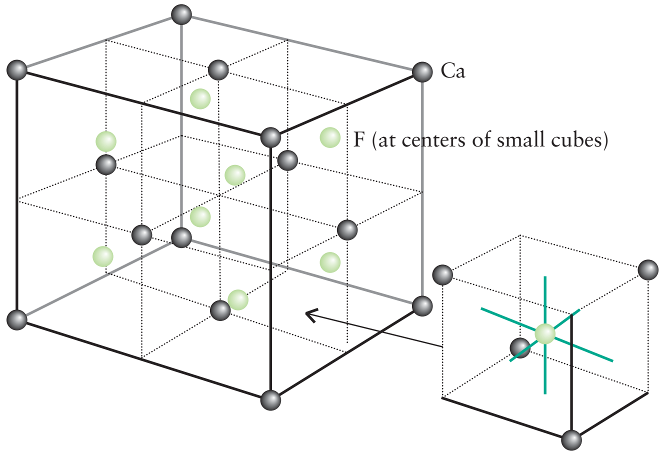
5.51 Indium arsenide crystallizes in the sphalerite structure (Fig. 5.45). (a) What are the coordination numbers of the indium and arsenide ions? (b) What is the formula of indium arsenide?

5.52 Uranium carbide crystallizes in the rock-salt structure (Fig. 5.41). (a) What are the coordination numbers of the uranium and carbide ions? (b) What is the formula of uranium carbide?

5.53 Calculate the number of cations, anions, and formula units per unit cell in each of the following solids: (a) the cesium chloride unit cell shown in Fig. 5.43; (b) the rutile (TiO_2) unit cell shown here. (c) What are the coordination numbers of the ions in rutile?



5.54 Calculate the number of cations, anions, and formula units per unit cell in each of the following solids: (a) the rock-salt unit cell shown in Fig. 5.41; (b) the fluorite (CaF_2) unit cell shown here. (c) What are the coordination numbers of the ions in fluorite?



5.55 An oxide of rhenium crystallizes with a cubic unit cell that has a rhenium cation at each corner and an oxide ion at the center of each edge of the crystal. (a) Determine the coordination numbers of the two ions. (b) Write the formula of the oxide.

5.56 When an oxide of uranium crystallizes the uranium cations form an expanded cubic close-packed array with an oxide ion in each tetrahedral hole. (a) Determine the coordination numbers of the two ions. (b) Write the formula of the oxide.

5.57 Use radius ratios to predict the coordination number of the cation in (a) RbF; (b) MgO; (c) NaBr. (See Fig. 1.48.)

5.58 Use radius ratios to predict the coordination number of the cation in (a) KBr; (b) LiBr; (c) BaO. (See Fig. 1.48.)

5.59 Estimate the density of each of the following solids from the ionic radii given in Fig. 1.48: (a) calcium oxide (rock-salt structure, Fig. 5.41); (b) cesium bromide (cesium chloride structure, Fig. 5.43).

5.60 Calculate the density of each of the following solids: (a) magnesium oxide (rock-salt structure, Fig. 5.41), distance between centers of Mg^{2+} and O^{2-} ions is 212 pm; (b) calcium sulfide (cesium chloride structure, Fig. 5.43), distance between the centers of the Ca^{2+} and S^{2-} ions is 284 pm.

5.61 Graphite forms extended two-dimensional layers (see Fig. 5.23). (a) Draw the smallest possible rectangular unit cell for a layer of graphite. (b) How many carbon atoms are in your unit cell? (c) What is the coordination number of carbon in a single layer of graphite?

5.62 The ammonium ion can be represented by a sphere of radius 151 pm. Use radius ratios to predict the type of lattice structure found in (a) NH_4F; (b) NH_4I.

5.63 If the edge length of a fcc unit cell of RbI is 732.6 pm, how long would the edge of a cubic single crystal of RbI be that contains 1.00 mol RbI?

5.64 The edge length of the fcc unit cell of NaCl is 562.8 pm. (a) How many unit cells are present in a single crystal of NaCl (table salt) that is a cube with edges 1.00 mm in length? (b) What amount (in moles) of NaCl is present in this crystal?

5.65 Why do long hydrocarbon molecules that do not have multiple bonds, such as decane, $CH_3(CH_2)_8CH_3$, not form liquid crystals?

5.66 Consider the structure of *p*-azoxyanisole (**14**). (a) Using the VSEPR model, draw a picture that represents the shape of the molecule and predict the CNN bond angles. (b) What features of the bonding of this molecule give rise to its rodlike nature? (c) Use your conclusions in part (b) to design another simple organic molecule that is composed only of C, H, N, and O and might be likely to form rodlike, liquid crystalline materials.

5.67 When long surfactant molecules having a polar headgroup and a nonpolar "tail" are placed into water, *micelles* are formed in which the nonpolar tails aggregate, with the polar headgroups pointing out toward the solvent. *Inverse micelles* are similar but have the nonpolar regions pointing outward. How can inverse micelles be produced?

5.68 *p*-Azoxyanisole (**14**) has a liquid crystalline range of approximately 117° to 137°C. How might this molecule be modified to lower the melting point of the solid and make it more suitable for lower-temperature applications (near room temperature, for example)?

5.69 Two solutes were used to study diffusion in liquids, methylbenzene, which is a small molecule that can be approximated as a sphere, and a liquid crystal that is long and rodlike. The two solutes were found to move and rotate in all directions to the same extent in benzene. In a liquid crystal solvent the methylbenzene again moved and rotated to the same extent in all directions, but the liquid crystal solute moved much more

rapidly along the long axis of the molecule than it did in a "sideways" mode, perpendicular to the long axis. It also was found to rotate more rapidly around the long axis than perpendicular to it. Explain this behavior.

5.70 The molecular structures of many common liquid crystals are long and rodlike. In addition, they contain polar groups. Explain how both characteristics of liquid crystals contribute to their anisotropic nature.

Integrated Exercises

5.71 Draw the Lewis structure of (a) NI_3 and (b) BI_3, name the molecular shape, and indicate whether each can participate in dipole–dipole interactions.

5.72 Draw the Lewis structure of (a) CF_4, (b) SF_4, name the molecular shape, and indicate whether each can participate in dipole–dipole interactions.

5.73 (a) Calculate the surface areas of the isomers 2,2-dimethylpropane and pentane. Assume that 2,2-dimethylpropane is spherical with a radius of 254 pm and that pentane can be approximated by a rectangular prism with dimensions 295 pm $\times$ 692 pm $\times$ 766 pm. (b) Which has the larger surface area? (c) Which do you expect to have the higher boiling point?

5.74 (a) Calculate the ratio of potential energies for an ion–ion interaction for Li^+ and for K^+ with the same anion. (b) Repeat the ratio calculation, but for an ion–dipole interaction between Li^+ and K^+ and a water molecule. (c) What do these numbers indicate about the relative importance of the hydration of salts of lithium compared with those of potassium?

5.75 All noble gases except helium crystallize with ccp structures at very low temperatures. Find an equation relating the atomic radius to the density of a ccp solid of given molar mass and apply it to deduce the atomic radius of each of the following noble gases, given the density of each (in $g{\cdot}cm^{-3}$): Ne, 1.20; Ar, 1.40; Kr, 2.16; Xe, 2.83; Rn, 4.4 (estimated).

5.76 All the alkali metals crystallize with bcc structures. (a) Find a general equation relating the metallic radius to the density of a bcc solid of an element in terms of its molar mass and use it to deduce the atomic radius of each of the following elements, given the density of each (in $g{\cdot}cm^{-3}$): Li, 0.53; Na, 0.97; K, 0.86; Rb, 1.53; Cs, 1.87. (b) Find a factor for converting the density of a bcc element into the density that it would have if it crystallized in a ccp structure. (c) Calculate what the densities of the alkali metals would be if they were ccp. (d) Which, if any, would float on water?

5.77 Metals with bcc structures, such as tungsten, are not close packed. Therefore, their densities would be greater if they were to change to a ccp structure (under pressure, for instance). What would the density of tungsten be if its structure were ccp rather than bcc? Its actual density is 19.3 $g{\cdot}cm^{-3}$.

5.78 An oxide of niobium has a unit cell in which there are oxide ions at the middle of each edge and niobium ions at the center of each face. What is the empirical formula of this oxide?

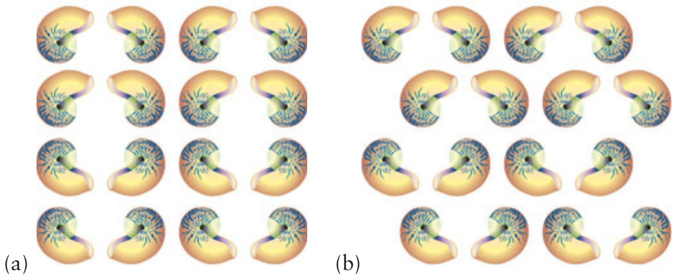
5.79 A number of metal oxides are known to form *nonstoichiometric* compounds, in which the ratios of atoms that make up the compound cannot be expressed in small whole numbers. In the crystal structure of a nonstoichiometric compound, some of the lattice points where one would have expected to find atoms are vacant. Transition metals most easily form nonstoichiometric compounds because of the number of oxidation states that they can have. For example, a titanium oxide with formula $TiO_{1.18}$ is known. (a) Calculate the average oxidation state of titanium in this compound. (b) If the compound has both Ti^{2+} and Ti^{3+} ions present, what fraction of the titanium ions will be in each oxidation state?

5.80 Uranium dioxide, UO_2, can be further oxidized to give a nonstoichiometric compound UO_{2+x}, where $0 < x < 0.25$. See Exercise 5.79 for a description of nonstoichiometric compounds. (a) What is the average oxidation state of uranium in a compound with composition $UO_{2.17}$? (b) If we assume that the uranium exists in either the +4 or the +5 oxidation state, what is the fraction of uranium ions in each?

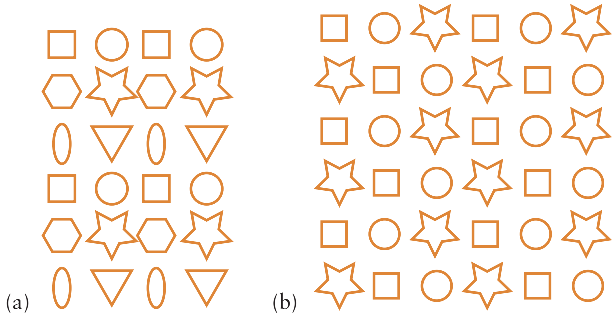
5.81 Are the following statements true or false? (a) If there is an atom present at the corner of a unit cell, there must be the same type of atom at all the corners of the unit cell. (b) A unit cell must be defined so that there are atoms at the corners. (c) If one face of a unit cell has an atom in its center, then the face opposite that face must also have an atom at its center. (d) If one face of a unit cell has an atom in its center, all the faces of the unit cell must also have atoms at their centers.

5.82 Are the following statements true or false? (a) Because cesium chloride has chloride ions at the corners of the unit cell and a cesium ion at the center of the unit cell, it is classified as having a body-centered unit cell. (b) The density of the unit cell must be the same as the density of the bulk material. (c) When x-rays are passed through a single crystal of a compound, the x-ray beam will be diffracted because it interacts with the electrons in the atoms of the crystal. (d) All the angles of a unit cell must be equal to 90°.

5.83 For each of the two-dimensional arrays shown here, draw a unit cell that, when repeated, generates the entire two-dimensional lattice.



5.84 For each of the two-dimensional arrays shown here, draw a unit cell that, when repeated, generates the entire two-dimensional lattice.



5.85 Buckminsterfullerene is an allotrope of carbon in which the carbon atoms form nearly spherical molecules of 60 atoms each (see Section 15.12). In the pure compound the spheres pack in a cubic close-packed array. (a) The length of a side of the face-centered cubic cell formed by buckminsterfullerene is 142 pm. Use this information to calculate the radius of the buckminsterfullerene molecule treated as a hard sphere. (b) The compound K_3C_{60} is a superconductor at low temperatures. In this compound the K^+ ions lie in holes in the C_{60}^- face-centered cubic lattice. Considering the radius of the K^+ ion and assuming that the radius of C_{60}^- is the same as for the C_{60} molecule, predict in what type of holes the K^+ ions lie (tetrahedral, octahedral, or both) and indicate what percentage of those holes are filled.

5.86 A reflection from a cubic crystal was observed at a glancing angle of 12.1° when x-rays of wavelength 152 pm were used. (a) What is the separation of layers causing this reflection? (b) At what glancing angle would you detect the reflection arising from planes at twice the layer separation? Refer to Major Technique 3 on x-ray diffraction, which follows this set of exercises.

5.87 Glass is composed mainly of silica, SiO_2, with various oxides added to change the properties. The property differences are substantial, and different amounts of added oxide compounds produce glasses with very different applications derived from these properties. Often the added material is B_2O_3 and the products are called borosilicate glasses. From standard reference sources, determine how the properties of glass change as the amount of B_2O_3 is increased.

5.88 In an aqueous solution, solute molecules or ions require a certain amount of time to migrate through the solution. The rate of this migration sets an upper limit on how fast reactions can take place, because no reaction can take place faster than the ions can be supplied. This limit is known as the *diffusion-controlled rate*. It has been found that the diffusion rate for hydrogen ions is about three times as fast as that for other ions in aqueous solution. Explain why this is so.

5.89 Iron corrodes in the presence of oxygen to form rust, which for simplicity can be taken to be iron(III) oxide. If a cubic block of iron of side 1.5 cm reacts with 15.5 L of oxygen at 1.00 atm and 25°C, what is the maximum mass of iron(III) oxide that can be produced? Iron metal has a bcc structure, and the atomic radius of iron is 124 pm. The reaction takes place at 298 K and 1.00 atm.

5.90 Real gases and vapors have intermolecular interactions. Recall that one equation of state for a real gas is the van der Waals equation, which is expressed in terms of two parameters, a and b. (a) For each of the following pairs of gases, decide which substance has the larger van der Waals a parameter: (i) He and Ne; (ii) Ne and O_2; (iii) CO_2 and H_2; (iv) H_2CO and CH_4; (v) C_6H_6 and $CH_3(CH_2)_{10}CH_3$. (b) For each of the following pairs of gases, decide which substance has the larger van der Waals b parameter: (i) F_2 and Br_2; (ii) Ne and F_2; (iii) CH_4 and $CH_3CH_2CH_3$; (iv) N_2 and Kr; (v) CO_2 and SO_2.

5.91 A commonly occurring mineral has a cubic unit cell in which the metal cations, M, occupy the corners and face centers. Inside the unit cell, anions, A, occupy all the tetrahedral holes created by the cations. What is the empirical formula of the M_mA_a compound?

5.92 Tetrahedral and octahedral interstitial holes are formed by the vacancies left when anions pack in a ccp array. (a) Which hole can accommodate the larger ions? (b) What is the size ratio of the largest metal cation that can occupy an octahedral hole to the largest that can occupy a tetrahedral hole while maintaining the close-packed nature of the anion lattice? (c) If half the tetrahedral holes are occupied, what will be the empirical formula of the compound M_xA_y, where M represents the cations and A the anions?

5.93 The density of cesium chloride is 3.988 $g\cdot cm^{-3}$. Calculate the percentage of empty space in a cesium chloride lattice with the ions treated as hard spheres.

5.94 Use information from Exercise 5.54 to calculate the percentage of empty space in a calcium fluoride lattice with the ions treated as hard spheres. The density of CaF_2 is 3.180 $g\cdot cm^{-3}$.

5.95 (a) If a pure element crystallizes with a primitive cubic lattice, what percentage of the unit cell is empty space? (b) How does this percentage compare with that of empty space in an fcc unit cell?

5.96 Many ionic compounds are considered to pack in such as way that the anions form a close-packed lattice in which the metal cations fill holes or interstitial sites left between the anions. These lattices, however, may not necessarily be as tightly packed as the label "close-packed" implies. The radius of an F^- ion is approximately 133 pm. The edge distances of the cubic unit cells of LiF, NaF, KF, RbF, and CsF, all of which pack in the rock-salt structure, are 568 pm, 652 pm, 754 pm, 796 pm, and 850 pm, respectively. Which of these lattices, if any, can be thought to be based on close-packed arrays of F^- ions? Justify your conclusions.

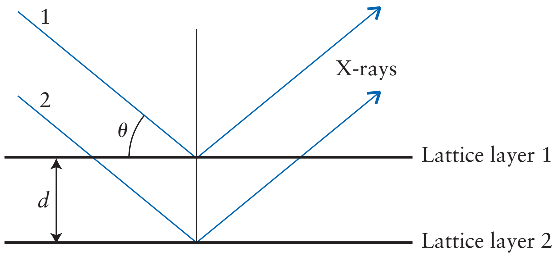
5.97 Due to its strong hydrogen bonds, in the vapor state hydrogen fluoride is found as short chains and rings. Draw the Lewis structure of an $(HF)_3$ chain and indicate the approximate bond angles.

5.98 Consider a metallic element that crystallizes in a cubic close-packed lattice. The edge length of the unit cell is 408 pm. If close-packed layers are deposited on a flat surface to a depth (of metal) of 0.125 mm, how many close-packed layers are present?

5.99 "Graphite bisulfates" are formed by heating graphite with a mixture of sulfuric and nitric acids. In the reaction, the graphite planes are partially oxidized. There is approximately one positive charge for every 24 carbon atoms, and the HSO_4^- anions are distributed between the planes. (a) What effect is this oxidation likely to have on the electrical conductivity? (b) What effect would you expect it to have on the x-ray diffraction pattern observed for this material? Refer to Major Technique 3 on x-ray diffraction, which follows this set of exercises.

5.100 Using the density of calcium fluoride (CaF_2, found in nature as the mineral fluorite), which is known to be 3.180 $g\cdot cm^{-3}$, and the information given in Exercise 5.54, calculate (a) the edge length of the unit cell and (b) the Ca–F separation in fluorite. (c) Compare this value to that expected from the ionic radii tabulated in Fig. 1.48.

5.101 The following diagram shows two lattice planes from which two parallel x-rays are diffracted. If the two incoming x-rays are in phase, show that the Bragg equation $2d \sin \theta = n\lambda$ is true when n is an integer. Refer to Major Technique 3 on x-ray diffraction, which follows this set of exercises.



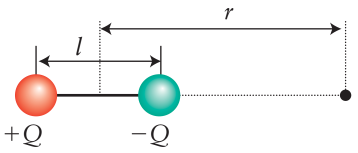
5.102 X-rays generated from a copper target have a wavelength of 154 pm. If an x-ray beam of this type is passed through a single crystal of NaBr, a diffracted beam is observed when the incident x-ray beam is at an angle of 7.42° to the surface of the crystal. What is the minimum spacing between the planes in the crystal that give rise to this diffracted beam? Refer to Major Technique 3 on x-ray diffraction, which follows this set of exercises.

5.103 The unit-cell edge length of lithium fluoride is 401.8 pm. What is the smallest angle at which the x-ray beam generated from a molybdenum source ($\lambda = 71.07$ pm) must strike the planes making up the faces of the unit cell for the beam to be diffracted from those planes? Refer to Major Technique 3 on x-ray diffraction, which follows this set of exercises.

5.104 Could electrons be used for diffraction studies of molecules? The energy of an electron accelerated through a potential difference V (in volts) is eV. What potential difference is needed to accelerate electrons from rest so that they have a wavelength of 100 pm? *Hint*: Use the de Broglie relation and the fact that acceleration of an electron to an energy eV gives it a kinetic energy of $\frac{1}{2}m_e v^2$. Refer to Major Technique 3 on x-ray diffraction, which follows this set of exercises.

5.105 Could neutrons be used for diffraction studies of molecules? The average kinetic energy of neutrons in a beam at a temperature T is $\frac{1}{2}kT$, where k is Boltzmann's constant. What temperature is needed to achieve a wavelength of 100. pm for a neutron? Refer to Major Technique 3 on x-ray diffraction, which follows this set of exercises.

5.106 Calculate the Coulomb potential energy at a point a distance r from a dipole composed of charges Q and $-Q$ separated by a distance l in the arrangement shown in the diagram. Use the fact that $l < r$ to expand the expression $1/(1 + x)$ into $1 - x + \cdots$ and identify the magnitude of the dipole moment as $\mu = Ql$. Show that the potential energy is proportional to $1/r^2$ (as in Eq. 2).



Chemistry Connections

5.107 Ethylammonium nitrate, $CH_3CH_2NH_3NO_3$, was the first ionic liquid to be discovered. Its melting point of 12°C was reported in 1914 and it has since been used as a nonpolluting solvent for organic reactions and for facilitating the folding of proteins.

(a) Draw the Lewis structure of each ion in ethylammonium nitrate and indicate the formal charge on each atom (in the cation, the carbon atoms are attached to the N atom in a chain: C—C—N).

(b) Assign a hybridization scheme to each C and N atom.

(c) Ethylammonium nitrate cannot be used as a solvent for some reactions because it can oxidize some compounds. Which ion is more likely to be the oxidizing agent, the cation or anion? Explain your answer.

(d) Ethylammonium nitrate can be prepared by the reaction of gaseous ethylamine, $CH_3CH_2NH_2$, and aqueous nitric acid. Write the chemical equation for the reaction. What type of reaction is this?

(e) 2.00 L of ethylamine at 0.960 atm and 23.2°C was bubbled into 250.0 mL of 0.240 M HNO_3(aq) and 4.10 g of ethylammonium nitrate was produced. What were the theoretical and percentage yields of the salt?

(f) Suggest ways in which the forces that hold ethylammonium nitrate ions together in the solid state differ from those that hold together salts such as sodium chloride or sodium bromide.

(g) Low-melting salts in which the cation is inorganic and the anion organic have been prepared. Explain the trend in melting point seen in the following series: sodium acetate ($NaCH_3CO_2$), 324°C; sodium propanoate ($NaCH_3CH_2CO_2$), 285°C; sodium butanoate ($NaCH_3CH_2CH_2CO_2$), 76°C; and sodium pentanoate ($NaCH_3CH_2CH_2CH_2CO_2$), 64°C.

A great deal of our knowledge about the interior of solids has come from *x-ray diffraction*. This important technique is used to determine the arrangement of atoms in solid compounds and to measure bond lengths and angles. Almost all recent advances in molecular biology have stemmed from the application of this technique to determine the structures of molecules such as proteins and nucleic acids.

The Technique

When two or more waves pass through the same region of space, the phenomenon of *interference* is observed as an increase or a decrease in the total amplitude of the wave (recall Fig. 1.20). *Constructive interference*, an increase in the total amplitude of the wave, occurs when the peaks of one wave coincide with the peaks of another wave. If the waves are electromagnetic radiation, the increased amplitude corresponds to an increased intensity of the radiation. *Destructive interference*, a decrease in the total amplitude of the waves, occurs when the peaks of one wave coincide with the troughs of the other wave: it results in a reduction in intensity.

The phenomenon of *diffraction* is interference between waves that arises when there is an object in their path. One of the earliest demonstrations of interference was the *Young's slit experiment*, in which light passes through two slits and gives rise to a pattern on a screen (see Fig. 1.19). If we were presented with the pattern and were told the wavelength of the light and the distance of the detection screen from the screen containing the slits, it would be possible to work out the spacing of the two slits. An x-ray diffraction experiment is a more elaborate version of the Young's slit experiment. The regular layers of atoms in a crystal act as a three-dimensional collection of slits and give rise to a diffraction pattern that varies as the crystal is rotated and the "slits" are brought into a new arrangement. The task for the x-ray crystallographer is to use the diffraction pattern to determine the spacing and arrangement of the "slits" that gave rise to it. This enormously complex task is universally carried out on computers.

Why x-rays? Diffraction occurs when the wavelength of the radiation is comparable to characteristic spacings within the object causing the diffraction. Therefore, to obtain diffraction patterns from layers of atoms, we need to use radiation with a wavelength comparable to the spacing of the layers. The separation between layers of atoms in a crystal is about 100 pm, and so electromagnetic radiation of that wavelength, which corresponds to the x-ray region, must be used.

Experimental Techniques

X-rays are generated by accelerating electrons to very high speeds and then letting them plunge into a metal target. This technique generates two types of x-radiation. One type comes from the bombarding electrons themselves. Because accelerating and decelerating charges emit electromagnetic radiation, the electrons generate radiation as they are brought to a standstill in the metal. The radiation covers a wide range of frequencies, including that of x-rays. However, for current versions of x-ray diffraction, we need a well-defined wavelength. Such radiation is generated by a second mechanism. The fast electrons hit electrons occupying orbitals in the inner shells of atoms and drive them out of the atom. That collision leaves a gap in the atom, which is filled when an electron in another shell falls into the vacancy. The difference in energy is given out as a photon. Because the energy difference between shells is so great, the photon has a very high energy, corresponding to the x-ray region. When copper is used as the target, for example, the x-radiation has a wavelength of 154 pm.

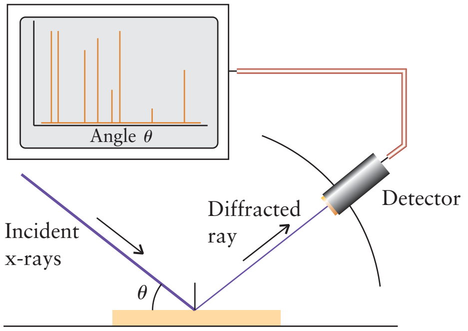


FIGURE 1 In the powder diffraction technique, a sample is spread on a flat plate and exposed to a beam of monochromatic (single-frequency) x-rays. The diffraction pattern (inset) is recorded by moving the detector to different angles.

In the *powder diffraction technique*, a monochromatic (single-frequency) beam of x-rays is directed at a powdered sample spread on a support, and the diffraction intensity is measured as the detector is moved to different angles (Fig. 1). The pattern obtained is characteristic of the material in the sample, and it can be identified by comparison with a database of patterns. In effect, powder x-ray diffraction takes a fingerprint of the sample. It can also be used to identify the size and shape of the unit cell by measuring the spacing of the lines in the diffraction pattern. The central equation for analyzing the results of a powder diffraction experiment is the *Bragg equation*

$$2d \sin \theta = \lambda$$

which relates the angles θ (theta), at which constructive interference occurs, to the spacing, d, of layers of atoms in the sample, for x-rays of wavelength λ (lambda). The illustration in Exercise 5.101 shows how the parameters λ and d relate to the crystal dimensions.

EXAMPLE MT 3.1 Determining the spacing between layers of atoms in a crystal

In an x-ray diffraction experiment on a single crystal of sodium chloride, with the use of radiation from a copper source (λ = 154 pm), constructive interference was observed at $\theta = 11.2°$. What is the spacing of the layers responsible for the diffraction?

PLAN Spacing between layers in a crystal can be obtained from the Bragg equation.

(continued)

SOLVE

Rearrange the Bragg equation to give d in terms of θ.

$$d = \frac{\lambda}{2 \sin \theta}$$

Substitute the data.

$$d = \frac{154 \text{ pm}}{2 \sin 11.2°} = 396 \text{ pm}$$

Self-Test MT3.1A Constructive interference at 7.23° was observed from a crystal when x-radiation from a molybdenum source ($\lambda = 71.0$ pm) was used. What is the spacing of the layers of atoms responsible for the diffraction?

[***Answer:*** 282 pm]

Self-Test MT3.1B Constructive interference at 12.1° was observed from a cubic crystal when x-radiation of wavelength 152 pm was used. What is the spacing of the layers of atoms responsible for the diffraction?

The x-ray diffraction pattern from a liquid resembles that from a powdered sample, but the lines are diffuse rather than sharp. This pattern indicates that the molecules of a liquid have a degree of short-range order but that the distances between molecules vary; this variation produces the diffuse lines.

The *single-crystal diffraction* technique is much more elaborate and gives much richer information. The first task is to grow a perfect single crystal of the sample. Whereas that task is usually straightforward for simple inorganic solids, it is often one of the most difficult parts of the investigation for the huge molecules characteristic of biologically important compounds such as proteins. Only a tiny crystal is needed, about 0.1 mm on a side, but the task of growing one can be very challenging. Once the crystal has been grown, it is placed at the center of a *four-circle diffractometer* (Fig. 2), a device for rotating the crystal and the detector so that the entire diffraction pattern can be recorded under the control of a computer.

The raw data consist of the intensities of the x-rays at all the settings of the angles in the diffractometer. The computational task is to analyze these measurements and convert them into the locations of the atoms. The process of conversion is called *Fourier synthesis* and requires lengthy calculations carried out on a computer that is an integral part of the diffractometer. The end product is a detailed description of the location of all the atoms in the molecule, the bond lengths, and the bond angles. The most spectacular achievement of this kind was the elucidation of the functioning of the genetic messenger, DNA, where x-rays were a source of insight into the workings of life itself. Even at this stage in your studies, you can begin to see the spark that ignited Watson and Crick's vision of the structure of DNA. Figure 3 shows the characteristic X pattern obtained by Rosalind Franklin. The two crossed arms of the X told Watson and Crick that the molecule must be a helix, and from the slopes of the arms and the diffraction spots along them they were able to deduce its pitch (the distance between turns) and radius. The two arcs at the top and bottom of the photograph represent diffraction through a big angle and therefore a narrow spacing: this they could interpret in terms of the spacing of the nucleotide bases along the helix, with 10 bases per turn of helix.

Related Exercises: 5.86, 5.99, and 5.101–5.105.

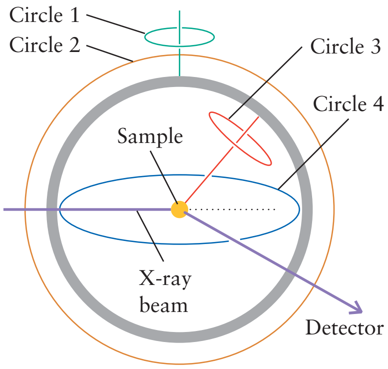

FIGURE 2 A four-circle diffractometer is used to obtain highly detailed information about x-ray diffraction patterns from single crystals. The diffraction pattern is monitored as the orientations around each of the four axes are changed.

FIGURE 3 The x-ray diffraction pattern that led to the elucidation of the structure of DNA.

6.20 Preparation of Nanomaterials

What Are the Key Ideas? The mechanical, electrical, magnetic, and optical properties of materials depend on their chemical composition, may be tailored to match the requirements of technology, and may open up paths to new technologies.

Why Do We Need to Know This Material? To select the best material for a purpose or to design a new one, we need to know what properties to expect from particular combinations of atoms. The chemical principles in the first five chapters of this book can help us to understand the properties of materials, to predict their properties, and to design materials for new tasks and new technologies.

What Do We Need to Know Already? This chapter assumes an understanding of periodic properties and electron configurations (Chapter 1), molecular structure (Chapters 2 and 3), and the solid state and intermolecular forces (Chapter 5). The discussion of bonding in solids builds on molecular orbital theory (Sections 3.9–3.12).

The growth of civilization to a large extent depends on the development of new materials that give rise to new technologies and thereby open up new opportunities. Concrete led to remarkable advances in architecture and construction, steel led to the industrial revolution, plastics transformed daily life, and silicon-based semiconductors transformed communication and calculation. The twenty-first century continues to thrive on the discovery and manufacture of new materials. Whether designing a building, crafting artificial limbs, or developing new means of communication, engineers, medical researchers, architects, and scientists must all understand the chemical basis of materials. Materials not yet imagined will be developed—perhaps by you—as our ability to fabricate new forms of matter increases.

Material used in technology, medicine, and construction is classified as either "hard" or "soft." **Hard matter** can withstand strong forces without deforming; **soft matter** responds more readily to applied force. Most hard matter is inorganic and most soft matter is organic and plays important roles in biology. Organic soft matter is described in more detail in Chapters 9 and 19; the focus of this chapter is largely on inorganic materials. In fact, the distinction between inorganic hard matter and soft organic matter is blurring as chemists find ways of making materials that have both inorganic and organic components, yet in some cases are hard and in others soft.

In this chapter you will see how the knowledge of the properties of atoms and of bulk matter that we have encountered so far can be used to develop and select materials for different applications. You will also see how some of the calculations introduced in earlier chapters are applied to questions related to materials.

METALLIC MATERIALS

Metals have been used as materials for more than 10 000 years. They are commonly used as an **alloy,** a mixture of metals formed in the melt and, in the case of steels, containing carbon. Steel is a **ferrous alloy**, meaning that it is based on iron and often includes various other d-block metals that confer strength and corrosion resistance. **Nonferrous alloys** are those based on metals other than iron, such as the brasses and bronzes that are based on copper.

6.1 The Properties of Metals

A metal can be thought of as an array of cations held together by a "sea" of mobile electrons (recall Fig. 1.53). This model explains many of their physical properties. For example, metals conduct electricity because the electrons of the sea can respond to an

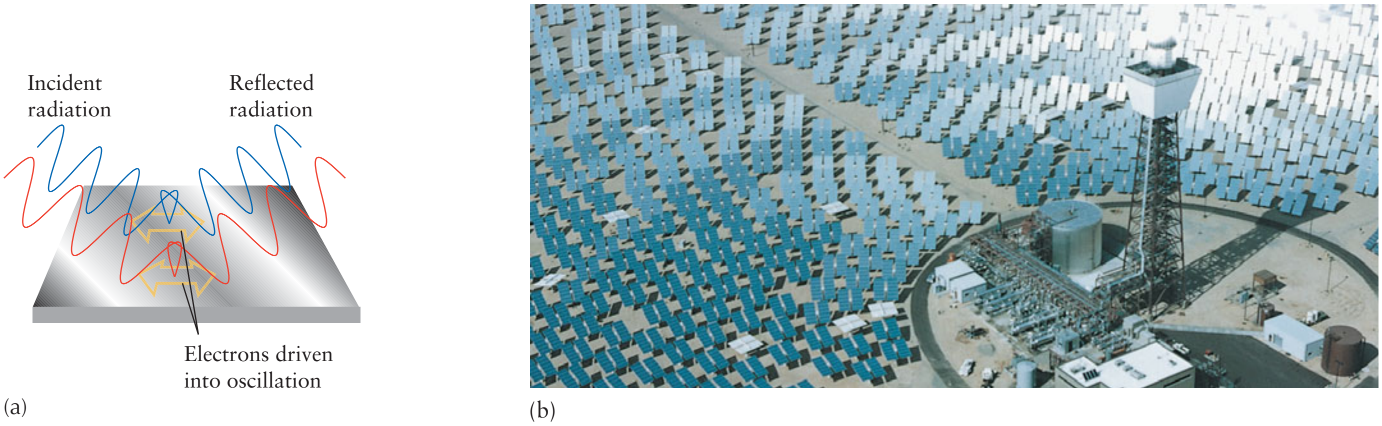

FIGURE 6.1 (a) When light of a particular color shines on the surface of a metal, the electrons at the surface oscillate in step. This oscillating motion gives rise to an electromagnetic wave that we perceive as the reflection of the source. (b) Each of these solar mirrors at Sandia National Laboratories in California is positioned at the best angle to reflect sunlight into a collector that uses the incident energy to generate electricity.

applied potential difference and move past the stationary cations. In contrast, ionic, molecular, and network solids are typically electrical insulators or semiconductors (see Section 6.12) because their electrons are confined to individual atoms and molecules. Notable exceptions include the ionic materials that act as high-temperature superconductors—which no one really understands yet—and the organic polymers (compounds formed by linking together large numbers of small molecules into chains) that are electrical conductors by virtue of their extended conjugated π-orbitals (see Box 19.1).

The characteristic luster of metals is due to the mobility of the electrons that form the sea. An incident light wave is an oscillating electromagnetic field. When it strikes the surface of a metal, the electric field of the radiation pushes the mobile electrons backward and forward. These oscillating electrons radiate light, and we see it as a luster—essentially a re-emission of the incident light (Fig. 6.1). The electrons oscillate in step with the incident light, and so they generate light of the same frequency. In other words, red light reflected from a metallic surface is red and blue light is reflected as blue. That is why an image in a mirror—a thin metallic coating on glass—is a faithful portrayal of the reflected object.

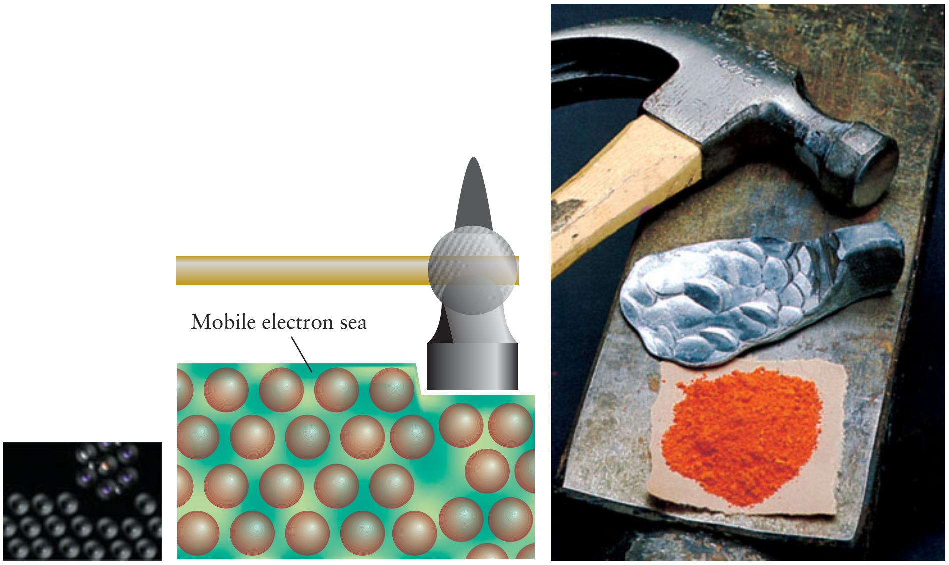
Self-Test 6.1A The pink color of copper is due to the absorption of light in the blue region of the spectrum, at wavelengths of about 470 nm. To what energy separation (in joules) does that wavelength correspond?

[***Answer:*** 4.2×10^{-19} J]

Self-Test 6.1B The yellow color of gold is due to the absorption of light in the violet region of the spectrum, at wavelengths of about 420 nm. To what energy separation (in joules) does that wavelength correspond?

The mobility of its electrons also explains a metal's **malleability,** the ability to be hammered into shape, and its **ductility**, the ability to be drawn into wires. Because the cations are surrounded by an electron sea, metallic bonding has very little directional character. As a result, a cation can be pushed past its neighbors without much effort. A blow from a hammer can drive large numbers of cations past their neighbors. The electron sea immediately adjusts, so that the atoms move relatively easily into their new positions (Fig. 6.2). Metals are more malleable than other solids: when groups of atoms are moved from one location to another, the electron sea follows them. Ionic solids are commonly brittle: the interaction between ions is lost when a group of them is moved by a hammer blow (Section 2.4).

The different malleabilities of various metals can be traced to their different crystal structures. The crystal structure of a metal typically has **slip planes,** which are planes of atoms that under stress may slip or slide relative to one another. The slip planes of a cubic close-packed (ccp) structure are the close-packed planes, and careful



(a) (b)

FIGURE 6.2 (a) When a metal's cations are displaced by a blow from a hammer, the mobile electrons can immediately respond and follow the cations to their new positions, and consequently the metal is malleable. (b) This piece of lead has been flattened by a hammer, whereas crystals of the orange-colored ionic compound lead(II) oxide have shattered.

Animation 6.2

inspection of a unit cell shows that there are eight sets of slip planes in different directions (Fig. 6.3). As a result, metals with ccp structures, such as copper, are malleable: they can be easily bent, flattened, or pounded into shape. In contrast, a hexagonal close-packed structure has only one set of slip planes (parallel to the close-packed layers), and metals with hexagonal close packing, such as zinc or cadmium, tend to be relatively brittle.

The mobility of the valence electrons in a metal accounts for its electrical conductivity, luster, malleability, and ductility.

6.2 Alloys

Some common alloys are listed in Table 6.1. The properties of alloys are affected by their composition, their crystalline structure, and the size and texture of the individual grains. In **homogeneous alloys,** atoms of the different elements are distributed uniformly, either randomly or in regular arrays, like true compounds. Examples are some varieties of brass and bronze and the alloys used for coinage. **Heterogeneous alloys** consist of mixtures of crystalline phases with different compositions. Examples are tin–lead solder and the mercury–silver amalgams once used to fill teeth. Unlike pure metals, which have a distinct melting point, alloys typically melt and solidify over a range of temperatures.

Because the metallic radii of the d-block elements are all similar, they can form an extensive series of alloys with one another when an atom of one element takes the place of another. An example is the copper–zinc alloy used for some "copper" coins. Zinc

(b)

FIGURE 6.3 (a) Three of the eight orientations of the slip planes found in a cubic close-packed crystal structure; and (b) the single orientation of the slip planes found in a hexagonal close-packed crystal structure. Sections of the crystal on opposite sides of one of these planes can easily move past one another along the plane.

TABLE 6.1 Compositions of Typical Alloys

Alloy	Mass percentage composition
brass	up to 40% zinc in copper
bronze	a metal other than zinc or nickel in copper (casting bronze: 10% Sn and 5% Pb)
cupronickel	nickel in copper (coinage cupronickel: 25% Ni)
pewter	6% antimony and 1.5% copper in tin
solder	tin and lead
stainless steel*	more than 12% chromium in iron

*For more detailed information on steels, see Tables 6.2 and 16.2.

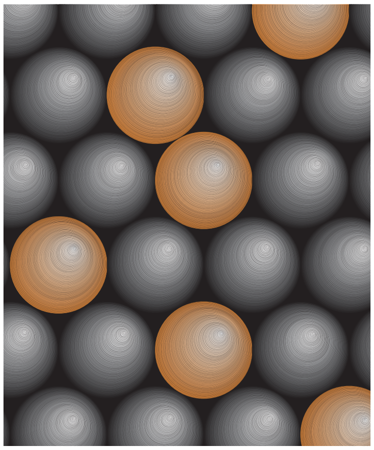

FIGURE 6.4 In a substitutional alloy, the positions of some of the atoms of one metal are taken by atoms of another metal. The two elements must have similar atomic radii.

atoms are nearly the same size as copper atoms (their radii are 133 pm and 128 pm, respectively) and have similar electronic structures (they belong to neighboring groups; the electron configuration of Cu is $[Ar]3d^{10}4s^1$ and that of Zn is $[Ar]3d^{10}4s^2$). Therefore, zinc atoms can take the place of some of the copper atoms in the crystal. An alloy in which atoms of one metal are substituted for atoms of another metal is called a **substitutional alloy** (Fig. 6.4). Elements that can form substitutional alloys have atoms with atomic radii that differ by no more than about 15%. Because there are slight differences in size and electronic structure, the less abundant atoms in a substitutional alloy distort the shape of the lattice of the more abundant atoms of the host metal and hinder the flow of electrons and the spread of thermal motion. A substitutional alloy therefore typically has lower electrical and thermal conductivity than the pure element. Because the lattice is distorted, it is more difficult for one plane of atoms to slip past another. Consequently, a substitutional alloy is harder and stronger than the pure metal.

Self-Test 6.2A Estimate the relative density of a brass (compared to pure copper) in which 20.00% of copper atoms have been replaced by zinc atoms without distortion of the crystal structure.

[***Answer:*** 1.006]

Self-Test 6.2B Estimate the relative density of a brass (compared to pure copper) in which 50.00% of copper atoms have been replaced by zinc atoms without distortion of the crystal structure.

Steel, which is discussed in Section 6.3, is a homogeneous alloy based on iron and containing up to 2% by mass of carbon. Carbon atoms (77 pm) are much smaller than iron atoms (124 pm), and do not substitute for iron in the crystal lattice. They are so small that they can fit into the **interstices** (the holes) in the iron lattice. The resulting material is called an **interstitial alloy** (Fig.6.5). For two elements to form an interstitial alloy, the atomic radius of the solute element must be less than about 60% of the atomic radius of the host metal. The interstitial atoms interfere with electrical conductivity and with the movement of the atoms forming the lattice. This restricted motion, with the interstitial atoms helping to pin the bigger atoms together, makes the alloy harder and stronger than the pure host metal.

In steel, carbon is so important and widely used that it is regarded as an "honorary metal" even though it is actually a nonmetal.

Some alloys are softer than the component metals and melt at lower temperatures. The presence of big lead atoms (175 pm) and bismuth atoms (155 pm) helps to soften a metal composed of smaller atoms and lower its melting point, much as melons in a display of oranges would destabilize the stack. A low-melting-point alloy of bismuth, lead, and tin (141 pm) is employed to control automatic water sprinklers used in certain fire-extinguishing systems. Whereas the individual metals melt at 271°C (Bi), 328°C (Pb), and 232°C (Sn), one such alloy melts at 95°C. The heat of the fire melts the alloy, which activates the sprinklers before the fire can spread.

Alloys of metals tend to be stronger and have lower electrical conductivity than pure metals. In substitutional alloys, atoms of the solute metal take the place of some atoms of a metal of similar atomic radius. In interstitial alloys, atoms of the solute element fit into the interstices in a lattice formed by atoms of a metal with a larger atomic radius.

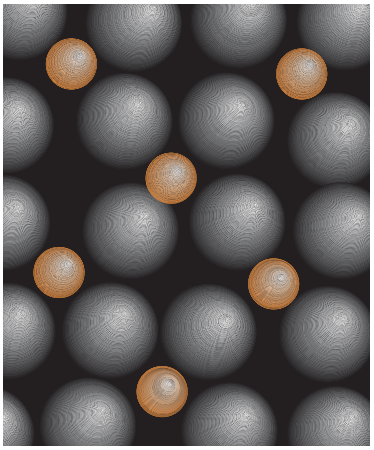

FIGURE 6.5 In an interstitial alloy, the atoms of one metal lie in the gaps between the atoms of another metal. The two elements need to have markedly different atomic radii.

6.3 Steel

Before about 1400 CE, iron was available primarily as *high-carbon wrought iron* or *cast iron*, which has a high carbon content, is hard, has a high melting point, and is brittle. Cast iron is still widely used for objects that experience little mechanical and thermal shock, such as ornamental railings, engine blocks, brake drums, and transmission housings. Steel was probably first prepared by heating iron in a charcoal fire, which results in a lower carbon content than cast iron, and thanks to its hardness, strength, and corrosion resistance, it is the primary form in which iron is used today.

The iron produced in blast furnaces (see Section 16.3) is *pig iron*. Basic grade pig iron is 90–95% by mass iron, 3.5–4.5% carbon, 0.4–1.0% manganese, 0.5–1.2% silicon,

TABLE 6.2 The Effect of Carbon Content on Steel

Type of steel	Carbon content (%)	Properties and applications
low-carbon steel	< 0.15	ductility and low hardness, iron wire
mild-carbon steel	0.15 to 0.25	cables, nails, chains, and horseshoes
medium-carbon steel	0.20 to 0.60	nails, girders, rails, and structural purposes
high-carbon steel	0.61 to 1.5	knives, razors, cutting tools, drill bits

and trace amounts of other elements found in the original ore, which include phosphorus and sulfur. It must be processed further to produce steel. The first stage is to lower the carbon content of the iron and to remove the remaining impurities. In the *basic oxygen process,* oxygen and powdered limestone are forced through the molten metal (Fig. 6.6). In the second stage, steels are produced by adding the appropriate metals, often as *ferroalloys* (mixtures of the metal with iron, such as ferrovanadium, a homogeneous mixture of iron and vanadium), to the molten iron. The steel that results is a homogeneous alloy of 2% or less carbon in iron. Different formulations of steels have various hardnesses, tensile strengths, and ductilities; the higher the carbon content, the harder and more brittle the steel (Table 6.2). Heat treatment can greatly increase the strength and toughness of steel by controlling the sizes of the tiny crystallites that form the solid metal.

FIGURE 6.6 In the basic oxygen process, a blast of oxygen and powdered limestone is used to purify molten iron by oxidizing and combining with the impurities present in it.

Animation 6.6

Self-Test 6.3A What is the minimum mass of oxygen needed to reduce the carbon content of 1.0 t of pig iron from 4.0% carbon to 1.5% carbon? Assume that the only product of the reaction with oxygen is CO_2.

[***Answer:*** 67 kg]

Self-Test 6.3B What is the minimum mass of oxygen needed to reduce the carbon content of 1.0 t of pig iron from 4.5% carbon to 1.0% carbon? Assume that the only product of the reaction with oxygen is CO_2.

The corrosion resistance of iron is significantly improved by forming alloys with other elements. *Stainless steels* are highly corrosion resistant; they are typically about 15% chromium by mass. The resistance to corrosion results from the thin layer of chromium(III) oxide that forms on the surface of the iron and protects it from further oxidation. The density of the Cr_2O_3 layer is about the same as that of the steel, so it adheres firmly to the surface and prevents oxidizing agents from reaching the iron.

The resistance to corrosion provided by some oxides is called passivation and is discussed further in Section 13.14

Steel is an alloy of iron with 2% or less carbon. It is produced from pig iron in the basic oxygen process and has properties that are modified by blending with other metals.

6.4 Nonferrous Alloys

Nonferrous alloys can be homogeneous or heterogeneous. Both types of alloy are often prepared by mixing the elements while molten and then pouring the mixture into a mold. An alternative method for making an alloy is *sintering*, in which finely powdered metals are mixed and pressed into a mold as a hot, sticky powder. Alloys prepared by sintering tend to be more porous than alloys prepared from mixing the molten metals. For example, sintered bronze is used for bearings because the porous metal can absorb lubricants.

Homogeneous alloys of metals with atoms of similar radius are typically substitutional alloys. For example, in brass, as already discussed, zinc atoms readily replace copper atoms in the crystalline lattice (Fig. 6.7). The presence of the zinc atoms changes the lattice parameters and distorts the local electronic structure. This distortion lowers the electrical and thermal conductivity of the host metal, but it also increases hardness and strength. The result is a strong, hard metal with good corrosion resistance that can be easily formed into desired shapes. The percentage of zinc in brass varies, but is generally around 30%. Other elements may be added to enhance desired properties. For example, tin, arsenic, and antimony improve the corrosion resistance of brass and iron increases its hardness.

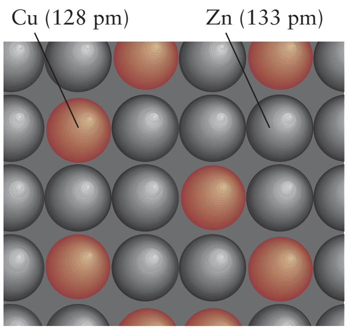

FIGURE 6.7 The atomic radii of copper and zinc are similar, and atoms of one element fit reasonably comfortably into the lattice of the other element to give the range of alloys that we know as brass.

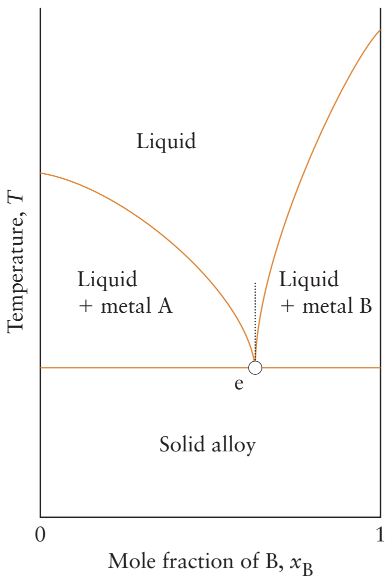

FIGURE 6.8 This temperature–composition plot shows how the melting point of a heterogenous alloy changes with temperature. Point e is the eutectic composition of the system. Note that it melts at the lowest temperature possible for the alloy.

One of the oldest alloys is bronze. The Bronze Age, from about 3000 to 1200 BCE, arose in eastern Turkey and Syria, when tin was extracted from its ore, cassiterite, and melted together with copper. Pure copper melts at a very high temperature (1083°C) and so is difficult to work and form in a hot charcoal fire. Tin melts at a low temperature (232°C), and so cannot be used to make cooking pots. Both metals are rather soft and so do not make good weapons. However, bronze melts at temperatures between the melting points of copper and tin, and the higher the proportion of copper, the higher the melting point. In addition, bronze is much harder than either copper or tin and is more resistant to corrosion than either pure metal.

Coinage alloys are usually substitutional alloys. They are selected for durability—a coin must last for at least 3 years—and electrical resistance so that genuine coins can be identified by vending machines.

As its name indicates, *alnico* is a homogeneous alloy of aluminum, nickel, and cobalt. It is a strong, hard alloy with good temperature stability and corrosion resistance that is usually manufactured by casting the melt in a mold or by sintering. However, alnico alloys tend to be brittle and so difficult to shape. Because they are ferromagnetic (Section 6.16), the primary use of alnico alloys is in permanent magnets, particularly in speakers, mobile phones, and high-temperature applications.

Bismuth and cadmium form a heterogeneous alloy. When a molten mixture of bismuth and cadmium solidifies, the solid is a mixture of small crystals of pure bismuth and pure cadmium. As a bismuth-rich melt is cooled, bismuth is deposited and the composition of the remaining liquid changes, becoming richer in cadmium. As a cadmium-rich melt is cooled, solid cadmium is deposited and the composition of the remaining liquid changes, becoming richer in bismuth. Because of the changing compositions, the alloys freeze and melt over a temperature range. However, there is one composition at which the entire sample freezes and melts at a single fixed temperature that is lower than the melting point of either pure metal (Fig. 6.8). A mixture that behaves in this way is called a *eutectic* (from the Greek words for "easily melted").

Self-Test 6.4A Suppose that the illustration in Fig. 6.8 corresponds to a mixture of lead (metal A) and tin (metal B). Estimate the mass percentage composition of the eutectic mixture.

[***Answer:*** 51% Pb, 0.49% Sn]

Self-Test 6.4B Suppose instead that the illustration in Fig. 6.8 corresponds to a mixture of silver (metal A) and nickel (metal B). Estimate the mass percentage composition of the eutectic mixture.

Alloys are mixtures of metals and other elements formulated to achieve desired properties. Generally, an alloy is harder and stronger than the pure metal but has lower electrical and thermal conductivity.

HARD MATERIALS

Structural materials are typically hard as they must withstand strong deforming forces. They include cement, concrete, and steel and are chosen for their strength and endurance. Some structural materials have been known since prehistoric times, but new materials have allowed architects to design ever taller, often more graceful buildings and to ensure that they are economical to inhabit and easy to maintain. Some of the older structural materials are also found in organisms, where their task is to form a rigid framework or to act as weapons.

6.5 Diamond and Graphite

The differences in the properties of the various allotropes of carbon can be traced to their structures. As described in Section 5.11, graphite consists of planar sheets of sp^2 hybridized carbon atoms in a hexagonal network (Fig. 6.9). Electrons spread through the delocalized π-network and this delocalization accounts for graphite being a black, lustrous, electrically conducting solid; indeed, graphite is used as an electrical conductor

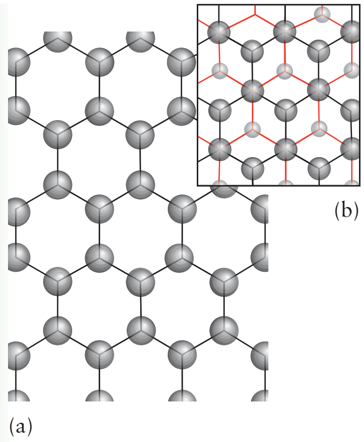

FIGURE 6.9 (a) Graphite consists of flat planes of hexagons lying above one another; (b) the ABAB stacking arrangement of adjacent planes. Only the σ-bonding framework is shown: the π-bonds spread above and below the planes. When impurities are present, the planes can slide past one another quite easily. The extensive delocalization through the network of bonding within the planes allows graphite to conduct electricity well along the planes but less well perpendicular to the planes.

Animation 6.9

in industry and as electrodes in electrochemical cells and batteries. Electrons can move within the sheets of graphite but much less readily from one sheet to another. Hence, graphite conducts electricity better parallel to the sheets than perpendicular to them. In commercially available forms of graphite, many impurity atoms are trapped between the sheets; these atoms weaken the already weak intersheet bonds and let the sheets of atoms slide over one another. Thus, graphite is soft and, when impure, slippery. In pencil lead the graphite is mixed with clay. When we write with a pencil, the mark left on the paper consists of rubbed-off layers of graphite.

Self-Test 6.5A Suppose you shade a square of side 1.0 cm with a pencil that leaves a layer of graphite 315 nm thick. Estimate (a) the number of carbon atoms that you deposited and (b) the amount in moles.

[***Answer:*** (a) 4.1×10^{18} atoms; (b) 6.7 μmol]

Self-Test 6.5B Suppose you draw a line of length 10 cm and width 0.5 mm with a pencil that leaves a layer of graphite 710 nm thick. Estimate (a) the number of carbon atoms that you deposited and (b) the amount in moles.

Each chicken-wire like sheet of carbon atoms in graphite is called a *graphene* sheet. Graphene itself, a single sheet of graphite, is a new material with exceptional promise in the electronics industry. Sheets of graphene can be prepared in a very pure state, then stacked together with water molecules that act as a kind of glue between them. The result is a very strong, flexible, but vanishingly thin paperlike material that conducts electricity but is tougher than diamond. Absorption of gas molecules changes its electrical properties, making graphene a good sensor for gas. It can also be used in transistors, as a protective coating, and as a substrate for scanning tunneling microscopy (see Box 5.1).

In diamond, each carbon atom is sp^3 hybridized and linked tetrahedrally to its four neighbors, with all electrons in C—C σ-bonds (Fig. 6.10). Diamond is a rigid, transparent, electrically insulating solid. It is the hardest substance known and the best conductor of heat, being about five times better than copper. These last two properties make it an ideal abrasive, because it can scratch all other substances, yet the heat generated by friction is quickly conducted away. Diamond is also used as a protective coating for drill bits. Its high heat conductivity makes thin films of diamond ideal for use as a base for some integrated circuits so that they do not overheat. The vigorous vibration of an atom in a hot part of the crystal is rapidly transmitted to distant, cooler parts through the covalent bonds, rather like the effect of slamming a door in a steel-framed building.

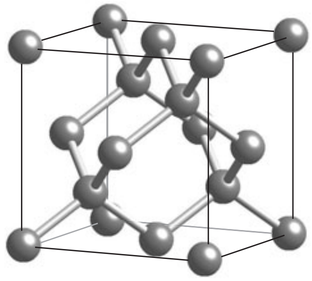

FIGURE 6.10 Structure of diamond. Each carbon atom is sp^3 hybridized and forms tetrahedral σ-bonds to four neighbors. This pattern is repeated throughout the crystal and accounts for diamond's great hardness.

Animation 6.10

In nature, diamond is found embedded in a soft rock called *kimberlite*. This rock rises in columns from deep in the Earth, where the diamonds are formed under intense pressure. One method used to make synthetic industrial diamonds recreates the geological conditions that produce natural diamonds by compressing graphite at pressures greater than 80 kbar and temperatures above 1500°C (Fig. 6.11). Small amounts of metals such as chromium and iron are added to the graphite. The molten metals are thought to dissolve the graphite and then, as they cool, to deposit crystals of diamond, which are less soluble than graphite in the molten metal. Most synthetic diamonds are produced by thermal decomposition of methane. In this technique, the carbon atoms settle on a cool surface as both graphite and diamond. However, because hydrogen atoms produced in the decomposition react more quickly with graphite, forming volatile hydrocarbons, more diamond than graphite survives.

Diamond and graphite are allotropes of carbon. They both have network structures, but diamond has greater strength and thermal conductivity due to its single bonds and sp^3 hybridization. Graphite has greater electrical conductivity due to the delocalization of its π-orbitals over its graphene sheets.

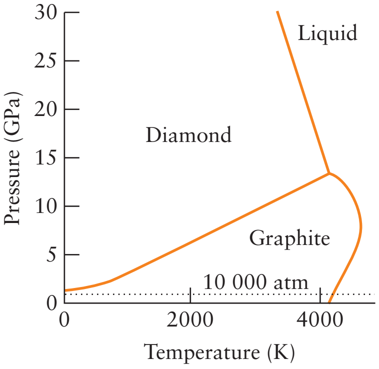

FIGURE 6.11 The phase diagram of carbon, showing the regions of phase stability.

6.6 Calcium Carbonate

Ionic compounds of calcium are often used as structural materials in organisms, buildings, and civil engineering, on account of the rigidity of their structures. This rigidity stems from the strength with which the small, highly charged Ca^{2+} cation interacts

with its neighbors. Because the carbonate ion is also doubly charged, calcium carbonate, $CaCO_3$, has a relatively high lattice energy (see Section 2.3). Consequently, one of the earliest building materials was limestone, an impure form of calcium carbonate, which takes its honey color from impurities such as Fe^{2+} ions. In its compressed and harder form, it is *marble*; in its less compacted form it is *chalk*. All these forms of calcium carbonate are aggregates of small crystals.

The two most common forms of crystalline calcium carbonate are calcite and aragonite. Although aragonite is harder and denser than calcite, it is less abundant and less stable. In addition, it converts to calcite at high temperatures. Therefore, most limestone buildings are blocks of aggregates of impure calcite. One problem with the use of limestone in construction today is that carbonates can react with acids. The acidity of rain has increased since the industrial revolution due to the presence of sulfur and nitrogen oxides in the air from burning coal, oil, and gasoline, which causes erosion of limestone buildings and statuary (see Box 11.1). Chalk was sometimes used in construction before power tools were available because it is easy to cut and shape. However, it is not as durable as limestone. Marble is a hard, dense form of calcium carbonate that can be given a high polish; it is often used to clad the exterior and interior walls of buildings to give them an attractive appearance.

Self-Test 6.6A What is the change in the length of a side of a 1.0-cm cube of aragonite (density 2.83 $g \cdot cm^{-3}$) when it converts to calcite (density 2.71 $g \cdot cm^{-3}$)?

[***Answer:*** +0.15 mm]

Self-Test 6.6B What is the change in the length of a side of a 1.0-cm cube of diamond (density 3.51 $g \cdot cm^{-3}$) when it converts to graphite (density 2.27 $g \cdot cm^{-3}$)?

Nature has made extensive use of the ability of calcium to form rigid structures. It is found as the calcium carbonate of the shells of shellfish and the calcium phosphate of bone. In fact, large deposits of limestone have resulted from seashells and microorganisms that accumulated on ocean floors millions of years ago. Both seashells and bones are much stronger than the pure calcium salts, because they have a composite structure, with the carbonate or phosphates imbedded in a tough matrix (see Section 6.17).

Calcium compounds are common in structural materials because the small, highly charged Ca^{2+} ion results in rigid structures.

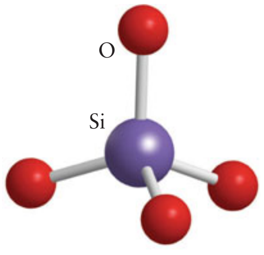
6.7 Silicates

Silica, SiO_2, is a hard, rigid material that differs from calcium carbonate in that it is a network solid. It is insoluble in water and occurs naturally as *quartz* and sand, which consists of small fragments of quartz, usually colored golden brown by iron oxide impurities (Fig. 6.12). Minerals based on silica and silicates, such as sandstone and granite, are used when a strong, durable, corrosion-resistant construction material is required.

(a) (b) (c)

FIGURE 6.12 Three common forms of silica (SiO_2): (a) quartz; (b) quartzite; and (c) cristobalite. The black parts of the sample of cristobalite are obsidian, a volcanic rock that contains silica. Sand consists primarily of small pieces of impure quartz.

Silica gets its strength from its covalently bonded network structure. In silica itself, each Si atom is at the center of a tetrahedron of O atoms, and each corner O atom is shared by two Si atoms (**1**). Hence, each tetrahedron contributes one Si atom and $4 \times \frac{1}{2} = 2$ O atoms to the solid, which has the empirical formula SiO_2. Quartz has a complicated structure; it is built from helical chains of SiO_4 units (for a net composition of SiO_2 when the sharing of O atoms between units is taken into account) wound around one another. When it is heated to about 1500°C, it changes to another arrangement, that of the mineral *cristobalite* (Fig. 6.13). This structure is easier to describe: its Si atoms are arranged like the C atoms in diamond; but, in cristobalite, an O atom lies between each pair of neighboring Si atoms.



1 An SiO_4 unit

There are a variety of silicates, which can be viewed as various arrangements of tetrahedral oxoanions of silicon in which each Si—O bond has considerable covalent character. The differences in properties between the various silicates are related to the number of negative charges on each tetrahedron, the number of corner O atoms shared with other tetrahedra, and the manner in which chains and sheets of the linked tetrahedra lie together. Differences in the internal structures of these highly regular network solids lead to a wide array of materials, ranging from gemstones to fibers. Most glasses are primarily mixtures of silicates and ionic compounds (see Section 6.10). Quartz itself is useful in spectroscopy because it is transparent to ultraviolet radiation.

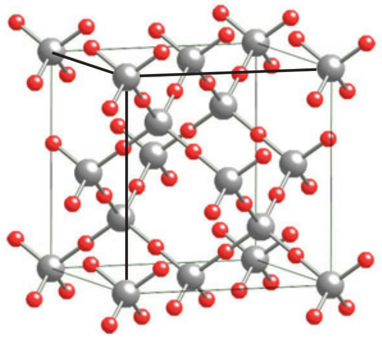


FIGURE 6.13 The structure of cristobalite is like that of diamond except that an O atom (red) lies between the Si atoms (gray). The arrangement about each Si atom is shown in structure 1.

The simplest silicates, the *orthosilicates*, are built from SiO_4^{4-} ions. They are not very common but include the mineral *zircon,* $ZrSiO_4$, which is used as a substitute for diamond in costume jewelry. The *pyroxenes* consist of chains of SiO_4 units in which two corner O atoms are shared by neighboring units (Fig. 6.14); the repeating unit is the metasilicate ion, SiO_3^{2-}. Electrical neutrality is provided by cations regularly spaced along the chain. The pyroxenes include *jade*, $NaAl(SiO_3)_2$.

Chains of silicate units can link together to form ladderlike structures that include *tremolite*, $Ca_2Mg_5(Si_4O_{11})_2(OH)_2$. Tremolite is one of the fibrous minerals called *asbestos,* which can withstand extreme heat (Fig. 6.15). Their fibrous quality is due to the way in which the ladders of SiO_4 units lie together but can easily be torn apart. Because of their great resistance to fire, asbestos fibers were once widely used for heat insulation in buildings. However, these fibers can lodge in lung tissue, where fibrous scar tissue forms around them, giving rise to asbestosis and a susceptibility to lung cancer. In some minerals, the SiO_4 tetrahedra link together to form sheets. An example is *talc*, a hydrated magnesium silicate, $Mg_3(Si_2O_5)_2(OH)_2$. Talc is soft and slippery because the silicate sheets slide past one another.

More complex (and more common) structures result when some of the silicon(IV) in silicates is replaced by aluminum(III) to form the *aluminosilicates*. The missing positive charge is made up by the presence of extra cations. These cations account for the difference in properties between the silicate talc and the aluminosilicate *mica*. One form of mica is $KMg_3(Si_3AlO_{10})(OH)_2$. In this mineral, the sheets of tetrahedra are held together by extra K^+ ions. Although it cleaves neatly into transparent layers when the sheets are torn apart, mica is not slippery like talc (Fig. 6.16). Because they are more heat resistant than glass, sheets of mica are used for windows in furnaces.

The *feldspars* are aluminosilicates in which as much as half the silicon(IV) has been replaced by aluminum(III). They are the most abundant silicate materials on Earth and are a major component of *granite*, a compressed mixture of mica, quartz, and feldspar that serves as one of the most valued and attractive building materials (Fig. 6.17). When some of the ions between the crystal layers are washed away as these rocks weather, the structure crumbles to clay, one of the main inorganic components of soil. A typical feldspar has the formula $KAlSi_3O_8$. Its weathering by carbon dioxide and water can be described by the equation

$$2\,KAlSi_3O_8(s) + 2\,H_2O(l) + CO_2(g) \longrightarrow K_2CO_3(aq) + Al_2Si_2O_5(OH)_4(s) + 4\,SiO_2(s)$$

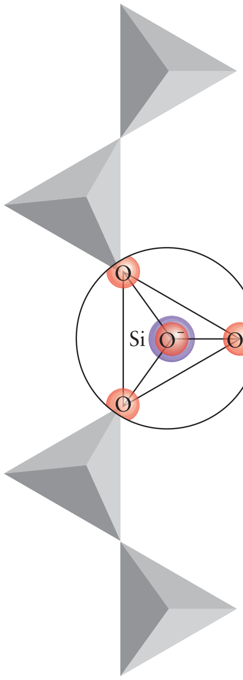

FIGURE 6.14 The basic structural unit of the minerals called pyroxenes. Each tetrahedron is an SiO_4 unit (like that in structure **1**), and a shared corner represents a shared O atom (red in the inset where one O atom lies directly over an Si atom). The two unshared O atoms each carry a negative charge.

FIGURE 6.15 The minerals commonly called asbestos (from the Greek words meaning "not burning") are fibrous because they consist of long chains based on SiO_4 tetrahedra linked through shared oxygen atoms.

FIGURE 6.16 The aluminosilicate mica cleaves into thin transparent sheets with high melting points. These properties allow it to be used for windows in furnaces.

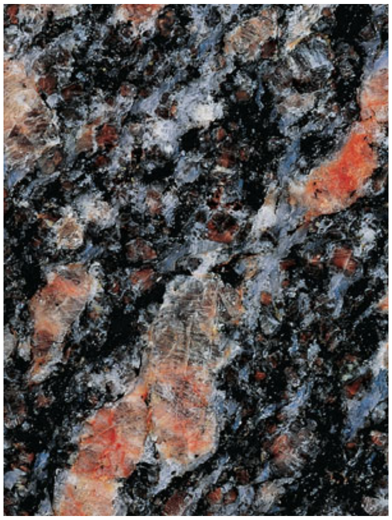

FIGURE 6.17 The mineral granite is a compressed mixture of mica, quartz, and feldspar.

The potassium carbonate is soluble and washes away, but the aluminosilicate remains as the clay.

Silicate structures are based on SiO_4 tetrahedral units with different negative charges and different numbers of shared O atoms.

6.8 Cement and Concrete

The building blocks used in construction are commonly held together by binders called *cements*. The most common type of cement is *Portland cement*, which is made by heating a mixture of crushed limestone, clay or shale, sand, and oxides such as iron ore in a kiln (Table 6.3). As shown in Table 6.3, different types of Portland cement have been developed to meet different requirements. Clays are primarily aluminosilicates (see Section 6.7), which are composed of layers of ions separated by water molecules. When they are heated with calcium carbonate, the water molecules are driven off. The hard pellets that result, the "clinkers," are a mixture of mainly calcium oxide, calcium silicates, and calcium aluminum silicates. These pellets are ground together with *gypsum*, $CaSO_4{\cdot}2H_2O$, into a powder that sets into a hard mass when mixed with water. The water reacts with the mixture to produce hydrates and hydroxides. The reactions are complex, but a representative equation is

$$(Al_2O_3){\cdot}(CaO)_3(s) + 3\ CaSO_4{\cdot}2H_2O(s) + 26\ H_2O(l) \longrightarrow (Al_2O_3){\cdot}(CaO)_3{\cdot}(CaSO_4)_3{\cdot}32\ H_2O(s)$$

TABLE 6.3 The Compositions of Common Portland Cement Clinkers

Type of cement	Typical composition*
1. General use	50–70% $(SiO_2){\cdot}(CaO)_3$, 15–30% $(SiO_2){\cdot}(CaO)_2$, 5–10% $(Al_2O_3){\cdot}(CaO)_3$, 5–15% $(4CaO){\cdot}Al_n{\cdot}Fe_{2-n}O_3$.
2. Moderate sulfate resistance	Resists attack by sulfates. Generates heat slowly and so sets slowly. Low $(Al_2O_3){\cdot}(CaO)_3$ content.
3. High early strength	Has more $(SiO_2){\cdot}(CaO)_3$ than Type 1 and has been ground finer to set faster.
4. Low heat	Used when hydration heat must be minimized. Has about half the percentage of $(SiO_2){\cdot}(CaO)_3$ and $(Al_2O_3){\cdot}(CaO)_3$ and double the abundance of $(SiO_2){\cdot}(CaO)_2$ of Type 1.
5. High sulfate resistance	Highly resistant to reaction with sulfates. Very low percentage of $(Al_2O_3){\cdot}(CaO)_3$ and high percentage of $(SiO_2){\cdot}(CaO)_2$.

*Small, variable amounts of other oxides are present in all Portland cements.

Because the particles in Portland cement are finely ground and mixed together, the hydrates bind the salts together into an intricate three-dimensional network, forming a hard, strong material as the cement dries and other reactions take place, such as:

$$6\ (SiO_2)\cdot(CaO)_3(s) + 18\ H_2O(l) \longrightarrow (SiO_2)_6\cdot(CaO)_5\cdot 5\ H_2O(s) + 13\ Ca(OH)_2(s)$$

Self-Test 6.7A What mass of water is needed to react completely with 1.0 kg of $Al_2O_3\cdot(CaO)_3(s)$?

[***Answer:*** 1.7 kg]

Self-Test 6.7B What mass of water is needed to react completely with 1.0 kg of $SiO_2\cdot(CaO)_3(s)$?

Concrete consists of a binder and a filler. The filler is usually gravel, but sometimes polymer or vermiculite pellets are added to lower the density. *Vermiculite* is a low-density clay-like silicate material with a structure that has been expanded by heating. The binder is cement, usually Portland cement. *Mortar* is a cement-like substance used to hold bricks and other building materials together. Portland cement mortar consists of about one part cement and three parts sand (largely silica, SiO_2). Lime mortar is a fast-setting mortar that contains limestone. It sets to a hard mass as the lime reacts with the carbon dioxide of the air to form the carbonate (Fig. 6.18).

Portland cement forms when a mixture of limestone, clay, and other substances are heated to a high temperature. It sets when water is added, forming a network of hydrates.

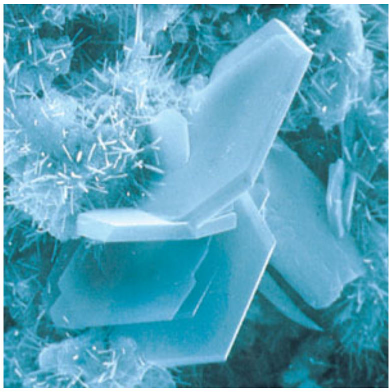

FIGURE 6.18 An electron micrograph of the surface of cement, showing the growth of tiny interlocking crystals as carbon dioxide reacts with calcium oxide and silica.

6.9 Borides, Carbides, and Nitrides

Numerous borides of the metals and nonmetals are known. Their formulas are typically unrelated to their location in the periodic table and include AlB_2, CaB_6, $B_{13}C_2$, $B_{12}S_2$, Ti_3B_4, TiB, and TiB_2. In some metal borides, the boron atoms are found at the centers of clusters of metal atoms. More commonly, the boron atoms form extended structures such as zigzag chains, branched chains, or networks of hexagonal rings of boron atoms, as in MgB_2, which is a superconductor below 39 K (Section 6.14). The hardness and heat stability related to their network structures make some borides suitable for rocket nozzles and turbine blades.

The *covalent carbides* include silicon carbide, SiC, which is sold as carborundum:

$$SiO_2(s) + 3\ C(s) \xrightarrow{2000°C} SiC(s) + 2\ CO(g)$$

Pure silicon carbide is colorless, but iron impurities normally impart an almost black color to the crystals. Carborundum is an excellent abrasive because it is very hard, with a diamondlike structure that fractures into pieces with sharp edges (Fig. 6.19).

FIGURE 6.19 Carborundum crystals, showing the sharp fractured edges that give the substance its abrasive power.

The interstitial carbides are compounds formed by the direct reaction of a d-block metal and carbon at temperatures above 2000°C. As in steel, the C atoms pin the metal atoms together into a rigid structure, resulting in very hard substances with melting points often well above 3000°C. Tungsten carbide, WC, is used for the cutting surfaces of drills.

When boron is heated to white heat in ammonia, boron nitride, BN, is formed as a fluffy, slippery powder:

$$2\ B(s) + 2\ NH_3(g) \xrightarrow{\Delta} 2\ BN(s) + 3\ H_2(g)$$

Its structure resembles that of graphite, but the latter's flat planes of carbon hexagons are replaced in boron nitride by planes of hexagons of alternating B and N atoms (Fig. 6.20). Although it is isoelectronic with graphite, boron nitride is white and has much lower electrical conductivity than graphite because the electrons are localized on the nitrogen atoms. Under high pressure, boron nitride is converted into a very hard, diamondlike crystalline form called Borazon (a proprietary name). In recent years, boron nitride nanotubes similar to those formed by carbon have been synthesized, and they have been found to be semiconducting (see Section 6.19).

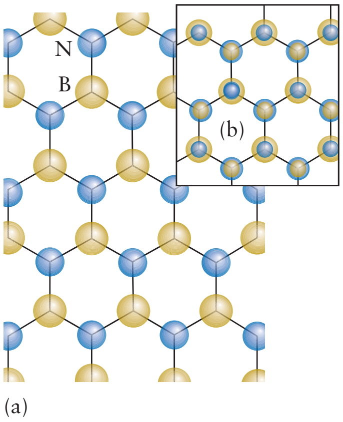

FIGURE 6.20 (a) The structure of hexagonal boron nitride, BN, resembles that of graphite, consisting of flat planes of hexagons of alternating B and N atoms (in place of C atoms) but, as shown for two adjacent layers in part (b), the planes are stacked differently, with each B atom directly over an N atom and vice-versa (compare with Fig. 6.9).

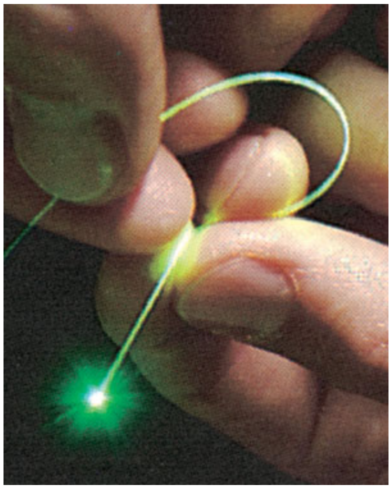

FIGURE 6.21 Glass fibers, such as this one, about the diameter of a human hair, are used in communication networks when large amounts of information must be transmitted in a short time.

FIGURE 6.22 When glass is etched by hydrofluoric acid the surface of the glass is first covered with wax and a design is scratched on the wax. The acid is then poured over it. This etched glass vase was designed by the artist Frederick Carder in the 1920s.

Self-Test 6.8A Assuming that the oxidation number of aluminum is +3 in both compounds, what is the oxidation number of silicon in (a) carborundum; (b) feldspar?

[***Answer:*** (a) +4; (b) +4]

Self-Test 6.8B What is the hybridization of boron and of nitrogen in (a) the graphite form of boron nitride; (b) the diamondlike form?

Borides form extended structures, covalent and interstitial carbides are very hard substances, and boron nitride has structures related to those of carbon.

6.10 Glasses

A **glass** is an ionic solid with an amorphous structure resembling that of a liquid, generally created by freezing a melt quickly so that crystals cannot form. Glass has a network structure based on a nonmetal oxide, usually silica, SiO_2, that has been melted together with metal oxides acting as "network modifiers," which alter the arrangement of bonds in the solid. Glass was first used in ancient times and has played an important role in the development of modern architecture. Today interest in glass is growing due to the use of optical fibers to provide wideband telecommunications networks.

To make glass, silica in the form of sand is heated to about 1600°C. Metal oxides, such as MO (where M is a metal cation), are added to the silica. As the mixture melts, many of the Si—O bonds break and the orderly structure of the individual crystals is lost. When the melt cools, the Si—O bonds re-form but are prevented from forming a crystalline lattice because some of the silicon atoms bond with the O^{2-} ions of the metal oxide to give —Si—O^-—M^+ groups in place of some of the —Si—O—Si— links present in pure silica. Because of the strong covalent character of the Si—O bonds, a short-range order is preserved in the glass; however, long-range order is lost. Silicate glasses are generally transparent and durable and can be formed in flat sheets, blown into bottles, or molded into desired shapes.

Almost 90% of all manufactured glass combines sodium and calcium oxides with silica to form *soda-lime glass*. This glass, which is used for windows and bottles, is about 12% by mass Na_2O prepared by the action of heat on sodium carbonate (the soda) and 12% CaO (the lime). When the proportions of soda and lime are reduced and 16% B_2O_3 is added, a *borosilicate glass*, such as Pyrex, is produced. Because borosilicate glasses do not expand much when heated, they survive rapid heating and cooling and are used for ovenware and laboratory beakers.

Because crystalline regions are not present in glass, light is not scattered by the tiny crystallites that make some minerals opaque, but instead can pass easily through the glass, just as it does through water. In general, silicate-based glasses are brittle, hard, and optically transparent. These properties make them desirable for use in optical fibers.

Optical fibers are made by drawing a thin fiber from an optically pure glass rod heated until it softens. The fiber is then coated with plastic (Fig. 6.21). Transmission of information through an optical fiber is much faster than it would be through a wire. However, for transmission of information it is important to avoid loss of light from the sides of the fiber. Typically in an optical fiber a gradient of composition from the center of the fiber to the edge is created, so that light is easily transmitted along the axis of the fiber, but not out to the sides.

Self-Test 6.9A The refractive index is the ratio $n_r = c/c'$, where c is the speed of light in a vacuum and c' the speed of light in matter. The refractive index of glass is typically 1.6. How far can a pulse of light travel through glass in 1.0 ns?

[***Answer:*** 19 cm]

Self-Test 6.9B The refractive index of water is 1.35 for blue light and 1.33 for red light. What is the spatial separation of pulses of blue and red light after 1.0 ns, given that they set out at the same instant? (See Self-Test 6.9A.)

Glass can be *etched* (by scratching or by roughening the surface abrasively or chemically) to create decorative effects or to change its optical properties (Fig. 6.22). It is

resistant to attack by most chemicals. However, the silica in glass reacts with the F^- ion from hydrofluoric acid to form fluorosilicate ions:

$$SiO_2(s) + 6\,HF(aq) \longrightarrow SiF_6^{\,2-}(aq) + 2\,H_3O^+(aq)$$

It is also attacked by the OH^- ion in hot, molten sodium hydroxide and by O^{2-} from the carbonate anion of hot molten sodium carbonate:

$$SiO_2(s) + Na_2CO_3(l) \xrightarrow{1400°C} Na_2SiO_3(s) + CO_2(g)$$

Self-Test 6.10A Water adheres to glass. Predict the type of intermolecular forces that form between glass and water.

[***Answer:*** Ion–dipole forces and hydrogen bonding between H_2O and the partially negative O atoms in SiO_2.]

Self-Test 6.10B Predict the products and write the chemical equation for the etching of the SiO_2 in glass by OH^- ions.

Silicate glasses have amorphous structures produced by addition of salts that disrupt the crystalline structure. They can be attacked by strong base and hydrofluoric acid.

6.11 Ceramics

Many of the materials used in the most advanced technologies are based on a material characteristic of one of the oldest technologies: common clay. Most clays used commercially are oxides of silicon, aluminum, and magnesium. *China clay* contains primarily *kaolinite*, a form of aluminum aluminosilicate that can be obtained reasonably free of the iron impurities that make many clays look reddish brown, and so it is white. However, other clays contain the iron oxides that cause the orange color of terra cotta tiles and flower pots.

The appearance of a flake of clay reflects its internal structure, which is something like an untidy stack of papers (Fig. 6.23). Sheets of tetrahedral silicate units or octahedral units of aluminum or magnesium oxides are separated by layers of water molecules that serve to bind the layers of the flake together. Each flake of clay is surrounded by a double layer of ions that separates the flakes by repelling the like charges on the other flakes. This repulsion allows the flakes to slide past one another and gives the clay the ability to flow in response to stress. As a result, clays can be easily molded.

When clay is baked in a kiln, it forms the hard, tough *ceramic* materials used in firebricks, tiles, and pots as the water is driven out and strong chemical bonds form between the flakes. Large amounts of china clay, which is used to make ceramics such as porcelain and china, are applied in the coating of paper (such as this page) to give a smooth, nonabsorbent surface. Clay was the first substance to be made into a **ceramic,** an inorganic material that has been hardened by heating to a high temperature. Today a wide variety of compounds, often oxides, are used to create ceramics with specific properties.

FIGURE 6.23 The layers of clay particles can be seen in this micrograph. Because the surfaces of these layers have like charges, they repel one another and easily slide past one another, making clay soft and malleable.

Typically, a ceramic material is very hard, insoluble in water, and stable to corrosion and high temperatures. These characteristics are the key to their technological value. Although many ceramics are brittle, they can be used at high temperatures without failing, and they resist deformation. Ceramics are often the oxides of elements that are on the border between metals and nonmetals, but d-metal oxides and some compounds of boron and silicon with carbon and nitrogen are also ceramic materials. Most ceramics are electrical insulators; however, some d-metal oxides, such as barium titanate, $BaTiO_3$, and zinc oxide, ZnO, are semiconductors. In addition, some of the most promising high-temperature superconductors are ceramics (see Section 6.14).

Many aluminosilicate ceramics are created by heating aluminosilicate clays to drive the water out from between the sheets of tetrahedra. This procedure leaves a rigid heterogeneous mass of tiny interlocking crystals bound together by glassy silica. Bone china, which is strong enough to be used for thin, lightweight dishes, is made from china clay with bone ash as a binder that strengthens the ceramic.

Aluminum oxide, Al_2O_3, is a ceramic oxide found in different solid forms, each of which is an important material. As α-alumina, it is the very hard, stable, crystalline substance *corundum*; impure microcrystalline corundum is the purple-black abrasive known as *emery*. Corundum makes up about 80% of the advanced ceramics used in high-technology applications. Its hardness, rigidity, thermal conductivity, stability at high temperatures, electrical insulating ability, and low cost make it suitable for a wide range of applications, including acting as the substrate for microchips. Corundum is prepared from powdered Al_2O_3 dispersed in liquid. Granules that form in the dispersion are compressed in a mold and sintered. Single-crystal forms of aluminum oxide are known and large single crystals of aluminum oxide called sapphires, which derive their color from iron and titanium impurities, are grown for specialized applications such as acoustic microscopes and as heat-resistant windows on heat-seeking missiles.

The challenge presented by corundum and most other ceramics is to find a way to overcome their brittleness when that needs to be avoided. One route used with some silicon dioxide ceramics is the *sol-gel process*. In this process, an organic silicon compound is dissolved in a solvent such as an alcohol; water is then added to create hydrate cross-links as the compound is polymerized into a network structure. Many cross-links form as the gel sets. These cross-links form a rigid, strong matrix that has few of the tiny cracks that can initiate breakage in brittle ceramics. If the solvent is removed at high temperatures and low pressures, an *aerogel*, a solid foam that has a density about the same as that of air, but is a good insulator, is formed (Fig. 6.24). Some of the TiO_2 and SiO_2 *nanoparticles* used in ink and coatings can be made by the sol-gel process if care is taken to control particle size and shape during synthesis (see Section 6.20).

FIGURE 6.24 An aerogel is a ceramic foam. Its low density and low thermal conductivity, combined with great strength, make it an ideal insulating material. Here a thin piece protects three wax crayons from the heat of a flame. Aerogels were used to insulate the Mars Rover.

The stability of ceramic materials at high temperatures has made them useful as furnace liners and has led to interest in ceramic automobile engines, which could endure overheating. Currently, a typical automobile contains about 35 kg of ceramic materials such as spark plugs, pressure and vibration sensors, brake linings, catalytic converters, and thermal and electrical insulation. Some fuel cells make use of a porous solid electrolyte such as zirconia, ZrO_2, that contains a small amount of calcium oxide. It is an electronic insulator, and so electrons do not flow through it, but oxide ions do.

Self-Test 6.11A Suppose a ceramic is made from pure Al_2O_3. What is the contribution of the electrons to the mass of a block of this ceramic of mass 10. kg?

[*Answer:* 2.7 g]

Self-Test 6.11B Suppose a ceramic is made from pure SiO_2. What is the contribution of the electrons to the mass of a block of this ceramic of mass 10. kg?

Ceramics are inorganic materials that have been hardened by heating.

MATERIALS FOR NEW TECHNOLOGIES

Solid-state chemistry is an exciting area of research, not only because of the importance of the applications, but because of what scientists are learning about the nature of matter. In these sections we shall see how an understanding of the nature of solids allows us to design materials that are magnetic, glow in the dark, make miniature electronics possible, and conduct electricity without resistance.

6.12 Bonding in the Solid State

Many of the interesting and desirable properties of solids stem from the ability of their electrons to migrate from one region to another, that is, their ability to conduct an **electric current,** which is the flow of electric charge. In **electronic conduction,** the charge is carried by electrons. Electronic conduction is the mechanism of conduction in metals and graphite. In **ionic conduction,** the charge is carried by ions. This is the mechanism of electrical conduction—the transport of charge—in a molten salt or an electrolyte solution. Because ions are too bulky to travel easily through most solids, the flow of charge through solids is in most cases a result of electronic conduction. However, solid

electrolytes that allow ions to move through their lattices are important materials used in rechargeable batteries. We can classify substances according to their resistance and how it varies with temperature (Fig. 6.25):

An **insulator** is a substance that has such a high resistance that it does not conduct electricity.
A **metallic conductor** is an electronic conductor with a resistance that *increases* as the temperature is raised.
A **semiconductor** is an electronic conductor with a resistance that *decreases* as the temperature is raised.
A **superconductor** is an electronic conductor that conducts electricity with zero resistance, usually at very low temperatures.
A **solid electrolyte** is an ionic conductor.

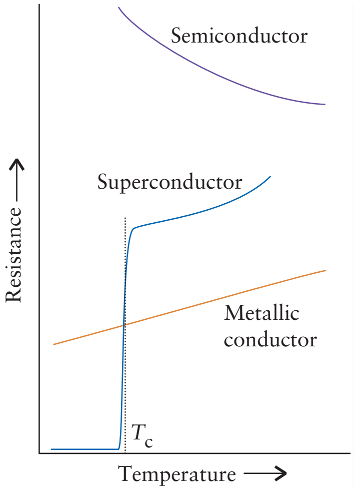

FIGURE 6.25 The resistance of a metallic conductor increases with temperature. That of a semiconductor decreases with increasing temperature. A superconductor is a substance that has zero resistance below a certain temperature (T_c). An insulator behaves like a semiconductor with a very high resistance.

Animation 6.25

The **electric conductivity**, κ (kappa), of a sample of length l and cross-sectional area A is defined in terms of its resistance R as

$$\kappa = \frac{l}{A \times R} \quad (1)$$

and is measured in siemens per meter ($S{\cdot}m^{-1}$, where $1\ S = 1\ \Omega^{-1}$, with Ω, omega, the symbol for ohm). The conductivity of a metal is typically about $10^7\ S{\cdot}m^{-1}$; that of a semiconductor about $10^{-4}\ S{\cdot}m^{-1}$. In most cases, a metallic conductor has a much higher electrical conductivity than a semiconductor, but it is the temperature dependence of the conductivity that distinguishes the two types of conductors.

Self-Test 6.12A What is the resistance of a copper wire of length 1.0 m and cross-sectional area 0.10 mm^2? The conductivity of copper at room temperature is 60.7 $MS{\cdot}m^{-1}$.

[***Answer:*** 0.16 Ω]

Self-Test 6.12B What is the resistance of a sheet of semiconductor of thickness 0.10 mm and cross-sectional area 1.0 cm^2? The conductivity of the semiconductor at room temperature is 0.2 $mS{\cdot}m^{-1}$.

Molecular orbital theory explains the electrical properties of metallic conductors, semiconductors, and insulators by treating them as one huge molecule and supposing that their valence electrons occupy delocalized orbitals that spread throughout the solid. We have already seen (in Section 3.9) that, when N atomic orbitals merge together in a molecule, they form N molecular orbitals. The same is true of a metal; but, for a metal, N is enormous (about 10^{23} for 10 g of copper, for example). Instead of the few molecular orbitals with widely spaced energies typical of small molecules, the huge number of molecular orbitals in a metal are so close together in energy that they form a nearly continuous band (Fig. 6.26). As a guide to the type of energy separation to expect, we saw in Section 1.7 that the separation of neighboring energy levels of a particle of mass m in a one-dimensional box of length L is

$$E_{n+1} - E_n = (2n + 1)\frac{h^2}{8mL^2}$$

For an electron ($m = m_e$) in a box of length 1.0 cm, $h^2/8mL^2 = 6.0 \times 10^{-42}$ J, so even when n is enormous, the separation is still very tiny.

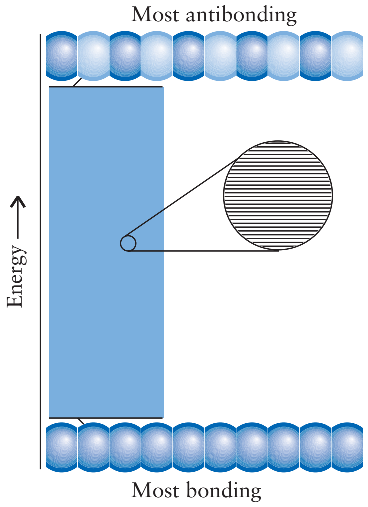

FIGURE 6.26 A line of atoms gives rise to an almost continuous band of molecular orbital energies. At the lower edge of the band, the molecular orbitals are fully bonding; at the upper edge, the molecular orbitals are fully antibonding. The enlargement shows that, although the band of allowed energies appears to be continuous, it is in fact composed of discrete, closely spaced levels.

Self-Test 6.13A Estimate the value of n for the uppermost filled level in a one-dimensional line of sodium atoms of length 1.0 cm. *Hint:* remember the Pauli exclusion principle, and take the radius of an Na atom as 154 pm.

[***Answer:*** $n \approx 1.6 \times 10^7$]

Self-Test 6.13B Estimate the value of n for the uppermost filled level in a one-dimensional line of calcium atoms of length 1.0 cm. *Hint:* Take the radius of a Ca atom as 197 pm.

Now consider a molecular orbital treatment. Consider, for instance, sodium. Each atom contributes one valence orbital (the 3s-orbital in this case) and one valence electron.

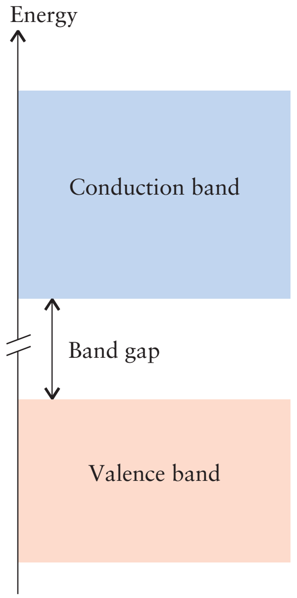

FIGURE 6.27 In a typical insulating solid, a full valence band is separated by a substantial energy gap from the empty conduction band. Note the break in the vertical scale.

If there are *N* atoms in the sample, then the *N* 3s-orbitals merge to form a band of *N* molecular orbitals, of which half are net bonding and half are net antibonding. We say "net" bonding or antibonding because, in general and as we saw in connection with benzene (Section 3.12), a molecular orbital is bonding between some neighbors and antibonding between others, depending on where its internuclear nodes lie; only the molecular orbital of lowest energy, with no internuclear nodes, is bonding between all neighboring atoms. The *N* electrons contributed by the *N* atoms occupy the orbitals according to the building-up principle. Because two electrons can occupy each orbital, the *N* electrons occupy the lower *N* bonding orbitals.

An empty or incompletely filled band of molecular orbitals is called a **conduction band.** Because neighboring orbitals in metals lie so close together in energy, it takes very little additional energy to excite the electrons from the topmost filled molecular orbitals to the empty orbitals of the conduction band. Electrons in the conduction band can move freely through the solid, and so they can carry an electric current. The resistance of the metal increases with temperature because, when it is heated, the atoms vibrate more vigorously. The passing electrons collide with the vibrating atoms and do not pass through the solid so easily.

In an insulator, the valence electrons fill all the available molecular orbitals to give a full band called a **valence band.** There is a substantial **band gap,** a range of energies for which there are no orbitals, before the next band, the conduction band composed of the empty orbitals, begins (Fig. 6.27). The electrons in the valence band can be excited into the conduction band only by a very large injection of energy. Because the valence band is full and because the conduction band is separated from it by a large energy gap, the electrons are not mobile and the solid does not conduct electricity.

Bonding in solids may be described in terms of bands of molecular orbitals. In metals, the conduction bands are incompletely filled orbitals that allow electrons to flow. In insulators, the valence bands are full and the large band gap prevents the promotion of electrons to empty orbitals.

6.13 Semiconductors

Semiconductors have revolutionized the electronics industry because very tiny semiconducting devices can be used to control the flow of an electrical current. As its name implies, an electrical current does not flow as well through a semiconductor as it does through a metal. In an **intrinsic semiconductor**, an empty conduction band lies close in energy to a full valence band. As a result, as the solid is warmed, electrons can be excited from the valence band into the conduction band, where they can travel throughout the solid. Hence, the resistance of a semiconductor decreases as its temperature is raised.

The ability of a semiconductor to carry an electric current can also be enhanced by adding electrons to the conduction band or by removing some from the valence band. This modification is carried out chemically by **doping** the solid, or spreading small amounts of impurities throughout it, and results in an **extrinsic semiconductor**. In one example, a minute amount of a Group 15/V element such as arsenic is added to very pure silicon. The arsenic increases the number of electrons in the solid: each Si atom (Group 14/IV) has four valence electrons, whereas each As atom (Group 15/V) has five. The additional electrons enter the upper, normally empty conduction band of silicon and allow the solid to conduct (Fig. 6.28). This type of material is called an **n-type semiconductor** because it contains excess *n*egatively charged electrons. When silicon (Group 14/IV) is doped with indium (Group 13/III) instead of arsenic, the solid has fewer valence electrons than does pure silicon; so the valence band is no longer completely full (Fig. 6.29). We say that the valence band now contains "holes." Because the valence band is no longer full, it has been turned into a conduction band, and an electric current can flow. This type of semiconductor is called a **p-type semiconductor,** because the absence of negatively charged electrons is equivalent to the presence of *p*ositively charged holes. The doped solids are overall electrically neutral, because the nuclei of the doping atoms have a charge that matches the number of their electrons.

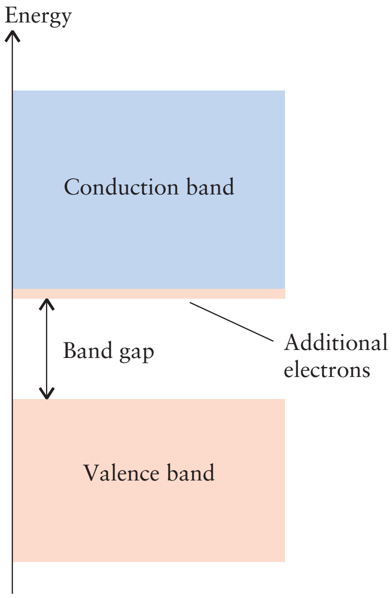

FIGURE 6.28 In an n-type semiconductor, the additional electrons supplied by the electron-rich dopant atoms enter the conduction band (forming the pink band at the bottom of the conduction band), where they can act as carriers for the current.

Solid-state electronic devices such as diodes, transistors, and integrated circuits contain **p–n junctions** in which a p-type semiconductor is in contact with an n-type semiconductor (Fig. 6.30). The structure of a p–n junction allows an electric current to flow in only one direction. When the electrode attached to the p-type semiconductor has a negative charge, the holes in the p-type semiconductor are attracted to it, the electrons in the n-type semiconductor are attracted to the other (positive) electrode, and current does not flow. When the polarity is reversed, with the negative electrode attached to the n-type semiconductor, electrons flow from the n-type semiconductor through the p-type semiconductor toward the positive electrode.

Self-Test 6.14A Which type of semiconductor is germanium doped with arsenic?

[***Answer:*** n-type]

Self-Test 6.14B Which type of semiconductor is antimony doped with tin?

In semiconductors, empty levels are close in energy to filled levels.

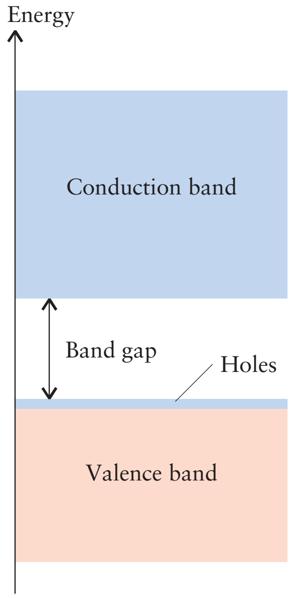

FIGURE 6.29 In a p-type semiconductor, the electron-poor dopant atoms effectively remove electrons from the valence band, and the "holes" that result (blue band at the top of the valence band) enable the remaining electrons to become mobile and conduct electricity through the valence band.

6.14 Superconductors

Three of the biggest problems facing scientists and engineers are to provide energy-efficient transportation, improve the capacity and quality of communication systems, and reduce the loss of scarce power resources during transmission. Currently, less than 40% of the energy generated by burning fossil fuels in an electrical power plant actually reaches our homes, much of it being lost during transmission. Scientists and engineers suspect that all three of these problems can be solved by the development of appropriate high-temperature superconductors. High-temperature superconductors, which were mentioned earlier (in Sections 6.9, 6.11, and 6.12), have enormous technological potential because they offer the prospect of efficient power transmission and the generation of high magnetic fields for use in transport systems (Fig. 6.31).

Superconductivity is the loss of electrical resistance when a substance is cooled below a characteristic transition temperature (T_s). Conventional superconductivity arises from the ability of electrons to pair by making use of lattice vibrations. The electron pairs, which are called **Cooper pairs** after the scientist who first proposed the mechanism, can travel almost freely through the lattice, rather like oxen yoked together are less deflected by obstacles than individual oxen. A Cooper pair forms when the presence of one electron distorts the cations of the lattice in its vicinity, and that region of distorted lattice attracts a second electron into its vicinity (Fig. 6.32).

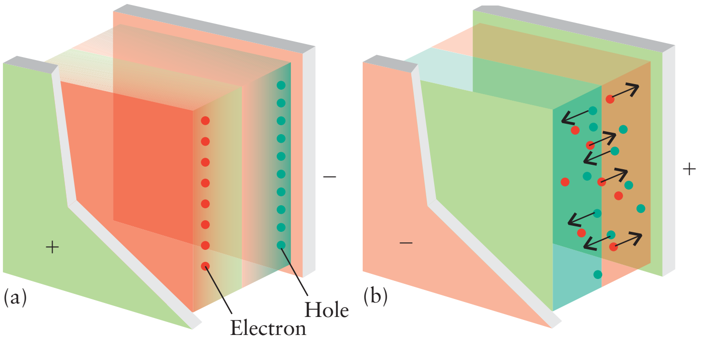

FIGURE 6.30 The structure of a p–n junction allows an electric current to flow in only one direction. (a) Reverse bias: the negative electrode is attached to the p-type semiconductor and current does not flow. (b) Forward bias: the electrodes are reversed to allow charge carriers to be regenerated.

FIGURE 6.31 Superconductors have the ability to levitate vehicles with embedded magnets. This picture shows an experimental zero-friction train in Japan, built to use helium-cooled metal superconductors.

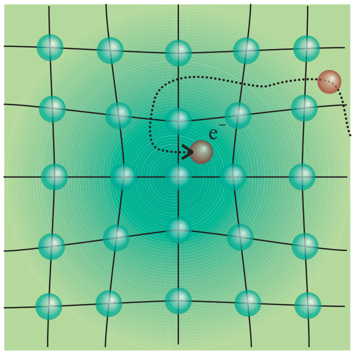

FIGURE 6.32 The formation of a Cooper pair. As one electron distorts the crystal lattice, the energy of a second electron is lowered as it enters that same region. These electron–lattice interactions bind the two electrons into a pair.

The two electrons are attracted together weakly in this way; the pair—and the resulting superconductivity—survives only if the temperature is so low that the pair is not shaken apart by lattice vibrations. Superconductivity was first observed in 1911 in mercury, for which $T_s = 4$ K. Over the years, many other metallic superconductors were identified, some having transition temperatures as high as 23 K. However, low-temperature superconductors need to be cooled with liquid helium, which is very expensive.

In 1986 a record-high transition temperature of 35 K was observed, not for a metal but for a ceramic material, a lanthanum–copper oxide doped with barium. Then early in 1987, a new record T_s of 93 K was set with a yttrium–barium–copper oxide and a series of related compounds. In 1988, two more oxide series of bismuth–strontium–calcium–copper and thallium–barium–calcium–copper exhibited transition temperatures of 110 K and 125 K, respectively. By 2006, the highest transition temperature attained was 130 K. These temperatures can be reached by cooling the materials with liquid nitrogen, at only 0.2% of the cost of liquid helium.

Almost all these high-temperature superconductors (HTSCs) are hard, brittle ceramic oxides that have sheets of copper and oxygen atoms sandwiched between layers of either cations or a combination of cations and oxide ions, and all are derived from their respective parent insulators by doping (Fig. 6.33). Because of their layered structure, their electrical and magnetic properties are strongly anisotropic (Section 5.15). The electric current flows easily along the planes of the copper–oxygen sheets, but only weakly perpendicular to them. Thus, the materials must be positioned with the copper–oxygen planes in a favorable orientation.

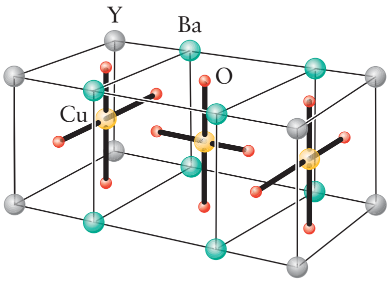

FIGURE 6.33 The structure of a "123 superconductor," a ceramic that has the variable formula $YBa_2Cu_3O_{6.5-7.0}$. The numbers 1, 2, and 3 refer to the implied or specified subscripts on the first three elements in the formula.

A major challenge to the use of superconductors for transmitting electrical power is the difficulty of making electrical wires from a brittle ceramic material. Superconducting materials need to be formed into very long, flexible cables that can carry high current without excessive heat loss and that can retain their superconducting properties for a long period of time without chemical or physical degradation. One solution has been to deposit the superconducting material on the surface of wire or tape made of a metal such as silver. The metal is usually prepared with a textured surface that helps to align the crystal grains in the desired direction. Twenty-five kilograms of superconducting wire made in this way can carry as much current as 1800 kg of today's copper-based electrical cable (Fig. 6.34).

A better option for the transmission of electricity being considered for use in transformers may be the metallic superconductor magnesium diboride, MgB_2, which is a superconductor below 39 K (Fig. 6.35). Magnesium diboride is so inexpensive to make that, even with the cost of cooling, it is less expensive than either copper wire or nonmetallic HTSC materials. It requires only inexpensive iron for cladding and can be used to make long, flexible wires. Although 39 K is a not a very high temperature, unlike T_s for metallic superconductors, it can be reached by the use of a refrigeration unit, and so liquid helium is not required.

Because superconductors can create a mirror image of a magnetic field within themselves, they trap magnetic fields and can even levitate objects. This property has

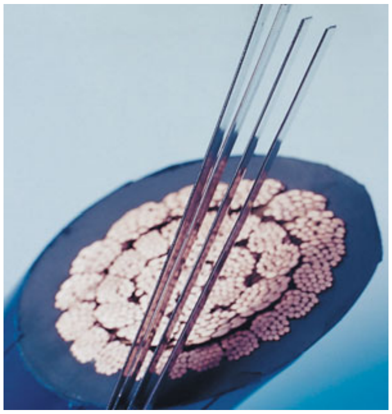

FIGURE 6.34 Twenty-five kilograms of the experimental superconducting wire in the foreground can carry as much current as 1800 kg of the bulky copper cable in the background.

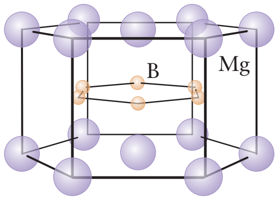

FIGURE 6.35 The unit cell of MgB_2 has six boron atoms in the center of a hexagonal array of magnesium atoms. The superconductivity appears to stem from the high-energy vibrational modes of the planes of boron atoms that extend throughout the crystal.

led to research on possibilities such as levitating railroad trains over magnetic tracks (see Fig. 6.31). However, many technical problems remain to be solved before the promise of high-temperature superconductivity can be realized.

Superconductors conduct electricity with no resistance at low temperatures. Metals and some ceramic materials have shown superconducting behavior.

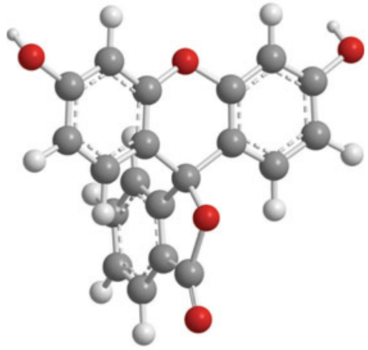
6.15 Luminescent Materials

Incandescence is light emitted by a hot body, such as the filament in a lamp or the particles of hot soot in a candle flame. **Luminescence** is the emission of light by a process other than incandescence. For example, when hydrogen peroxide reacts with chlorine, the O_2 formed by the oxidation of H_2O_2 may be produced in an energetically excited state and emit light as it discards its excess energy. This process is an example of **chemiluminescence,** the emission of light by products formed in energetically excited states in a chemical reaction (Fig. 6.36). The light sticks used for emergency lighting glow with light from a chemiluminescent process. *Bioluminescence* is a form of chemiluminescence generated by a living organism. For example, the enzyme *luciferase* produces the luminescent compound *luciferin* in fireflies and some bacteria.

FIGURE 6.36 Chemiluminescence, the emission of light as the result of a chemical reaction, occurs when hydrogen peroxide is added to a solution of the organic compound perylene. Although hydrogen peroxide itself can fluoresce, in this case the light is emitted by the perylene.

Fluorescence and phosphorescence are the emission of light from molecules excited by radiation of higher frequency, such as visible light being emitted when a substance is illuminated with ultraviolet radiation. In **fluorescence** emission of light persists for only a few nanoseconds after the illumination ceases. In **phosphorescence** the emission persists, sometimes for seconds, as in the element phosphorus, from which the phenomenon gets its name (see Section 15.15). The crucial difference in mechanism is that fluorescence involves the retention of the relative spin orientation of the excited electron whereas in phosphorescence the electron becomes unpaired and it takes time for its spin to reverse again. Technically, we say that in phosphorescence a "singlet state" (in which a pair of electron spins are $\uparrow\downarrow$) becomes a "triplet state" (with spins parallel, $\uparrow\uparrow$). Because the spins can revert to $\uparrow\downarrow$ only slowly, the excited state survives for long periods and the phosphorescent glow normally lasts longer than fluorescence.

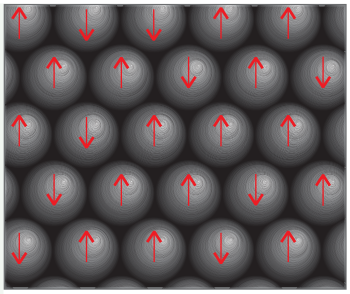
Fluorescent materials are very important in the electronic industry, as narrow fluorescent light tubes about the size of a pencil are used to provide the backlight for LCD displays in laptop computers (Section 5.15). A dim light generated in the tube excites fluorescent material coating the inside surface of the tube, which shines brightly and illuminates the screen. Fluorescent materials are also vital for medical research. Dyes such as fluorescein (**2**) can be attached to protein molecules, and the protein can be traced in a biological system by exciting the fluorescein and looking for its emissions. The use of a fluorescent material allows the detection of much smaller concentrations than would otherwise be possible. Because fluorescent materials can be activated by radioactivity, they are also used in scintillation counters to measure radiation (see Box 17.2).



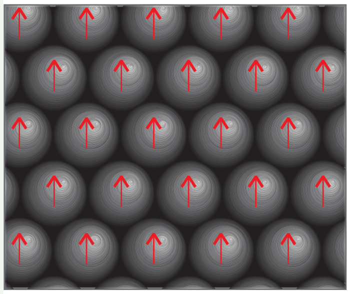
2 Fluorescein

Triboluminescence is luminescence that results from mechanical shock to a crystal. It is observed in many crystalline substances and can be detected by striking or grinding sugar crystals in a dark room. The grinding creates crystal defects that trap electrons. When the electrons fall back into their usual locations, light is emitted.

The cathode ray tubes that were once widely used for television and computer displays and the plasma screens that (together with liquid-crystal displays) have replaced them, both make use of **phosphors,** phosphorescent materials that glow when they are excited by the impact of electrons or ultraviolet radiation. In a cathode ray color monitor or television set tube, clusters of three phosphors consisting of zinc sulfide doped by a d-block metal are used for each dot in the screen. The red phosphor is often yttrium oxysulfide, Y_2O_2S, activated by europium. Silver-activated ZnS is often used for the blue phosphor and copper-activated ZnS for the green phosphor. Solid zinc sulfide is an insulator, with a large energy difference between the conductance and the valence bands, and the activating metal has an energy level between those two bands. When the zinc sulfide is struck by electrons of sufficient energy, one of its electrons is excited to the conduction band, leaving a positively charged hole in the lattice. The hole travels to an atom of the activating metal (in other words, electrons move into the hole, leaving



(a)



(b)

FIGURE 6.37 Ferromagnetic materials include iron, cobalt, and the iron oxide mineral magnetite. They consist of crystals in which the electrons of many atoms spin in the same direction and give rise to a strong magnetic field. (a) Before magnetization, when the spins are almost randomly aligned; (b) after magnetization. The orange arrows represent the electron spins.

Lab Video 6.37

a hole elsewhere, and so the hole effectively travels through the solid). The excited electron then drops back from the conduction band into that hole, emitting light of a wavelength corresponding to the energy separation between the activating metal and the excited state. The phosphors must stop glowing as soon as the excitation beam passes on, so that the picture can change rapidly. In a plasma screen the excitation is caused by the ultraviolet radiation emitted by an electric discharge through a low-pressure mixture of noble gases in a cell behind each dot of phosphor.

Light-emitting diode (LED) displays also use luminescent materials. In an LED a luminescent material generates light when an electric current is applied to a p–n junction. Compounds used to make different colors of light vary, but commonly aluminum gallium arsenide is used to make red LEDs, indium gallium nitride green LEDs, and zinc selenide blue LEDs. When tiny LEDs of these three colors are clustered tightly together on a display screen, any color can be generated depending on which of the three colors are activated.

Organic light-emitting diodes (OLEDs) use a film consisting of an organic polymer that conducts electricity to generate light of different colors. Although LCD displays (Section 5.15) are more common, LED displays do not require backlighting, and so can be made much thinner. LED lights are being investigated for many applications, as they use much less power than incandescent lights.

Self-Test 6.15A Explain how fluorescent materials can be used to detect radioactivity.

[***Answer:*** The fluorescent materials absorb energy from the radiation and release it as light.]

Self-Test 6.15B Explain the difference between chemiluminescence and phosphorescence.

Luminescent materials release energy as light as they return from excited states to lower energy states.

6.16 Magnetic Materials

As remarked in Box 3.2, paramagnetism is the tendency of a substance to move into a magnetic field. It arises when an atom or molecule has at least one unpaired electron, which aligns with the applied field. However, because the spins on neighboring atoms or molecules are aligned almost randomly, paramagnetism is very weak and the alignment of electron spins is lost when the magnetic field is removed. In some d-metals, however, when the unpaired electrons of many neighboring atoms align with one another in an applied magnetic field, the much stronger effect of **ferromagnetism** arises. The regions of aligned spins, which are called **domains** (Fig. 6.37), survive even after the applied field is turned off.

Ferromagnetism is much stronger than paramagnetism, and ferromagnetic materials are used to make permanent magnets. They are also used in the coatings of cassette tapes and computer disks. The electromagnetic recording heads align large numbers of spins as the tape passes underneath, and the spin alignment in the domains remains for years. In an **antiferromagnetic** material, neighboring spins are locked into an *antiparallel* arrangement; so the magnetic moments cancel. Manganese is antiferromagnetic. In a **ferrimagnetic material,** the spins on neighboring atoms are different, and although they are locked together in an antiparallel arrangement, the two magnetic moments do not completely cancel.

Ferromagnetism also occurs in alloys such as alnico (Section 6.4) and some compounds of the d-metals, such as the oxides of iron and chromium. Ceramic magnets, which are used in refrigerator magnets, are made of barium ferrite ($BaO{\cdot}nFe_2O_3$) or strontium ferrite ($SrO{\cdot}nFe_2O_3$). They are made by compressing the powdered ferrite in a magnetic field and heating it until it hardens. Because these magnets are ceramic, they are hard and brittle, with low densities. However, they are the most widely used magnets because of their low cost.

Ferrofluids are ferromagnetic liquids. They are suspensions of finely powdered magnetite, Fe_3O_4, in a viscous, oily liquid (such as mineral oil) that contains a detergent (such as oleic acid, a long-chain carboxylic acid). The iron oxide particles do not settle out, because they are attracted to the polar ends of the detergent molecules, which form compact clusters called *micelles* (Section 9.9) around the particles. The nonpolar ends of the detergent molecules point outward, allowing the micelles to form a colloidal suspension

FIGURE 6.38 When a magnet is pulled up from this viscous ferrofluid, the particles of iron(III) oxide align themselves with the magnetic field. Because strong attractions exist between the particles and the detergent molecules in the oil, the liquid is pulled into the field along with the particles.

in the oil. When a magnet is brought near a ferrofluid, the particles in the liquid try to align themselves with the magnetic field, but they are kept in place by the oil (Fig. 6.38). As a result, it is possible to control the flow and position of the ferrofluid by means of an applied magnetic field. One application of ferrofluids is in the braking systems of exercise machines. The stronger the magnetic field, the greater the resistance to motion.

Recently interest in single molecule magnets has grown. Individual **molecular magnets** contain several d-block metal atoms bonded to groups of nonmetal atoms such as carbon, hydrogen, and oxygen. They can respond to a magnetic field as if they were nano-size compass needles and thus have great potential for miniaturizing electronic storage media such as computer disks. Typically the d-block metal atoms are imbedded in cage-like structures and some of the nano-size molecular magnets have interesting shapes, such as rings, tubes, or spheres (Fig. 6.39).

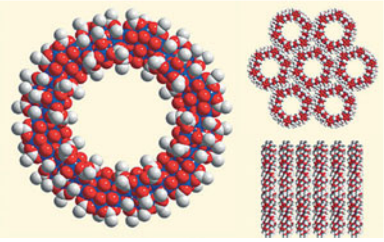


FIGURE 6.39 The structure of a molecular magnet. The nano-size molecular torus contains 84 manganese atoms and is approximately 4 nm in diameter. The manganese atoms are bonded to groups of carbon atoms in the form of acetate ions, water molecules, and chlorine atoms. In this molecule the manganese atoms act as ferromagnets.

Magnetic materials can be paramagnetic, ferromagnetic, or antiferromagnetic. In ferromagnetic materials, large domains of electron spins are locked together in the same orientation.

6.17 Composite Materials

A **composite material** consists of two or more substances that have been combined into a heterogeneous material, while retaining their individual characteristics. Composite materials are found in nature. For instance, seashells owe their strength to a tough organic matrix and their hardness to the calcium carbonate crystals imbedded in the matrix (Fig. 6.40). Bones have low density, but they are strong because of their composite nature. In bone tissue, crystals of phosphate salts are embedded in fibers of a natural polymer (an organic compound with long chains) called *collagen* that hold them in place but allow a small amount of flexibility. Artificial bone and cartilage are now becoming realities through the preparation of synthetic composite materials such as fiberglass. These materials mimic bone in that they have inorganic solids mixed into a crack-resistant polymer matrix. The result is a material that has great strength yet remains flexible. Some lightweight composites, such as the graphite composite used for tennis rackets, in which graphite fibers are imbedded in a polymer matrix, and the fibrous refractory composite insulation tiles used on the body of the space shuttle, in which alumina-borosilicate fibers are added to a silica ceramic matrix, can have three times the strength-to-density ratio of steel (Fig. 6.41).

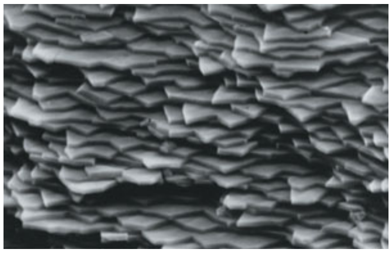

FIGURE 6.40 A photomicrograph of the cross section of the mother-of-pearl lining a mollusk shell. The composite material making up mother-of-pearl consists of flat crystals of calcium carbonate embedded in a tough, flexible organic matrix that resists cracking.

Ceramic materials are hard, but tend to be brittle. Flakes of very strong, tough materials such as titanium diboride, TiB_2, can be distributed throughout ceramics to strengthen them. Even if a crack did form, it would be unable to propagate past the first flake that it encountered. A composite material containing ceramic flakes in a polylactic acid polymer is being used to provide instant mends for broken bones. The material is

FIGURE 6.41 This state-of-the-art sports car makes use of a design related to that of the mollusk shell in Fig. 6.40. The body of the car is constructed of composite materials that are stronger than steel, but much lighter, resulting in higher performance.

injected as a paste into the cracked bone, where it sets at body temperature into a scaffold that acts like bone tissue and promotes healing as new bone cells form around it.

Composite materials combine the advantages of more than one component material. Copolymers contain more than one type of monomer.

NANOMATERIALS

Nano is derived from the Greek word for dwarf.

A new area of research with the potential, among other things, for revolutionizing medical diagnosis and treatment and improving our quality of life is **nanoscience,** the study of the properties of nanomaterials, and its application, **nanotechnology,** the procedures used to manipulate matter on this scale. These procedures include new imaging technologies such as the scanning tunneling microscope and atomic force microscope (see Box 5.1). **Nanomaterials** are materials with particle sizes in the range 1 to 100 nm; they are larger than individual molecules but too small to exhibit most bulk properties. Nanotechnology has the promise to provide new materials such as biosensors that monitor and even repair bodily processes, microscopic computers, artificial bone, and lightweight, remarkably strong materials.

6.18 The Nature and Uses of Nanomaterials

In this section we summarize what nanomaterials are, how they are prepared, some of the ways the properties of nanomaterials differ from atomic properties or those of bulk matter, and why they have raised such interest in the scientific and business communities. The discovery of how some nonmetals and metalloids can be manipulated into assembling themselves into regular, extended structures is creating entirely new areas of research (Box 15.2).

In a block of metal the separation of neighboring energy levels is infinitesimal. However, the separation is significant in a cluster of atoms with dimensions in the nanometer scale. A cluster of atoms in a medium can act as a trap for electrons, and to a good approximation we can treat the cluster as a potential well and use what we already know about electrons trapped in wells to estimate the allowed energy levels. The fact that the well is not empty does not matter; it is a region in which an electron has lower potential energy than when in its surroundings. The difference between the one-dimensional well treated in Section 1.7 (where we saw that the energy levels are $E_n = n^2h^2/8m_eL^2$) and the present case is that the well we now consider is three-dimensional and best regarded as spherical. Therefore, we need to consider the energies of electrons trapped in a region rather like a hydrogen atom without the central nucleus but with a surrounding wall. A spherical well is more difficult to deal with than a rectangular well, but the results are very similar. For instance, the spherically symmetrical energy levels ($l = 0$, corresponding to the s-orbitals of a hydrogen atom) of an electron in a spherical cavity of radius r are given by

$$E_n = \frac{n^2h^2}{8m_er^2} \qquad (2)$$

As usual, n is the quantum level, h is Planck's constant, and m_e is the mass of an electron.

What does this equation tell us? Equation 2 shows that as the radius of the well decreases, the separation of energy levels increases (as $1/r^2$) , and so the wavelength of light (from $\Delta E = h\nu = hc/\lambda$) that can cause excitation decreases. That is, as the size of the cavity varies, so does the color of the material.

Three-dimensional clusters of semiconducting materials, such cadmium selenide (CdSe), containing 10 to 10^5 atoms are called **quantum dots**. They can be made in solution or by depositing atoms on a surface, with the size of the nanocrystal being determined by the details of the synthesis. The variation of color with the radius of the quantum dot is readily observed in suspensions of CdSe quantum dots of different sizes (Fig. 6.42).

Some quantum dots emit light when an excited electron falls back to a lower level in the dot. One application of this phenomenon is to monitor processes going on in biological cells. For example, a CdSe quantum dot can be attached to the surface of a

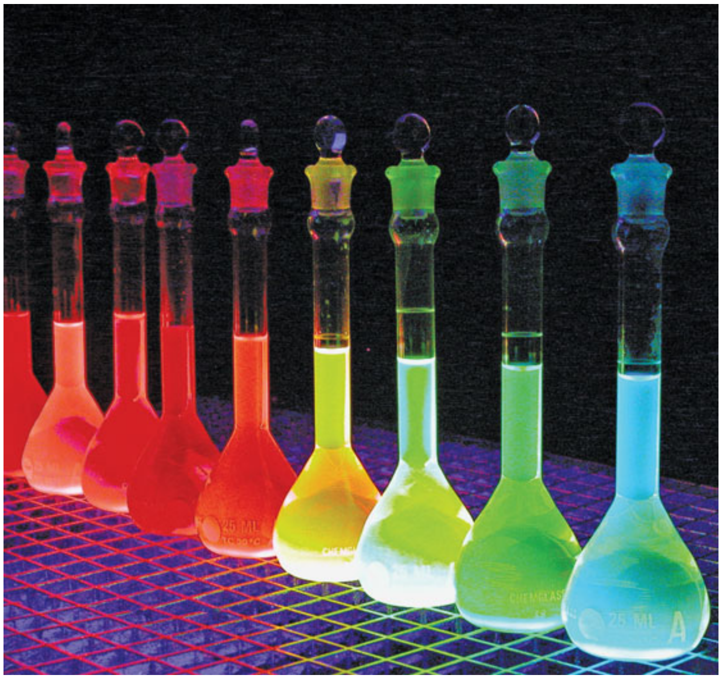

FIGURE 6.42 The different colors of these CdSe/ZnS quantum dot suspensions indicate the different sizes of the quantum dots that they contain. The longer the wavelength of the color emitted, the larger the diameter of the quantum dots.

cell, perhaps to a protein or another component, through an organic linking molecule. The spatial distribution of emission intensity and, consequently, of the labeled molecule can then be measured with a microscope.

In nanomaterials, such as quantum dots, differences between energy levels may give rise to transitions in the visible region of the spectrum.

6.19 Nanotubes

In 1991 scientists identified a previously unknown form of carbon when they sealed two graphite rods inside a container of helium gas and passed an electric discharge between them. Much of one rod evaporated, but some surprising structures resulted (Fig. 6.43). As well as the tiny 60-atom carbon spheres known as buckminsterfullerene, which had been known since 1985, hollow, perfectly straight carbon nanotubes were detected. A nanotube can be thought of as a graphene sheet of millions of carbon atoms rolled into a cylinder only 1–3 nm in diameter.

Carbon nanotubes conduct electricity because of the extended network of delocalized π-bonds that runs from one end of the tube to the other. The conductivity of nanotubes depends on the way the tubes are rolled (Fig. 6.44). If the points of the hexagons

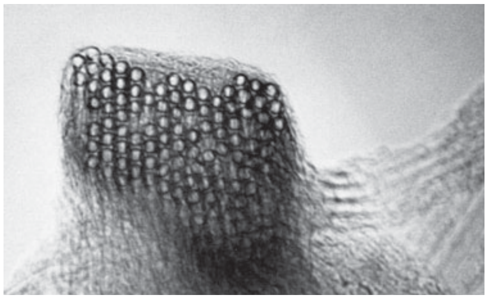

FIGURE 6.43 A cluster of carbon nanotubes that has formed a "rope." The surrounding material below the rope in the photograph consists of fullerenes and other carbon structures.

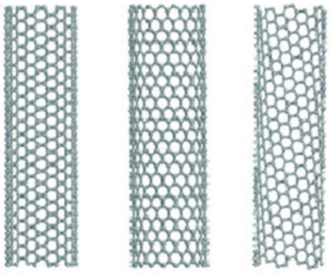

(a) (b) (c)

FIGURE 6.44 Three versions of single-walled carbon nanotubes: (a) "armchair", (b) zigzag, and (c) chiral. Most tubes have ends capped by hemispheres of atoms. The electrical conducting properties of the nanotubes depend on their structures.

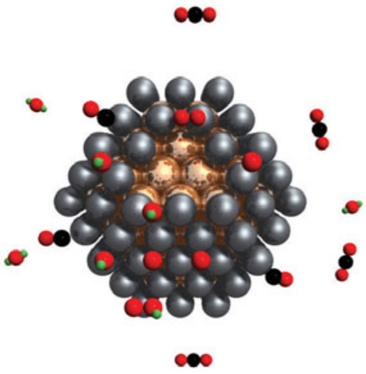

FIGURE 6.45 This catalyst consists of a nanosphere of platinum atoms surrounding a ruthenium core 3 nm in diameter. These nanospheres catalyze the conversion of CO to CO_2 at a lower temperature than is possible with conventional catalysts and can be used to purify hydrogen for use as a fuel.

are aligned along the long axis of the tube, their conductivity is high enough to be considered metallic. In this configuration electrons can travel through the π-orbitals with little resistance. If the points are aligned perpendicular to the long axis, the nanotubes act as semiconductors. Like diamonds, carbon nanotubes are good conductors of heat. Their interesting electrical conductivity and high thermal conductivity make carbon nanotubes good candidates for the development of miniature integrated circuits.

Carbon nanotubes are very strong, and their tensile strength parallel to the axis of the tube is the greatest of any material that has been measured. Because they have a very low density, their strength-to-mass ratio is 40 times that of steel. This may seem surprising at first, because we do not associate graphite with great strength. However, graphite consists of flat sheets, not tubes. If you were to roll a graphene sheet into a tight cylinder, it would form a strong structure, just as a tightly rolled sheet of paper can support a weight.

At least 50 different types of nanotubes and nanospheres have been synthesized from substances other than carbon. For example, MoS_2 and WS_2 nanotubes and nanospheres serve as solid lubricants, TiO_2 nanotubes show promise as a means of storing hydrogen gas, and nanospheres of ruthenium coated with platinum serve as a catalyst for the purification of hydrogen fuel (Fig. 6.45). Nanotubes formed from boron nitride are also of great interest. Unlike carbon nanotubes, boron nitride nanotubes have electrical characteristics that do not depend on the diameter of the tube or the way the sheets are rolled. They have a moderately large band gap, and so they are considered to be only weakly semiconducting. Carbon nanotubes grow until they are capped by bonds to another element or by five-membered rings. The five-membered rings pucker the structure, forming bends along the length of tubes and domes at their ends. In the case of BN nanotubes, however, five-membered rings cannot form, because they would require boron–boron or nitrogen–nitrogen bonds, which would be too weak to maintain the structure. Instead, BN nanotubes are capped by the atom of a metal such as tungsten.

The rigidity of nanotubes may also allow them to be used as minute molds or templates for nanostructures of other elements. For example, they can be filled with molten lead to create lead wires one atom in diameter. They can also serve as tiny "test tubes" that hold individual molecules in place. Nanotubes that are filled with biomolecules such as cytochrome *c* hold the promise of acting as nanosensors for medical applications.

The very large surface area provided by the highly porous nanotubes means that atoms of gases are readily adsorbed on the inner surfaces of the tubes. Nanotubes carrying hydrogen molecules could therefore become a high-energy-density storage medium for hydrogen-powered vehicles (see Box 13.1). Such a material would solve a major obstacle to the use of hydrogen fuel cells—the problem of a safe, compact storage medium for hydrogen. Hydrogen absorbed into nanotubes can be stored in a volume much smaller than that required to store the gas.

Nanotubes are tiny cylinders only a few nanometers in diameter that are constructed of rolled sheets of a graphite-like array of atoms. Carbon and boron nitride are the most extensively studied nanotubes.

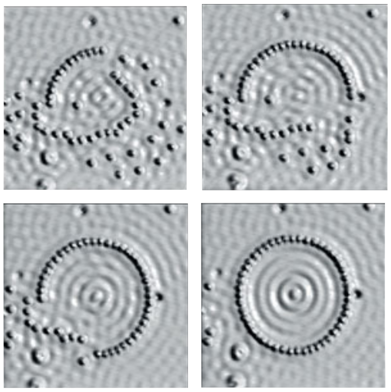

FIGURE 6.46 The images show four stages in the construction of a ring of iron atoms on a copper substrate. The scientists used "top-down" techniques to place 48 iron atoms into a ring. The circular waves seen in the final image show the density of the surface electrons inside the ring, which acts as a "corral" for the electrons.

6.20 Preparation of Nanomaterials

Nanomaterials can be manufactured by one of two groups of methods. In "top-down" approaches, nanoscale materials are carved into shape by the use of physical nanotechnology methods such as lithography (Fig. 6.46). In "bottom-up" approaches, molecules are encouraged to assemble themselves into desired patterns by making use of specific intermolecular interactions (Fig. 6.47). In solution-based bottom-up methods, tiny crystals are formed in solution and prevented from growing larger by the addition of stabilizers in the form of surfactant molecules. In **vapor-phase synthesis** a substance is vaporized and then condensed or mixed with a reactant and the product condensed to form the desired tiny crystals. In both methods one-molecule-thick layers of different materials in which the molecules are oriented in a particular direction can be formed, giving the nanomaterial interesting electrical and optical properties.

One type of bottom-up approach used for creating very regular arrays of nanotubes is **template synthesis.** In this approach, porous membranes of polymers such as polycarbonates or ceramics such as alumina are prepared, then placed into a solution

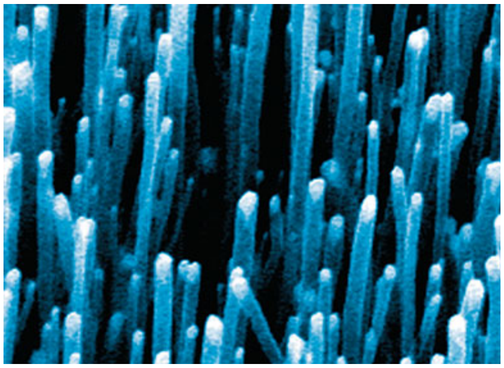

FIGURE 6.47 A "forest" of carbon nanotubes that grew in vertical alignment in a "bottom-up" fashion.

of a salt. The metal cation of the salt is reduced electrochemically and the metal plates onto the insides of the pores in the membranes. The membrane in then removed or dissolved away, leaving the nanotubes.

Thinking point: The physicist Richard Feynman is credited with foreseeing the nanotechnology revolution in a talk called "There is plenty of room at the bottom." What did he mean?

EXAMPLE 6.1 Investigating quantum dots

A team of chemists wants to make a series of quantum dot suspensions by forming colloidal suspensions of nanospheres. (a) Of the following, which compounds would not be suitable for the formation of quantum dots by this method: CdS, ZnSe, CaO, CaS, K_2S? Explain your answer. (b) Describe how you could prepare a quantum dot sample that emits white light. (c) The chemists prepare a CdSe quantum dot sample by mixing 5.0 mL of 0.0020 M $Cd(NO_3)_3$(aq) with 5.0 mL of 0.0020 M Na_2Se(aq) in the presence of a polymer that coils into pockets that serve as templates for the spheres. Each quantum dot contains an average of 155 formula units of CdSe. What is the concentration of the quantum dots in the final suspension? (d) What is the average molar mass of the quantum dot? (e) The suspension fluoresces at 528 nm. What color is the sample and what is the diameter of the quantum dots it contains?

PLAN (a) Find the solubilities of the compounds in Table I.1 in the *Fundamentals* section, because only compounds that are insoluble in water will be suitable (soluble compounds will simply dissolve). (b) Consider the nature of white light (a mixture of different wavelengths) and how to produce it. (c) Calculate the amount (in moles) of CdSe formed, then the molar concentration of CdSe in the solution; divide that value by the average number of CdSe formula units in a quantum dot. (d) Find the molar mass from the number of formula units per particle. (e) Find the color of the light in Table 1.1, convert wavelength to frequency, and use Eq. 2 to determine the diameter (twice the radius) of the particle.

What should we assume? That the transition responsible for the color occurs between the lowest two energy levels of an electron in a spherical cavity.

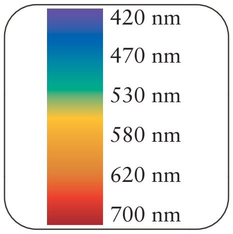
SOLVE

(a) According to Table I.1, CdS, ZnSe (noting that selenides resemble sulfides), and CaS are insoluble, but CaO and K_2S are soluble (and react with water).

CaO and K_2S would not be suitable.

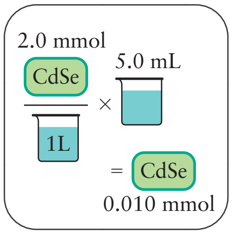
(b) White light contains many different wavelengths of visible light.

Prepare a series of samples, each of which emits a different wavelength when excited, and mix them together.



(c) From the knowledge that each mole of Cd^{2+} reacts with 1 mol of Se^{2-}, from $n = c \times V$, and converting milliliters to liters,

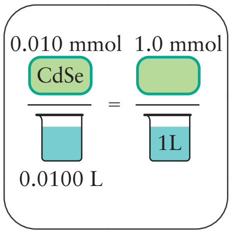
$$n(\text{CdSe}) = \frac{0.0020 \text{ mol CdSe}}{1 \text{ L}} \times (5.0 \times 10^{-3} \text{ L})$$
$$= 1.0 \times 10^{-5} \text{ mol CdSe}$$



From $c = n/V$, and using the total volume of the two solutions that were added together,

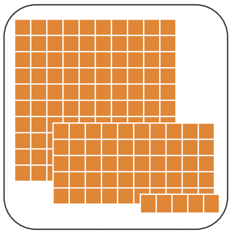
$$V_{\text{total}} = 0.0050 \text{ L} + 0.0050 \text{ L} = 0.0100 \text{ L}$$

$$c(\text{CdSe}) = \frac{1.0 \times 10^{-5} \text{ mol}}{0.0100 \text{ L}} = 0.0010 \text{ mol·L}^{-1}$$



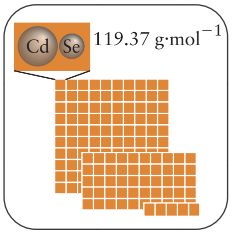
From c/(number of formula units per quantum dot),

$$c(\text{quantum dots}) = \frac{0.0010 \text{ mol·L}^{-1}}{155} = 6.5 \times 10^{-6} \text{ mol·L}^{-1}$$



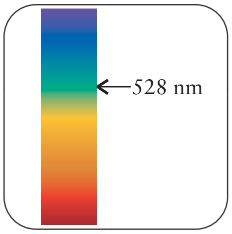
(d) From M(CdSe) × (number of formula units per quantum dot),

$M(\text{CdSe}) = 112.41 \text{ g·mol}^{-1} + 78.96 \text{ g·mol}^{-1} = 191.37 \text{ g·mol}^{-1}$
$M(\text{quantum dot}) = 191.37 \text{ g·mol}^{-1} \times 155 = 2.97 \times 10^{4} \text{ g·mol}^{-1}$
or 29.7 kg·mol^{-1}



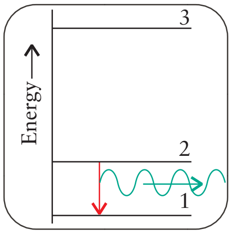
(e) By referring to Table 1.1 we can identify the color of 528-nm radiation:

528-nm radiation is green light



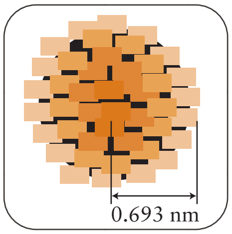
From Eq. 2 ($E_n = n^2h^2/8m_er^2$), the energy separation of the two lowest levels ($n = 2$ and $n = 1$) is

$$\Delta E = \frac{4h^2}{8m_er^2} - \frac{h^2}{8m_er^2} = \frac{3h^2}{8m_er^2}$$



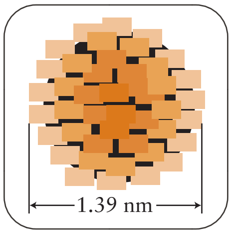
From $\Delta E = h\nu = hc/\lambda$, the wavelength and radius are related by

$$r = \left(\frac{3h\lambda}{8m_ec}\right)^{1/2}$$
$$= \left(\frac{3 \times (6.626 \times 10^{-34} \text{ J·s}) \times (528 \times 10^{-9} \text{ m})}{8 \times (9.109 \times 10^{-31} \text{ kg}) \times (2.998 \times 10^{8} \text{ m·s}^{-1})}\right)^{1/2}$$
$$= 6.93 \times 10^{-10} \text{ m}$$



The diameter ($d = 2r$) of the quantum dot is therefore

$$d = 2 \times 6.93 \times 10^{-10}\,\text{m} = 1.39 \times 10^{-9}\,\text{m, or } 1.39\,\text{nm}$$



Self-Test 6.16A A CdS quantum dot sample is prepared by mixing 5.0 mL of 0.0016 M $Cd(NO_3)_3(aq)$ with 5.0 mL of 0.0016 M $Na_2S(aq)$ Each quantum dot contains an average of 151 formula units of CdS. (a) What is the concentration of the quantum dots in the final suspension? (b) What is the average molar mass of the quantum dot? (c) The suspension fluoresces at 499 nm. What color is the sample and what is the diameter of the quantum dots it contains?

[***Answer:*** (a) $5.3 \times 10^{-6}\,\text{mol·L}^{-1}$; (b) $21.81\,\text{kg·mol}^{-1}$; (c) blue-green, 1.35 nm]

Self-Test 6.16B A PbSe quantum dot sample is prepared by mixing 6.0 mL of 0.0012 M $Pb(NO_3)_3(aq)$ with 6.0 mL of 0.0012 M $K_2Se(aq)$ Each quantum dot contains an average of 165 formula units of PbSe. (a) What is the concentration of the quantum dots in the final suspension? (b) What is the average molar mass of the quantum dot? (c) The suspension fluoresces at 601 nm. What color is the sample and what is the diameter of the quantum dots it contains?

Nanomaterials are particles between 1 and 100 nm in diameter. They have properties that differ from the properties of atoms and from those of bulk materials and are used to create miniature circuits and drug delivery systems.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Distinguish the main types of alloys and explain how their properties differ from those of pure metals (Sections 6.2 and 6.4).

❑ 2 Describe the operation of a blast furnace and how steel is made by the basic oxygen process (Section 6.3).

❑ 3 Explain why calcium carbonate is the basis of so many structural materials (Section 6.6).

❑ 4 Distinguish the principal silicate structures and describe their properties (Section 6.7).

❑ 5 Describe the nature and properties of glasses and ceramics (Sections 6.10 and 6.11).

❑ 6 Use molecular orbital theory to account for the differences between metals, insulators, and semiconductors (Sections 6.12 and 6.13).

❑ 7 Explain the properties of luminescent materials (Section 6.15).

❑ 9 Distinguish the principal types of magnetism (Section 6.16).

❑ 10 Describe the nature of nanomaterials and how they differ from other materials (Sections 6.18 and 6.19).

❑ 11 Describe the primary routes for the preparation of nanomaterials (Section 6.20).

EXERCISES

Metallic Materials

6.1 The gold color of a certain brass is due to the absorption of light in the violet region of the spectrum, at wavelengths of 445 nm. To what energy separation (in joules) does that wavelength correspond?

6.2 The pink color of a certain bronze is due to the absorption of light in the blue-violet region of the spectrum, at wavelengths of 465 nm. To what energy separation (in joules) does that wavelength correspond?

6.3 Estimate the relative density (compared to pure aluminum) of magnalium, a magnesium–aluminum alloy in which 30.0% of the aluminum atoms have been replaced by magnesium atoms without distortion of the crystal structure.

6.4 Estimate the relative density (compared to pure copper) of coinage cupronickel, an alloy in which 25.0% of the copper atoms have been replaced by nickel atoms without distortion of the crystal structure.

6.5 How is the impurity present in pig iron removed to create high-quality steel?

6.6 What metal is generally added to steel to make it corrosion resistant?

6.7 How do alloys differ from the pure metals from which they are made?

6.8 What is the difference between homogeneous and heterogeneous alloys?

6.9 When iron surfaces are exposed to ammonia at high temperatures, "nitriding"—the incorporation of nitrogen into the iron lattice—occurs. The atomic radius of iron is 124 pm. (a) Is the alloy interstitial or substitutional? Justify your answer. (b) How do you expect nitriding to change the properties of iron?

6.10 Silicon can be doped with small amounts of phosphorus to create a semiconductor used in transistors. (a) Is the alloy interstitial or substitutional? Justify your answer. (b) How do you expect the properties of the doped material to differ from those of pure silicon?

6.11 Calculate the relative number of atoms of each element contained in each of the following alloys: (a) coinage cupronickel, which is 25% Ni by mass in copper; (b) a type of pewter that is about 7% antimony and 3% copper by mass in tin.

6.12 Calculate the relative number of atoms of each element contained in each of the following alloys: (a) Wood's metal, which is a low-melting-point alloy used to trigger automatic sprinkler systems and is 12.5% tin, 12.5% cadmium, and 24% lead by mass in bismuth; (b) a steel that is 1.75% by mass carbon in iron.

Hard Matter

6.13 Compare the hybridization and structure of carbon in diamond and graphite. How do these features explain the physical properties of the two allotropes?

6.14 Ordinary "hexagonal" graphite has a structure that repeats the ABAB . . . alternation of layers; "rhombohedral graphite" has the repetition ABCABC . . . , with the C layer displaced from the other two. Sketch a structure for rhombohedral graphite.

6.15 One-atom-thin sheets of graphene were first prepared in the laboratory of Andre Geim at the University of Manchester. The scientists picked up flecks of graphite with adhesive tape and then pulled the layers apart with another piece of tape until one layer remained. Suppose you repeated this process with a piece of tape 2.0 cm wide until one layer remained that completely covered 1.0 cm of the tape. Estimate (a) the number of carbon atoms that remain on the tape and (b) the amount in moles.

6.16 A ten-atom-thin layer of graphene was deposited on a circular silicon wafer 1 cm in diameter. Estimate (a) the number of carbon atoms deposited and (b) the amount in moles.

6.17 When the mineral dolomite, $CaCO_3{\cdot}MgCO_3$, is heated, it gives off carbon dioxide and forms a mixture of a metal oxide and a metal carbonate. Which oxide is formed, CaO or MgO? Which carbonate remains, $CaCO_3$ or $MgCO_3$? Justify your answer.

6.18 (a) Calculate the heat released when 25 kg of quicklime, the amount needed to produce 500. kg of iron, reacts with water to produce slaked lime. (b) Describe a chemical process that could be used to reconvert the slaked lime into quicklime.

6.19 A very pure crystalline form of silicon carbide called moissanite has attracted interest because it is as bright as diamond, is nearly as hard, and has similar thermal conductivity. The structure of moissanite is hexagonal close-packed, with alternating C and Si atoms. (a) Draw one unit cell of moissanite (see Fig. 5.28). (b) Despite the fact that silicon atoms are heavier than carbon atoms, moissanite has a density of $3.2\ g{\cdot}cm^{-3}$, which is less than the density of diamond ($3.5\ g{\cdot}cm^{-3}$). Account for the difference in densities of the two substances.

6.20 In Fig. 6.20 we see that the planes in hexagonal boron nitride take positions in which the B atoms are located directly over N atoms, whereas in graphite (Fig. 6.9), the carbon atoms are offset. Explain this difference in structure between the two substances.

6.21 A unit cell for the calcite structure can be found on the Web site for this book. From this structure, determine (a) the crystal system and (b) the number of formula units present in the unit cell.

6.22 Using the Web site for this book, examine the unit cells of calcite and dolomite. (a) How are these two structures the same? (b) What makes them different? (c) Where are the magnesium and calcium ions located in dolomite?

6.23 Iron pyrite (FeS_2) is known as Fool's Gold because of its resemblance to gold metal. However, it can easily be distinguished from gold by the difference in their densities. The density of gold is $19.28\ g{\cdot}cm^3$ and that of Fool's Gold is $5.01\ g{\cdot}cm^3$. What volume of Fool's Gold would have the same mass as a $4.0\ cm^3$ piece of gold?

6.24 Mica with a density of $1.5\ g{\cdot}cm^3$ can be expanded into vermiculite, which is used as a low-density soil amendment. The vermiculite used in soils has an average density of $0.10\ g{\cdot}cm^3$. Estimate the volume of the vermiculite obtained by expanding $12.0\ cm^3$ of mica.

6.25 Write a Lewis structure for the orthosilicate anion, SiO_4^{4-}, and deduce the formal charges and oxidation numbers of the atoms. Use the VSEPR model to predict the shape of the ion.

6.26 Use the VSEPR model to estimate the Si—O—Si bond angle in silica.

6.27 Describe the structures of a silicate in which the silicate tetrahedra share (a) one O atom; (b) two O atoms.

6.28 What is the empirical formula of a potassium silicate in which the silicate tetrahedra share (a) two O atoms and form a chain or (b) three O atoms and form a sheet? In each case, there are single negative charges on the unshared O atoms.

6.29 What is the oxidation number of silicon in the anion formed when glass is etched by HF?

6.30 In a typical procedure for etching glass, the glass surface is covered by a mask (a protective coating). The mask is then removed from the areas that are to be etched and a paste made of fluorite and sulfuric acid is placed on the surface. From standard reference sources, determine the chemical formula of fluorite and describe the chemical reactions that take place to achieve the etching.

6.31 What mass of clay, $Al_2Si_2O_5(OH)_4$, can be produced by the weathering of 2.0 kg of feldspar, $KAlSi_3O_8$?

6.32 What mass of carbon is required for complete conversion of 3.0 kg of SiO_2 to SiC?

6.33 Why is it unwise to store metal fluorides in glass bottles?

6.34 Solutions of strong bases stored in glass bottles react slowly with their containers. Write the balanced chemical equations for four possible reactions between OH^- and SiO_2.

6.35 Why is it desirable to remove iron from ceramic clays?

6.36 Draw a simple chemical picture to show how the removal of water helps to make aluminosilicates into rigid ceramics.

6.37 What is the oxidation number of (a) phosphorus in $Li_7P_3S_{11}$, which forms in some ceramic electrolytes; (b) titanium in $BaTiO_3$?

6.38 Assuming that the oxidation number of aluminum is +3 in both compounds, what is the oxidation number of silicon in (a) clay, $Al_2Si_2O_5(OH)_4$; (b) mica, $KMg_3(Si_3AlO_{10})(OH)_2$?

Materials for New Technologies

6.39 How does the change in conductivity of a semiconductor differ from that of a metal as temperature is increased?

6.40 Normally, in conducting materials, we think of current as being carried by electrons as they move through a solid. In semiconductors, it is also common to talk about the current being carried by the "holes" in the valence band. (a) Explain how holes move through a solid material. (b) If, in a p-type semiconductor device, electric current is moving from left to right, in which direction will the holes be moving?

6.41 What is the resistance of an aluminum wire of length 2.0 m, cross-sectional area 0.12 mm^2? The conductivity of aluminum at room temperature is 60.7 $MS \cdot m^{-1}$.

6.42 What is the resistance of a sheet of semiconductor of thickness 0.10 mm, cross-sectional area 1.0 cm^2? The conductivity of the semiconductor at room temperature is 0.2 $mS \cdot m^{-1}$.

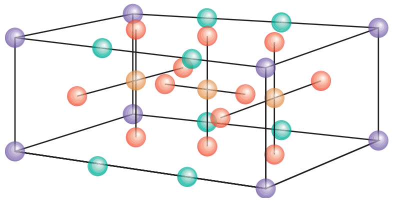
6.43 Estimate the value of n for the uppermost filled level in a one-dimensional line of silver atoms of length 1.0 mm. *Hint*: Take the radius of an Ag atom as 144 pm.

6.44 Estimate the value of n for the uppermost filled level in a one-dimensional line of copper atoms of length 1.0 mm. *Hint*: Take the radius of a Cu atom as 128 pm.

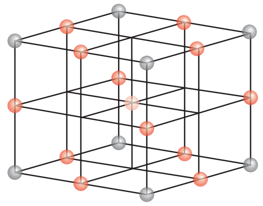
6.45 Germanium is a semiconductor. If small amounts of the elements In, P, Sb, and Ga are present as impurities, which of them will make germanium into (a) a p-type semiconductor; (b) an n-type semiconductor?

6.46 Gallium arsenide is a semiconducting material. If we wish to modify the sample by replacing a small amount of the arsenic with an element to produce an n-type semiconductor, which element would we choose: selenium, phosphorus, or silicon? Why?

6.47 The unit cell of a high-temperature superconductor is shown here. What is its formula?



6.48 The unit cell of the mineral perovskite, which has a structure similar to that of some of the ceramic superconductors, is shown here. What is its formula?



6.49 Distinguish between fluorescence and phosphorescence.

6.50 Describe how triboluminescence and fluorescence are produced.

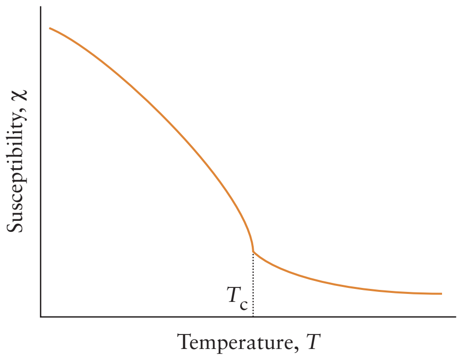
6.51 What is the main advantage of using a fluorescent dye to trace the function of biomolecules in a living cell?

6.52 In fluorescence, how does the energy of the emitted radiation compare with the energy of the exciting radiation?

6.53 Identify the elements in the d-block that are paramagnetic.

6.54 Identify the elements in the d-block that are ferromagnetic.

6.55 The *magnetic susceptibility*, χ (chi), is an indication of the number of unpaired electrons in a compound; it varies with temperature, T. A graph of magnetic susceptibility as a function of temperature for a typical ferromagnetic material is shown here. The temperature labeled T_C is known as the *Curie temperature*. On one side of the Curie temperature, the compound is a simple paramagnetic material and, on the other side, the substance is ferromagnetic. From the graph, determine whether this compound is ferromagnetic above or below the Curie temperature. Explain your reasoning.



6.56 Describe the differences between diamagnetism, paramagnetism, ferromagnetism, and antiferromagnetism.

Nanomaterials

6.57 Distinguish between the "top down" and "bottom up" approaches to manufacturing nanomaterials.

6.58 Describe the structure of a nanowire and how it conducts electricity.

6.59 A quantum dot suspension fluoresces at 580.8 nm. What color is the sample and what is the diameter of the quantum dots it contains?

6.60 A quantum dot suspension fluoresces at 490.1 nm. What color is the sample and what is the diameter of the quantum dots it contains?

6.61 The uncertainty principle is negligible for macroscopic objects. However, the properties of nanoparticles may be different from those of larger particles as a result of quantum mechanical phenomena. Calculate the minimum uncertainty in the speed of an electron confined in a nanoparticle of diameter 200. nm and compare that uncertainty with the uncertainty in speed of an electron confined to a wire of length 1.00 mm.

6.62 (a) Calculate the minimum uncertainty in the speed of a Li^+ ion confined in a nanoparticle that has a diameter of 200. nm and is composed of a lithium compound through which the lithium ions can move at elevated temperatures. (b) Which could be measured more accurately in a nanoparticle, the speed of an electron (see Exercise 6.61) or the speed of a Li^+ ion?

6.63 An electron trapped within a nanoparticle can be approximated as a particle of mass m_e confined to a cubic box of side L. The energy levels of the electron are

$$E = \frac{h^2}{8m_e L^2}\left(n_x^2 + n_y^2 + n_z^2\right)$$

(a) Write expressions for the energies of the three lowest levels. Which of these levels are degenerate? For those levels that are degenerate, give the quantum numbers corresponding to each degenerate level.

6.64 Buckminsterfullerene is form of carbon having nearly spherical molecules that are composed of 60 carbon atoms (see Section 15.12). The interior of a C_{60} molecule is about 0.7 nm in diameter and is being considered as a container for various atoms and molecules. Suppose that buckminsterfullerene were used to transport molecular hydrogen. It can be approximated as a cube with a side of 0.7 nm. Approximating the hydrogen molecule as a point mass, how much energy does a hydrogen molecule inside a C_{60} molecule need to be excited from the lowest energy level to (a) the second energy level; (b) the third energy level? (See Exercise 6.63.)

Integrated Exercises

6.65 Solid silicon carbide reacts with molten sodium hydroxide and oxygen gas at high temperatures to form solid Na_2SiO_3, gaseous water, and carbon dioxide. Write a balanced equation for the reaction.

6.66 Aluminum carbide is considered a covalent carbide. However, it reacts with water as ionic carbides do, to produce solid aluminum hydroxide and methane gas, CH_4. Write a balanced equation for the reaction.

6.67 What is the total mass of (a) the electrons; (b) the protons in a block of the ceramic ZrO_2 of mass 15.0 kg?

6.68 What is the total mass of (a) the electrons; (b) the protons in a block of the ceramic $BaTiO_3$ of mass 12.0 kg?

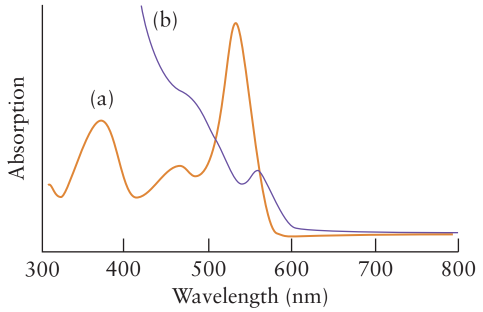
6.69 Zinc oxide is a semiconductor. Its conductivity increases when it is heated in a vacuum but decreases when it is heated in oxygen. Account for these observations.

6.70 The surface of glass contains many —OH groups that are bonded to the silicon atoms of SiO_2, which is the major component of glass. If the glass is treated with $Si(CH_3)_3Cl$ (chlorotrimethylsilane), a reaction takes place to eliminate HCl and attach the Si atom to the oxygen atom:

$$\text{(surface of glass)—OH} + Si(CH_3)_3Cl \longrightarrow \text{(surface of glass)—OSi}(CH_3)_3 + HCl$$

How will this rearrangement affect the interaction of liquids with the glass surface?

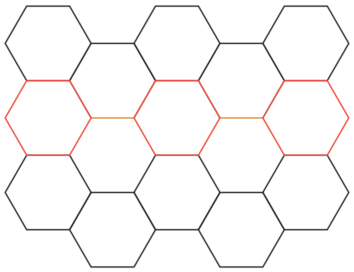
6.71 Below are two *absorption* plots. One was obtained from a solution of an organic dye and the other from a quantum dot suspension. Which plot was obtained from which solution? Explain your reasoning.



6.72 Light-emitting diodes (LEDs) contain p–n junctions. The circuit in an LED is arranged so that electrons from the power source flow into the conduction band of the n-type side. As electrons continue to flow, they are pushed to the conduction band of the p-type side, which can hold more electrons. These electrons enter the conduction band of the p-type side, because they already occupy the higher-energy band in the n-type side. However, once the electrons are in the higher-energy band of the p-type side, they fall into the lower-energy band unless it is full. As these electrons make transitions to the lower-energy band, energy is released in the form of light. (a) Explain, in terms of the movement of electrons, why an LED cannot be made from the junction of pure silicon and silicon doped with phosphorus. (b) If the direction of the circuit in the LED is reversed, so that the electrons flow from the power source into the p-type side of the p–n junction directly, where would the electrons go once they enter the p–n junction? (That is, indicate which bands would receive the electrons and whether the electrons would then migrate to other bands.)
(c) Would you expect the LED to emit light when it is placed in the reverse circuit described in part (b)? Explain your answer.

Chemistry Connections

6.73 The tiny structures such as spheres and tubes formed by carbon atoms are the basis for a large part of the field of nanotechnology. Boron nitride forms similar structures.
(a) What is the hybridization of carbon atoms in carbon nanotubes and of boron and nitrogen atoms in boron nitride nanotubes?
(b) A simple carbon nanotube is made up of a sheet resembling a layer of graphite (similar to chicken wire) that has been curled up and bonded to itself. How many hexagons must be strung together (the hexagons denoted by the colored bonds in the following diagram) around the circumference of a nanotube to form a tube that is approximately 1.3 nm in diameter? The diagram shows the orientation of hexagons with respect to the curvature of the nanotube. The C—C bond distance in carbon nanotubes is 142 pm.



(c) Buckminsterfullerene, C_{60}, can be hydrogenated, but, to date, a compound with the formula $C_{60}H_{60}$ has not been prepared. The most hydrogenated form of C_{60} known is $C_{60}H_{36}$. Suggest an explanation for why the hydrogenation stops at this point. See Section 15.12.
(d) Boron nitride can form nanotubes, but does not form spheres that resemble buckminsterfullerene. Suggest a reason why BN cannot form spheres.
(e) In its cubic crystalline form the nitrogen atoms of BN form a face-centered cubic unit cell in which half the tetrahedral interstitial sites are occupied by B atoms (if all B and N atoms were replaced by C atoms, the diamond structure would result). Calculate the density of cubic BN if the edge length of the unit cell is 361.5 pm.
(f) The density of hexagonal BN is 2.29 $g{\cdot}cm^{-3}$. Which form of BN is favored at high pressures, hexagonal or cubic?

7.21 The Variation of Reaction Enthalpy with Temperature

What Are the Key Ideas? Heat and work are equivalent ways of transferring energy between a system and its surroundings. The total energy of an isolated system is constant. The enthalpy change for a process is equal to the heat released at constant pressure.

Why Do We Need to Know This Material? The laws of thermodynamics govern chemistry and life. They explain why reactions take place and let us predict how much heat reactions release and how much work they can do. Thermodynamics plays a role in every part of our lives. For example, the energy released as heat can be used to compare fuels, and the energy resources of food are used to assess its nutritional value. The material in this chapter provides a foundation for the following chapters, in particular Chapter 8, which deals with the driving force of chemical reactions.

What Do We Need to Know Already? This chapter assumes that we are familiar with the concept of energy (Section A), stoichiometry (Sections L and M), and the ideal gas law (Chapter 4). Some of the explanations refer to intermolecular forces (Sections 4.12 and 5.1–5.6). Ionic bonding (Sections 2.3–2.4) and bond strengths (Sections 2.14–2.15) are developed further in this chapter.

Energy is the basis of civilization. Every day we use energy in its various forms to maintain life, to stay sufficiently cool or warm, to move about, and to think. All these processes involve the release, absorption, transfer, or conversion of energy. A huge global effort is currently under way to find new sources of energy, to use what energy is available more efficiently, and to conserve its use. Access to energy is one of the major problems facing humanity, for so much depends on it.

Thinking point: Can you identify any human activity that does not make use of energy?

The study of the transformations of energy from one form into another is called **thermodynamics.** The *first law of thermodynamics*, which is introduced in this chapter, is concerned with keeping track of energy changes. It allows us to calculate, for instance, how much heat a reaction can produce. The *second law of thermodynamics*, which is the subject of Chapter 8, explains why some chemical reactions take place but others do not. Both laws are summaries of experience with bulk matter and are independent of any model that we might have of its microscopic structure—you could do thermodynamics even if you had never heard of atoms! However, we can use the models of atoms and molecules we have been developing to elucidate these laws and enrich our understanding of them. The link between the properties of atoms and those of bulk matter is **statistical thermodynamics,** the interpretation of the laws of thermodynamics in terms of the *average* behavior of the large numbers of atoms and molecules that make up a typical sample.

SYSTEMS, STATES, AND ENERGY

Two of the fundamental concepts of thermodynamics are *heat* and *work*. People once thought that heat was a material fluid called *caloric*, which flowed from a hot substance to a cooler one. The French engineer Sadi Carnot (Fig. 7.1), who helped to lay the foundations of thermodynamics, believed that work resulted from the flow of caloric, just as the flow of water does work by turning a water wheel. Some of Carnot's conclusions survive, but we now know that there is no such substance as caloric. About 25 years after Carnot proposed his ideas in the early nineteenth century, the English physicist James Joule (Fig. 7.2) showed that heat and work are simply two ways in which energy can be transferred. In this chapter we first examine work, then heat, and see that in fact heat is not a substance that flows.

FIGURE 7.1 Nicolas Leonard Sadi Carnot (1796–1832).

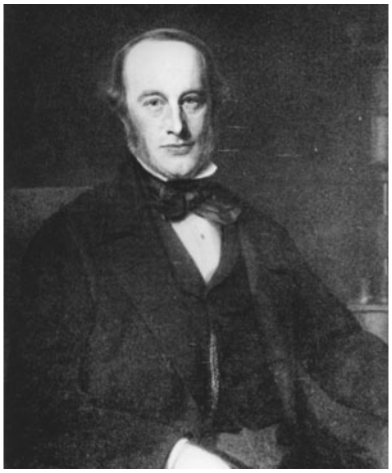

FIGURE 7.2 James Prescott Joule (1818–1889).

7.1 Systems

In thermodynamics we study how energy is transformed from one form into another and transferred from one place to another. For instance, electricity may be generated in a power station but used a great distance away; food may be digested in your stomach but the energy released may be used in your head. To keep track of changes in energy, we divide the world into two parts. The region in which we are interested, such as a flask of gas, a beaker of acid, a reaction mixture, or a muscle fiber, is called a **system** (Fig. 7.3). Everything else, such as the water bath in which a reaction mixture may be immersed, is called the **surroundings.** The surroundings are where we make observations on the energy transferred into or out of the system. The system and the surroundings jointly make up the **universe.** However, often the only part of the universe significantly affected by a process consists of the sample, a flask, and a water bath; in such cases, which include most of the processes in this book, we need to measure changes only in the sample and its immediate surroundings.

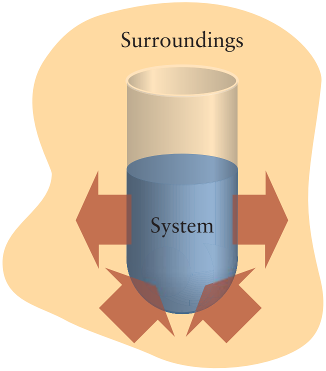

FIGURE 7.3 The system is the sample or reaction mixture in which we are interested. Outside the system are the surroundings. The system plus its surroundings is sometimes called the universe.

A system can be open, closed, or isolated (Fig. 7.4). An **open system** can exchange both matter and energy with the surroundings. Examples of open systems are automobile engines and the human body. A **closed system** has a fixed amount of matter, but it can exchange energy with the surroundings. An example of a closed system is a cold pack used for treating athletic injuries. An **isolated system** has no contact with its surroundings. We can think of an isolated system as sealed inside rigid, thermally insulating walls. A good approximation to an isolated system is a hot liquid inside a sealed vacuum flask.

In thermodynamics, the universe consists of a system and its surroundings. An open system can exchange both matter and energy with the surroundings; a closed system can exchange only energy; an isolated system can exchange nothing.

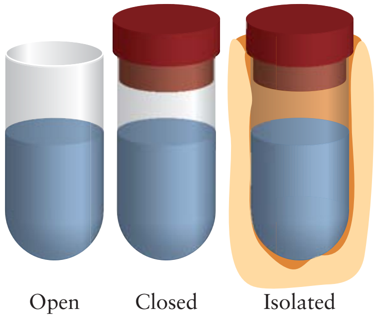

FIGURE 7.4 We can classify any system according to its interactions with its surroundings. An open system can exchange matter and energy with its surroundings. A closed system can exchange energy but not matter. An isolated system can exchange neither matter nor energy.

7.2 Work and Energy

The most fundamental property in thermodynamics—in the sense that it provides a basis for defining the principal concepts—is **work,** the process of achieving motion against an opposing force (Section A). All forms of work can be thought of as equivalent to the work of raising a weight against the pull of gravity. The chemical reaction in a battery does work when it pushes an electric current through a circuit. Gas in a cylinder—such as the hot gas mixture in the cylinder of an automobile engine—does work when it expands and pushes back a piston. We can identify whether a process can do work by noting whether, in principle at least, it can be harnessed to raise a weight in the surroundings. The expansion of a gas, for example, can be used to raise a weight

because the piston can be connected to the weight. An electric current produced by a battery can be used to raise a weight if it is used to power an electric motor.

The work required to move an object a certain distance against an opposing force is calculated by multiplying the opposing force by the distance moved against it:

$$\text{Work} = \text{opposing force} \times \text{distance moved} \tag{1}$$

As pointed out in Section A, the unit in which work is reported is the *joule*, J, with $1\ \text{J} = 1\ \text{kg·m}^2\text{·s}^{-2}$. This unit is consistent with Eq. 1, because force is measured in newtons ($1\ \text{N} = 1\ \text{kg·m·s}^{-2}$), so the units of force × distance are $\text{kg·m·s}^{-2} \times \text{m} = \text{kg·m}^2\text{·s}^{-2}$, or J.

Energy is the capacity of a system to do work (and ultimately, to lift a weight). If a system can do a lot of work, we say that it possesses a lot of energy. A hot compressed gas can do more work than the same gas after it has expanded and cooled, so we say that it possesses more energy initially. A wound spring can do more work than an unwound spring, so we say that it possesses more energy. When a system does work in the surroundings, its capacity to do work is reduced, so we say that its energy has fallen. If we do work on a system, such as by winding a spring, then we increase its capacity to do work and therefore can say that its energy has increased.

In thermodynamics, the total store of energy in a system is called its **internal energy,** U. We cannot measure the absolute value of the internal energy of a system, because that value includes the energies of all the atoms, their electrons, and the components of their nuclei. The best we can do is to measure *changes* in internal energy. For instance, if a system does 15 J of work (and no other changes take place), then it has used up some of its store of energy, and we say that its internal energy has fallen by 15 J and write $\Delta U = -15$ J. Throughout thermodynamics, the symbol ΔX means a difference in a property X:

$$\Delta X = X_{\text{final}} - X_{\text{initial}} \tag{2}$$

A *negative* value of ΔX, as in $\Delta U = -15$ J, signifies that the value of X has decreased.

A note on good practice: Except in the special cases we shall specify, always show the sign of ΔU (and other ΔX) explicitly, even if it is positive. Thus, if the internal energy increases by 15 J during a change, we write $\Delta U = +15$ J, not simply $\Delta U = 15$ J.

When we do work *on* a system (and, once again, there are no other changes taking place), the internal energy of the system is increased. Compressing a gas inside a thermally insulated container increases its internal energy, because the hot compressed gas can do more work than the uncompressed cooler gas when it pushes out again. Winding a spring transfers energy to the spring: when the spring is fully wound, it can do work as it unwinds. Passing an electric current through a system, as we do when we charge a battery, is another way to do work on a system.

We use the symbol w to denote the energy transferred to a system by doing work and, *provided that no other type of transfer of energy is taking place*, write $\Delta U = w$. When energy is transferred *to* a system as work, the internal energy of the system increases and w is positive. When energy *leaves* the system as work, the internal energy of the system decreases and w is negative. For example, if a system does 40 J of work, $w = -40$ J and $\Delta U = -40$ J.

Work is the transfer of energy to a system by a process that is equivalent to raising or lowering a weight. For work done on a system, w is positive, for work done by a system w is negative. The internal energy of a system may be changed by doing work: in the absence of other changes, $\Delta U = w$.

7.3 Expansion Work

A system can do two kinds of work. The first type is **expansion work,** the work arising from a change in the volume of a system. A gas expanding in a cylinder fitted with a piston pushes out against the atmosphere and thus does expansion work. The second type of work is **nonexpansion work,** work that does not involve a change in volume of

TABLE 7.1 Varieties of work

Type of work	w	Comment	Units*
expansion	$-P_{ex}\Delta V$	P_{ex} is the external pressure ΔV is the change in volume	Pa m^3
extension	$f\Delta l$	f is the tension Δl is the change in length	N m
raising a weight	$mg\Delta h$	m is the mass g is the acceleration of free fall Δh is the change in height	kg $m\cdot s^{-2}$ m
electrical	$\phi\Delta q$	ϕ is the electrical potential Δq is the change in charge	V C
surface expansion	$\gamma\Delta A$	γ is the surface tension ΔA is the change in area	$N\cdot m^{-1}$ m^2

*For work in joules (J). Note that 1 N·m = 1 J and 1 V·C = 1 J.

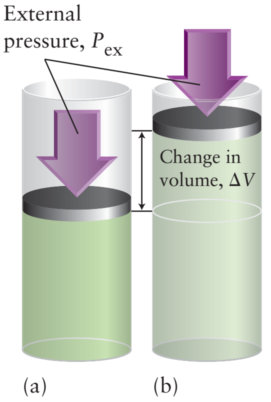

FIGURE 7.5 A system does work when it expands against an external pressure. (a) A gas in a cylinder with a piston held in place. (b) The piston is released and (provided the pressure of the gas is greater than the external pressure, P_{ex}) the gas expands and pushes out against P_{ex}. The work done is proportional to P_{ex} and the change in volume, ΔV, that the system undergoes.

the system. A chemical reaction in a battery can do nonexpansion work by causing an electrical current to flow, and our bodies do nonexpansion work when we move about. Table 7.1 lists some of the kinds of work that a system can do.

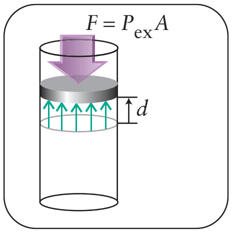
First, we consider expansion work. The simplest example is the work done by a system consisting of a gas in a cylinder. The external pressure acting on the outer face of the piston provides the force opposing expansion. We shall assume initially that the external pressure is constant, as when the piston is pressed on by the atmosphere (Fig. 7.5). We need to find how the work done when the system expands through a volume ΔV is related to the external pressure P_{ex}.

HOW DO WE DO THAT?

We relate pressure to the work of expansion against a constant pressure by using the fact that pressure is the force divided by the area to which it is applied: $P = F/A$ (Section 4.2). Therefore, the force opposing expansion is the product of the pressure acting on the outside of the piston, P_{ex}, and the area of the piston, A ($F = P_{ex}A$). The work needed to drive the piston out through a distance d is therefore

From work = force × distance,

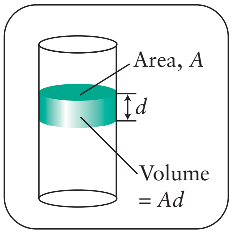
$$\text{Work} = P_{ex}A \times d$$



However, the product of area and distance moved is equal to the change in volume of the sample:

From volume = area × height,

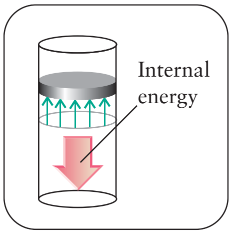
$$A \times d = \Delta V$$



Therefore, the work done by the expanding gas is $P_{ex}\Delta V$. At this point, we match the signs to our convention. When a system expands, it loses energy as work; so, when ΔV is positive (an expansion), w is negative. Therefore,

From the sign convention,

$$w = -P_{ex}\Delta V$$



We have deduced that the work done when a system expands by ΔV against a constant external pressure P_{ex} is

$$w = -P_{ex}\Delta V \qquad (3)^*$$

This expression applies to all systems. A gas is easiest to visualize, but the expression also applies to an expanding liquid or solid. However, Eq. 3 applies *only when the external pressure is constant* during the expansion.

> ***What does this equation tell us?*** The minus sign in Eq. 3 tells us that the internal energy of the system decreases because some energy is lost as work when the system expands. The factor P_{ex} tells us that more work has to be done by the system when the external pressure (which is responsible for the opposing force) is high. The factor ΔV tells us that, for a given external pressure, more work is done when the system expands by a large amount than when it expands only a little.

In SI units, the external pressure is expressed in pascals ($1\ \text{Pa} = 1\ \text{kg}\cdot\text{m}^{-1}\cdot\text{s}^{-2}$, Section 4.2) and the change in volume is expressed in cubic meters (m^3). The product of 1 Pa and 1 m^3 is

$$1\ \text{Pa}\cdot\text{m}^3 = 1\ \text{kg}\cdot\text{m}^{-1}\cdot\text{s}^{-2} \times 1\ \text{m}^3 = 1\ \text{kg}\cdot\text{m}^2\cdot\text{s}^{-2} = 1\ \text{J}$$

Therefore, if we work in pascals and cubic meters, the work is obtained in joules. However, we might have expressed the pressure in atmospheres and the volume in liters. In this case, we may need to convert the answer (in liter-atmospheres) into joules. The conversion factor is obtained by noting that $1\ \text{L} = 10^{-3}\ \text{m}^3$ and $1\ \text{atm} = 101\ 325\ \text{Pa}$ exactly; therefore

$$1\ \text{L}\cdot\text{atm} = 10^{-3}\ \text{m}^3 \times 101\ 325\ \text{Pa} = 101.325\ \text{Pa}\cdot\text{m}^3 = 101.325\ \text{J}\ \text{(exactly)}$$

If the external pressure is zero ($P_{ex} = 0$, a vacuum), it follows from Eq. 3 that $w = 0$: that is, *a system does no expansion work when it expands into a vacuum*, because there is no opposing force. You do no work by pushing if there is nothing to push against. Expansion against zero pressure is called **free expansion.**

EXAMPLE 7.1 Calculating the work done when a gas expands

Suppose a gas expands by 500. mL (0.500 L) against a pressure of 1.20 atm and no heat is exchanged with the surroundings during the expansion. (a) How much work is done in the expansion? (b) What is the change in internal energy of the system?

Anticipate Because work is done by the system, we expect w and therefore ΔU to be negative, signifying that energy has been lost from the system.

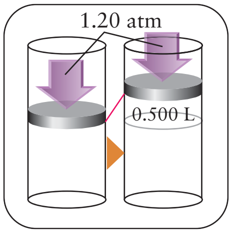
PLAN We use Eq. 3 to calculate the work, and then convert liter-atmospheres into joules.

What should we assume? That the only energy exchanged with the surroundings is the work of expansion.

SOLVE

(a) From $w = -P_{ex}\Delta V$,

$$w = -(1.20 \text{ atm}) \times (0.500 \text{ L}) = -0.600 \text{ L·atm}$$

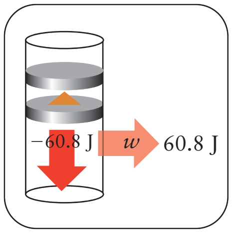


Convert into joules by using 1 L·atm = 101.325 J.

$$w = -(0.600 \text{ L·atm}) \times \frac{101.325 \text{ J}}{1 \text{ L·atm}} = -60.8 \text{ J}$$

(b) Because no energy is transferred as heat, $w = \Delta U$.

$$\Delta U = -60.8 \text{ J}$$



Evaluate The negative sign in $w = -60.8$ J (which we anticipated) means that the internal energy decreases by 60.8 J when the gas expands and the system does 60.8 kJ of work on its surroundings (and there are no other changes).

Self-Test 7.1A Water expands when it freezes. How much work does 100. g of water do when it freezes at 0°C and pushes back the metal wall of a pipe that exerts an opposing pressure of 1070 atm? The densities of water and ice at 0°C are 1.00 g·cm^{-3} and 0.92 g·cm^{-3}, respectively.

[***Answer:*** $w = -0.9$ kJ]

Self-Test 7.1B The gases in the four cylinders of an automobile engine expand from 0.22 L to 2.2 L during one ignition cycle. Assuming that the gear train maintains a steady pressure of 9.60 atm on the gases, how much work can the engine do in one cycle?

To calculate the work done by a gas that expands against a *changing* external pressure, we need to specify exactly how we want the pressure to change during the course of the expansion. In particular, we consider the very important case of "reversible" expansion of an ideal gas. In everyday language, a reversible process is one that can take place in either direction. This common usage is refined in science: in thermodynamics, a **reversible process** is one that can be reversed by an *infinitely small* change in a variable (an "infinitesimal" change). For example, if the external pressure exactly matches the pressure of the gas in the system, then the piston moves in neither direction. If the external pressure is increased infinitesimally, the piston moves in. If, instead, the external pressure is reduced infinitesimally, the piston moves out. Expansion against an external pressure that differs by a finite (measurable) amount from the pressure of the system is an **irreversible process** in the sense that an infinitesimal change in the external pressure does not reverse the direction of travel of the piston. For instance, if the pressure of the system is 2.0 atm at some stage of the expansion and the external pressure is 1.0 atm, then a tiny increase in the latter does not convert expansion into compression. Reversible processes are of the greatest importance in thermodynamics because, as we shall see, the work a system can do is greatest in a reversible process.

Thinking point: How could you ensure that an electric battery produced an electric current reversibly?

The simplest kind of reversible change to consider is the reversible, isothermal (constant temperature) expansion of an ideal gas. We can maintain the same temperature

by ensuring that the system is in thermal contact with a constant-temperature water bath at all stages of the expansion. In an isothermal expansion, the pressure of the gas falls as it expands (by Boyle's law); so, to achieve reversible expansion, the external pressure must be reduced in step with the change in volume so that at every stage the external pressure is the same as the pressure of the gas (Fig. 7.6). To calculate the work, we have to take into account the gradual reduction in external pressure and therefore the changing opposing force.

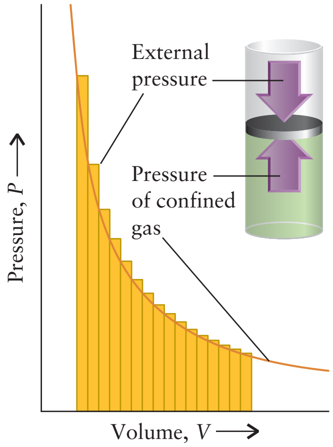


FIGURE 7.6 When a gas expands reversibly, the external pressure is matched to the pressure of the gas at every stage of the expansion. This arrangement (when the steps corresponding to the increase in volume are infinitesimal) achieves maximum work (the area under the curve).

HOW DO WE DO THAT?

To calculate the work of reversible, isothermal expansion of a gas, we have to use calculus, starting at Eq. 3 written for an infinitesimal change in volume, dV:

$$dw = -P_{ex}dV$$

Because the external pressure is matched to the pressure, P, of the gas at every stage of a reversible expansion, we write $P_{ex} = P$ and the expression for dw becomes

$$dw = -PdV$$

At each stage of the expansion, the pressure of the gas is related to its volume by the ideal gas law, $PV = nRT$, so we can replace P by nRT/V:

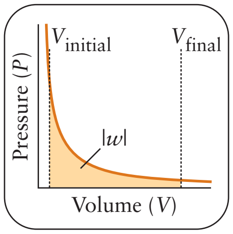
From $dw = -PdV$ and $P = nRT/V$,

$$dw = -\frac{nRT}{V}dV$$

The total work done is the sum (integral) of these infinitesimal contributions as the volume changes from its initial value to its final value. That is, we have to integrate dw from the initial to the final volume with nRT a constant (because the change is isothermal):

From $w = \int dw$, with nRT a constant,

$$w = -nRT\int_{V_{initial}}^{V_{final}}\frac{dV}{V} = -nRT\ln\frac{V_{final}}{V_{initial}}$$



In the final step we used the standard integral

$$\int\frac{dx}{x} = \ln x + \text{constant}$$

and then $\ln x - \ln y = \ln(x/y)$.

We have found that the work of reversible, isothermal expansion of an ideal gas from the volume $V_{initial}$ to the volume V_{final} is

$$w = -nRT\ln\frac{V_{final}}{V_{initial}} \quad (4)^*$$

where n is the amount of gas molecules (in moles) in the container and T is the temperature. One way to visualize Eq. 4 is to realize that, apart from the sign, the work done by the system as it expands is equal to the *area* beneath the ideal gas isotherm lying between the initial and the final volumes (Fig. 7.7).

What does this equation tell us? For a given initial and final volume, more work is done when the temperature is high than when it is low. For a given volume and amount of molecules, a high temperature corresponds to a high gas pressure, and so the expansion takes place against a stronger opposing force and therefore must do more work. More work is also done if the final volume is very much greater than the initial volume.

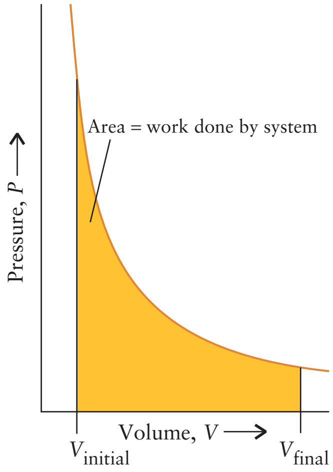


FIGURE 7.7 The work done by a system is equal to the area below the curve of the graph of external pressure as a function of volume. The work done *on* a system is equal to the negative of that area.

If the external pressure were to be increased even infinitesimally at any stage of the expansion, the piston would move in instead of out. Therefore, the work done during a reversible expansion of a gas is the maximum expansion work possible.

Thinking point: How could you achieve maximum work from an electric battery?

EXAMPLE 7.2 Calculating the work of isothermal expansion

A piston confines 0.100 mol Ar(g) in a volume of 1.00 L at 25°C. Two experiments are performed. (a) The gas is allowed to expand through an additional 1.00 L against a constant pressure of 1.00 atm. (b) The gas is allowed to expand reversibly and isothermally to the same final volume. Which process does more work?

Anticipate Provided the initial and final states are the same, a change carried out reversibly always does more work than a change carried out irreversibly, so we should expect the second path to produce more work and therefore correspond to a more negative w (because more energy is lost from the system).

PLAN For expansion against constant external pressure we use Eq. 3 and for reversible, isothermal expansion we use Eq. 4.

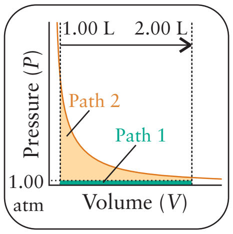
What should we assume? That the gas is ideal.

SOLVE

(a) Irreversible path: From Eq. 3, $w = -P_{ex}\Delta V$, and then converting to joules,

$$w = -(1.00\text{ atm}) \times (1.00\text{ L})$$

$$= -1.00 \times 1.00\text{ L·atm} \times \frac{101.325\text{ J}}{1\text{ L·atm}} = -101\text{ J}$$



(b) Reversible path: From Eq, 4, $w = -nRT \ln (V_{final}/V_{initial})$,

$$w = -(0.100\text{ mol}) \times (8.3145\text{ J·K}^{-1}\text{·mol}^{-1}) \times (298\text{ K}) \times \ln\frac{2.00\text{ L}}{1.00\text{ L}}$$

$$= -172\text{ J}$$

Evaluate We see that the gas does more work in the reversible process, as we expected.

Self-Test 7.2A A cylinder of volume 2.00 L contains 0.100 mol He(g) at 30°C. Which process does more work on the system, compressing the gas isothermally to 1.00 L with a constant external pressure of 5.00 atm or compressing it reversibly and isothermally to the same final volume?

[***Answer:*** Reversible compression]

Self-Test 7.2B A cylinder of volume 2.00 L contains 1.00 mol He(g) at 30°C. Which process does more work on the surroundings, allowing the gas to expand isothermally to 4.00 L against a constant external pressure of 1.00 atm or allowing it to expand reversibly and isothermally to the same final volume?

The change in internal energy is the same regardless of the path taken between the same initial and final states. However, in an irreversible process some of the potential of the system to do work is wasted because the opposing pressure is less than the maximum possible at each stage of the expansion.

The work done by any system on its surroundings during expansion against a constant pressure is calculated from Eq. 3; for a reversible, isothermal expansion of an ideal gas, the work is calculated from Eq. 4. A reversible process is a process that can be reversed by an infinitesimal change in a variable.

7.4 Heat

The internal energy of a system, its capacity to do work, can also be changed by transferring energy to or from the surroundings as heat. *Heat* is a familiar term, but in thermodynamics it has a special meaning. In thermodynamics, **heat** is the energy transferred as a result of a temperature difference. Energy flows as heat from a high-temperature region to a low-temperature region. Therefore, provided that the walls of the system are not thermally insulating, if the system is cooler than its surroundings, energy flows into the system from the surroundings.

In the introduction to this chapter we remarked that heat is not a substance and that heat does not flow. What, then, is heat and what is it that is transferred during heating? As described in Section A, what is often called the "thermal energy" of a system is the sum of the potential and kinetic energies arising from the chaotic thermal motion of atoms, ions, and molecules. Molecules in a high temperature region move more vigorously than molecules in a lower temperature region. When the two regions are brought into contact, the energetic molecules in the higher temperature region stimulate the motion of the molecules in the lower temperature regions. As a result, the internal energy of the cooler system increases as that of the hotter system decreases. The "flowing" of energy due to a temperature difference is simply the transfer of the energy of thermal motion, the energy associated with the random motion of molecules.

Recall from Section 4.10 that the temperature of a gas is proportional to the mean square speed of its molecules.

A note on good practice. Be careful not to confuse the terms *heat* and *thermal energy*. Heat is energy in transition as a result of a temperature difference. Thermal energy, or better the *energy of thermal motion*, is the energy associated with the chaotic motion of molecules at temperatures above absolute zero.

We write the energy transferred *to* a system as heat as q. Therefore, when the internal energy of the system is changed by transferring energy as heat (and no other processes take place), $\Delta U = q$. If energy enters a system as heat, the internal energy of the system increases and q is positive; if energy leaves the system as heat, the internal energy of the system decreases and q is negative. Thus, if 10 J enters the system as heat, we write $q = +10$ J and (provided no work is done on or by the system) $\Delta U = +10$ J. Likewise, if 10 J leaves the system as heat, we write $q = -10$ J and $\Delta U = -10$ J.

As these examples show, energy transferred as heat (like any energy) is measured in joules, J. However, a unit still widely used in biochemistry and related fields is the *calorie*, cal. Originally, 1 cal was the energy needed to raise the temperature of 1 g of water by 1°C. The modern definition is

$$1 \text{ cal} = 4.184 \text{ J (exactly)}$$

This exact relation defines the calorie in terms of the joule; the joule is the fundamental unit. The **nutritional calorie,** Cal, is actually 1 kilocalorie (kcal), and so it is important to note which unit is being used when assessing the energy content of food.

A process that releases heat into the surroundings is called an **exothermic process.** Most common chemical reactions—and all combustions, such as those that power transport and heating—are exothermic (Fig. 7.8). Less familiar are chemical reactions that absorb heat from the surroundings. A process that absorbs heat is called an **endothermic process** (Fig. 7.9). A number of common physical processes are endothermic. For instance, vaporization is endothermic, because heat must be supplied to drive molecules of a liquid apart from one another. The dissolution of ammonium nitrate in water is endothermic; in fact, this process is used in instant cold packs for sports injuries.

Heat is the transfer of energy as a result of a temperature difference. When energy is transferred as heat and no other processes occur, $\Delta U = q$. When energy enters a system as heat, q is positive; when energy leaves a system as heat, q is negative.

FIGURE 7.8 The thermite reaction is so exothermic that it melts the metal that it produces and is used to weld railroad tracks together. Here, aluminum metal is reacting with iron(III) oxide, Fe_2O_3, causing a shower of molten iron sparks.

Lab Video 7.8

7.5 The Measurement of Heat

The measurement of heat produced or absorbed by a process is used to monitor the change in internal energy of a system. However, before we see how this is done, we have to distinguish between two types of walls between the system and its surroundings.

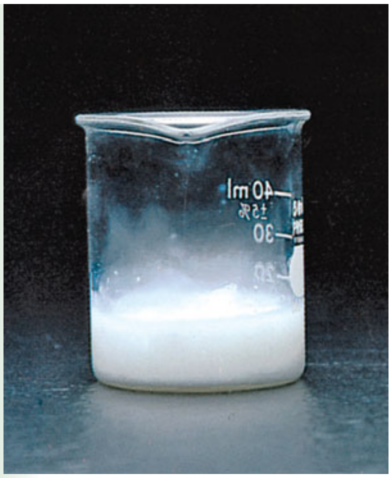


FIGURE 7.9 The endothermic reaction between ammonium thiocyanate, NH_4SCN, and barium hydroxide octahydrate, $Ba(OH)_2{\cdot}8H_2O$, absorbs a lot of heat and can cause water vapor in the air to freeze on the outside of the beaker.

Lab Video 7.9

If the walls are thermally insulating, heat cannot be transferred across them even if there is a temperature difference across them. The walls of a vacuum flask are a good approximation because the vacuum between them does not allow energy to be conducted from one wall to another by molecules and their silvered surfaces cuts down the transfer of energy by radiation. The technical term for a thermally insulating wall is an **adiabatic** wall (from the Greek words for "not passing through"). A system with adiabatic walls is not necessarily an isolated system: energy may be transferred to or from a system in an adiabatic container as work. In a closed adiabatic system, $\Delta U = w$. **Diathermic** walls do permit the transfer of energy as heat.

Provided the system does not lose energy as work, an influx of energy through the walls of a diathermic container typically raises the temperature of the system, so monitoring the temperature change is a way to monitor the heat transferred and therefore to infer the change in internal energy. To convert a temperature change into energy, we need to know the **heat capacity,** C, the ratio of the heat supplied to the rise in temperature produced:

$$\text{Heat capacity} = \frac{\text{heat supplied}}{\text{temperature rise produced}} \qquad \text{that is,} \qquad C = \frac{q}{\Delta T} \tag{5a}$$

A large heat capacity means that a given supply of heat produces only a small rise in temperature. A small heat capacity means that even a small transfer of energy as heat will produce a large rise in temperature. Once we know the heat capacity, we can measure the change in temperature, ΔT, of the system and calculate how much heat has been supplied by using Eq. 5a in the form

$$q = C\Delta T \tag{5b}$$

Heat capacity is an extensive property: the larger the sample, the more heat is required to raise its temperature by a given amount (Fig. 7.10). It is therefore common to report either the **specific heat capacity** (often called just "specific heat"), C_s, which is the heat capacity divided by the mass of the sample ($C_s = C/m$), or the **molar heat capacity,** C_m, the heat capacity divided by the amount (in moles) of the sample ($C_m = C/n$). For example, the specific heat capacity of liquid water at room temperature is $4.18\ \text{J}{\cdot}(°\text{C})^{-1}{\cdot}\text{g}^{-1}$, or $4.18\ \text{J}{\cdot}\text{K}^{-1}{\cdot}\text{g}^{-1}$, and its molar heat capacity is $75\ \text{J}{\cdot}\text{K}^{-1}{\cdot}\text{mol}^{-1}$.

We can calculate the heat capacity of a substance from its mass and its specific heat capacity by using $C = m \times C_s$. If we know the mass of a substance, its specific heat capacity, and the temperature rise it undergoes in a process, then the energy supplied as heat to the substance is

$$q = C\Delta T = mC_s\Delta T \tag{6a}$$

We use a similar expression, $C = n \times C_m$, for the molar heat capacity of a substance and write

$$q = nC_m\Delta T \tag{6b}$$

These expressions may be rearranged to calculate the specific or molar heat capacity from the measured temperature rise caused by a known quantity of heat. A point to note is that the specific heat capacity of a dilute solution is normally taken to be the same as that of the pure solvent (which is commonly water). Table 7.2 lists the specific and molar heat capacities of some common substances.

Thinking point: The molar heat capacity of lead is much greater than that of diamond at room temperature. Can you think of a reason for the difference?

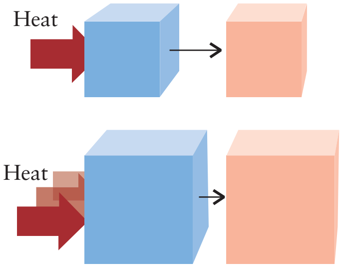

FIGURE 7.10 The heat capacity of an object determines the change in its temperature brought about by the quantity of energy transferred as heat: an object with a large heat capacity requires a lot of heat to bring about a given rise in temperature. Heat capacity is an extensive property; so a large object (bottom) has a larger heat capacity than a small object (top) made of the same material. Heat capacities also, in general, depend on temperature.

EXAMPLE 7.3 Calculating the heat needed to bring about a rise in temperature

Calculate the heat necessary to increase the temperature of (a) 100. g of water, (b) 2.00 mol $H_2O(l)$ by 20.°C from room temperature.

Anticipate Because the molar mass of water is about $18\ \text{g}{\cdot}\text{mol}^{-1}$, 100 g of water is greater than 2.00 mol H_2O, so we expect more heat to be required in (a) than in (b).

TABLE 7.2 Specific and Molar Heat Capacities of Common Materials*

Material	Specific heat capacity $(J\cdot(°C)^{-1}\cdot g^{-1})$	Molar heat capacity $(J\cdot K^{-1}\cdot mol^{-1})$
air	1.01	—
benzene	1.05	136
brass	0.37	—
copper	0.38	33
ethanol	2.42	111
glass (Pyrex)	0.78	—
granite	0.80	—
marble	0.84	—
polyethylene	2.3	—
stainless steel	0.51	—
water: solid	2.03	37
liquid	4.184	75
vapor	2.01	34

*More values are available in Appendices 2A and 2D; values assume constant pressure. Specific heat capacities commonly use Celsius degrees in their units, whereas molar heat capacities commonly use kelvins. All values except that for ice are for 25°C.

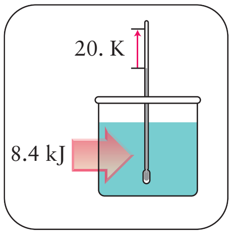
PLAN The heat required is given by Eq. 6. In each case, $\Delta T = +20.\ K$.

What should we assume? That no energy is lost to the container or the surroundings during the heating and that the water is thoroughly mixed, so that it is at the same temperature throughout.

SOLVE

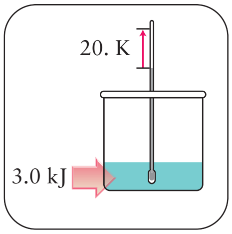
(a) From $q = mC_s\Delta T$,

$$q = (100.\ g) \times (4.18\ J\cdot K^{-1}\cdot g^{-1}) \times (20.\ K) = +8.4\ kJ$$



(b) From $q = nC_m\Delta T$,

$$q = (2.00\ mol) \times (75\ J\cdot K^{-1}\cdot mol^{-1}) \times (20.\ K) = +3.0\ kJ$$



Evaluate As we anticipated, more heat is needed for (a) than for (b). It will be useful to keep these magnitudes in mind.

Self-Test 7.3A Potassium perchlorate, $KClO_4$, is used as an oxidizer in fireworks. Calculate the heat required to raise the temperature of 10.0 g of $KClO_4$ from 25°C to an ignition temperature of 900.°C. The specific heat capacity of $KClO_4$ is $0.8111\ J\cdot K^{-1}\cdot g^{-1}$.

[***Answer:*** 7.10 kJ]

Self-Test 7.3B Calculate the heat necessary to increase the temperature of 3.00 mol $CH_3CH_2OH(l)$, ethanol, by 15.0°C from room temperature (see Table 7.2).

Transfers of energy as heat are measured with a **calorimeter,** a device in which heat transfer is monitored by recording the change in temperature that it produces, and then using $q = C_{cal}\Delta T$, where C_{cal} is the heat capacity of the calorimeter (which is sometimes called the "calorimeter constant"). A calorimeter can be as simple as a thermally

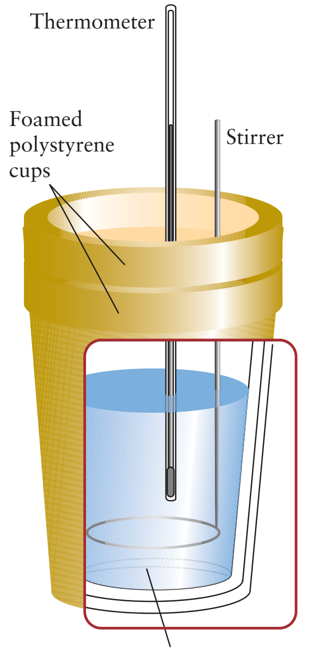


FIGURE 7.11 The energy released or absorbed as heat by a reaction at constant pressure can be measured in this simple calorimeter. The outer polystyrene cup acts as an extra layer of insulation to ensure that no heat enters or leaves the inner cup. The quantity of energy released or absorbed as heat is proportional to the change in temperature of the calorimeter.

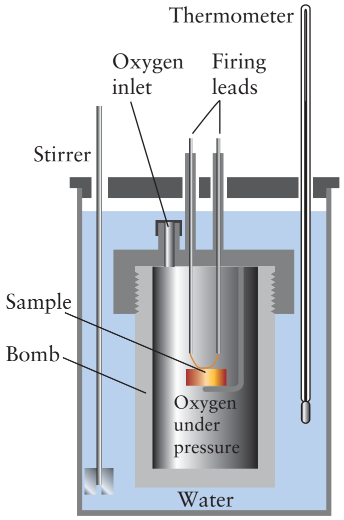

FIGURE 7.12 A bomb calorimeter is used to measure heat transfers at constant volume. The sample in the central rigid container called the bomb is ignited electrically with a fuse wire. Once combustion has begun, energy released as heat spreads through the walls of the bomb into the water. The heat released is proportional to the temperature change of the entire assembly.

insulated container equipped with a thermometer (Fig. 7.11). A more sophisticated version is a *bomb calorimeter* (Fig. 7.12). The reaction takes place inside the sturdy sealed metal vessel (the bomb), which is immersed in water, and the rise in temperature of the entire assembly is monitored. Its heat capacity is first measured by supplying a known quantity of heat and noting the resulting rise in temperature. This process is called "calibrating" the calorimeter.

EXAMPLE 7.4 Determining the internal energy change accompanying a reaction

A constant-volume calorimeter was calibrated by carrying out a reaction known to release 1.78 kJ of heat in 0.100 L of solution in the calorimeter, resulting in a temperature rise of 3.65°C. Next, 50. mL of 0.20 M HCl(aq) and 50. mL of 0.20 M NaOH(aq) were mixed in the same calorimeter and the temperature rose by 1.26°C. What is the change in the internal energy of the neutralization reaction?

Anticipate The rise in temperature in the actual experiment is about one-third the rise in the calibration, so we can suspect that the heat released by the reaction is about one-third of 1.78 kJ, or about 0.6 kJ.

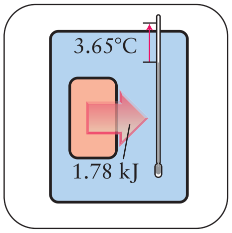
PLAN The calculation has two steps. First, calibrate the calorimeter by calculating its heat capacity with data from the first reaction, $C_{cal} = q_{cal}/\Delta T$. Second, use that value of C_{cal} to find the energy change of the neutralization reaction. For the second step, use the same equation rearranged to $q_{cal} = C_{cal}\Delta T$, but with ΔT now the change in temperature observed during the reaction. Note that the calorimeter contains the same volume of liquid in both cases. Finally, relate the energy transferred as heat to the change in internal energy by using $\Delta U = q$ and decide on the sign of ΔU by judging whether the system loses or gains energy.

What should we assume? Because dilute aqueous solutions have approximately the same heat capacities as pure water, assume that the heat capacity for the calorimeter during the reaction is the same as in the calibration.

SOLVE

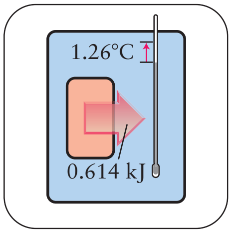
Calibration: From $C_{cal} = q_{cal}/\Delta T$,

$$C_{cal} = \frac{1.78\ \text{kJ}}{3.65°\text{C}} = \frac{1.78}{3.65}\ \text{kJ}\cdot(°\text{C})^{-1}$$



Application: From $q_{cal} = C_{cal}\Delta T$,

$$q_{cal} = \left(\frac{1.78}{3.65}\ \text{kJ}\cdot(°\text{C})^{-1}\right) \times (1.26°\text{C}) = 0.614\ \text{kJ}$$



Evaluate Because the temperature rises, the process is exothermic, energy leaves the system as heat, and $\Delta U = -0.614$ kJ, in agreement with our expectation.

Self-Test 7.4A A small piece of calcium carbonate was placed in the same calorimeter, and 0.100 L of dilute hydrochloric acid was poured over it. The temperature of the calorimeter rose by 3.57°C. What is the value of ΔU for the reaction of the hydrochloric acid with the calcium carbonate?

[***Answer:*** −1.74 kJ]

Self-Test 7.4B A calorimeter was calibrated by mixing two aqueous solutions together, each of volume 0.100 L. The heat output of the reaction that took place was known to be 4.16 kJ, and the temperature of the calorimeter rose by 3.24°C. Calculate the heat capacity of this calorimeter when it contains 0.200 L of water.

The heat capacity of an object is the ratio of the heat supplied to the temperature rise produced. Heat transfers are measured by using a calibrated calorimeter.

7.6 The First Law

So far, we have considered the transfer of energy as work or heat separately. However, in many processes, the internal energy changes as a result of both work and heat. For example, when a spark ignites the mixture of gasoline vapor and air in the engine of a moving automobile, the vapor burns and expands, transferring energy to its surroundings as both work and heat. In general, the change in the internal energy of a closed system is the net result of both kinds of transfers; so we write

$$\Delta U = q + w \qquad (7)^*$$

This expression summarizes the experimental fact that both heat and work are means of transferring energy and thereby changing the internal energy of a system. The fundamental molecular difference between work and heat is that when energy is transferred as work, the system moves molecules in the surroundings in a definite direction (think of the atoms of a rising weight all moving upward simultaneously), but during the transfer of energy as heat, the molecules of the surroundings are moved in random directions (think of the atoms of a hot object jostling the atoms of the surroundings into more vigorous random motion, Fig. 7.13).

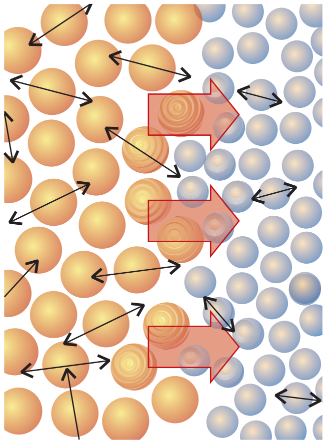


FIGURE 7.13 On an atomic scale, the transfer of energy as heat can be pictured as a process in which the vigorous thermal motion of atoms in the system jostle the less vigorously moving atoms of the surroundings and transfer some of their energy to them. The double-headed arrows represent the motion of the atoms; the large pink arrows represent the direction of heat transfer.

Self-Test 7.5A An automobile engine does 520. kJ of work and loses 220. kJ of energy as heat. What is the change in the internal energy of the engine? Treat the engine, fuel, and exhaust gases as a closed system.

[***Answer:*** −740. kJ]

Self-Test 7.5B A system was heated by using 300. J of heat, yet it was found that its internal energy decreased by 150. J (so $\Delta U = -150.$ J). Calculate w. Was work done on the system or did the system do work?

It is an experimental fact—a fact supported by thousands of experiments—that we cannot use a system to do work, leave it isolated for a while, and then return to it to find its internal energy restored to its original value and ready to provide the same amount of work again. Despite the great amount of effort that has been spent trying to build a "perpetual motion machine," a device that would be an exception to this rule by producing work without using fuel, no one has ever succeeded in building one. In other words, Eq. 7 is a *complete* statement of how changes in internal energy may be achieved in a closed system of constant composition: the only way to change the internal energy of such a system is to transfer energy into it as heat or as work. If the system is isolated, then even that ability is eliminated, and the internal energy cannot change at all. This conclusion is known as the **first law of thermodynamics,** which states:

The internal energy of an isolated system is constant.

The first law is closely related to the conservation of energy (Section A) but goes beyond it: the concept of heat does not apply to the single particles treated in classical mechanics.

According to the first law, if an isolated system has a certain internal energy at one instant and we inspect it again later, then we shall find that it still has exactly the same internal energy, no matter how much time has passed. Alternatively, if we allow the system to go through a series of changes but ensure that it is restored to its original state, then we would find that it has the same internal energy as it had originally. We summarize these statements by saying that the internal energy is a **state function,** a property that depends only on the current state of the system and is independent of how that state was prepared. The pressure, volume, temperature, and density of a system are also state functions.

The importance of state functions in thermodynamics is that, *because a state function depends only on the current state of the system, then if the system is changed from one state to another, the change in a state function is independent of how that change was brought about.* A state function is like altitude on a mountain (Fig. 7.14). We may

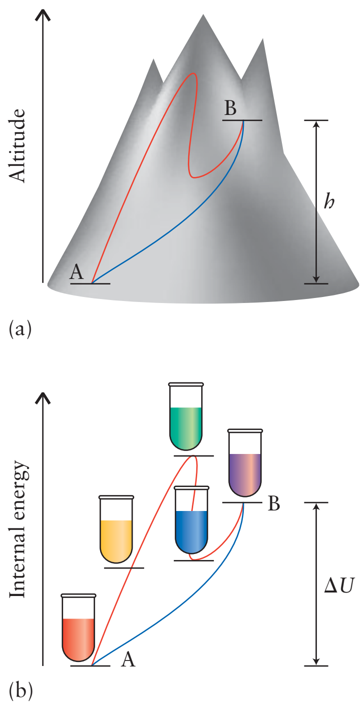

FIGURE 7.14 (a) The altitude of a location on a mountain is like a thermodynamic state function: no matter what route is taken between points A and B, the net change in altitude is the same. (b) Internal energy is a state function: if a system changes from state A to state B (as depicted diagrammatically here), the net change in internal energy is the same whatever the route—the sequence of chemical or physical changes—between the two states.

take any number of different paths between two huts on the mountain, but the change in altitude between the two huts is the same regardless of the path. Similarly, if we took 100 g of water at 25°C and raised its temperature to 60°C, its internal energy would change by a certain amount. However, if we took the same mass of water at 25°C and heated it to boiling, vaporized it, condensed the vapor, and then allowed the water to cool to 60°C, the net change in the internal energy of the water would be exactly the same as if we had heated it to 60°C in one step.

The work done by a system is *not* a state function: it depends on how the change is brought about. For example, we could let a gas at 25°C expand at constant temperature (by keeping it in touch with a water bath) through 100 cm^3 by two different paths. In the first experiment, the gas might push on a piston and do a certain amount of work against an external force. In the second experiment, the gas might push a piston into a vacuum; it then does no work, because there is no external opposing force (Fig. 7.15). The change in the state of the gas is the same in each case, but the work done by the system is different: in the first case, w is nonzero; in the second case, $w = 0$. Indeed, even everyday language suggests that work is not a state function, because we never speak of a system as possessing a certain amount of "work."

Similarly, heat is not a state function. The energy transferred as heat during a change in the state of a system depends on how the change is brought about. For example, suppose we want to raise the temperature of 100 g of water from 25°C to 30°C. One way to raise the temperature would be to supply energy as heat by using an electric heater. The heat required can be calculated from the specific heat capacity of water: $q = (4.18\ \text{J}\cdot°\text{C}^{-1}\cdot\text{g}^{-1}) \times (100\ \text{g}) \times (5°\text{C}) = +2\ \text{kJ}$. Another way to raise the temperature would be to stir the water vigorously with paddles until 2 kJ of work has been supplied. In the latter case, all the energy required is transferred as work; none is supplied as heat. So, in the first case, $q = +2$ kJ; and, in the second case, $q = 0$. However, the final state of the system is the same in each case. Because heat is not a state function, we should not speak of a system as possessing a certain amount of "heat."

Because internal energy is a state function, we can choose any convenient path between the given initial and final states of a system and calculate ΔU for that path. The result will have the same value of ΔU as the actual path between the same two states, even if the actual path is so complicated that ΔU cannot be calculated directly. In some cases we can use our molecular insight to give the change in internal energy for a process without doing a calculation. For instance, when an ideal gas expands isothermally, its molecules continue to move at the same average speed, so their total kinetic energy remains the same. Because there are no forces between the molecules, their total potential energy also remains the same even though their average separation has increased. Because neither the total kinetic energy nor the total potential energy changes, the internal energy of the gas is unchanged too. That is, $\Delta U = 0$ for the isothermal expansion (or compression) of an ideal gas. It follows that when a sample of an ideal gas changes by *any* path between two states, then provided the initial and final states have the same temperature we know at once that $\Delta U = 0$.

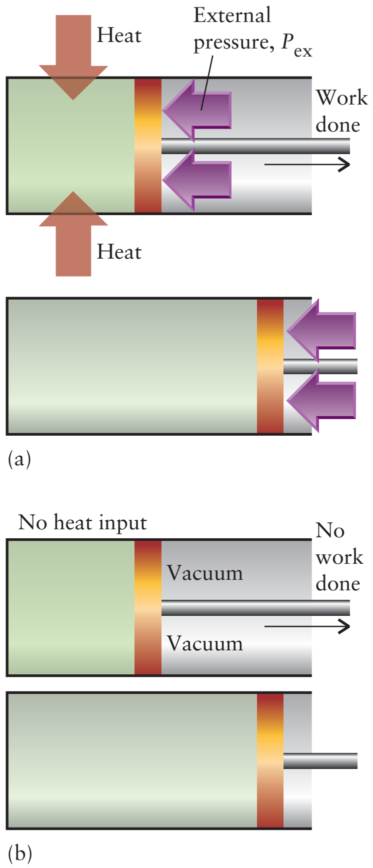

FIGURE 7.15 Two different paths between the same initial and final states of an ideal gas. (a) The gas does work as it expands isothermally against an applied, matching pressure. Because energy flows in as heat to restore the energy lost as work, the temperature remains constant. (b) The gas does no work as it expands isothermally into a vacuum. Because internal energy is a state function, the change in internal energy is the same for both processes: $\Delta U = 0$ for the isothermal expansion of an ideal gas on any path. However, the exchange of heat and work is different in each case.

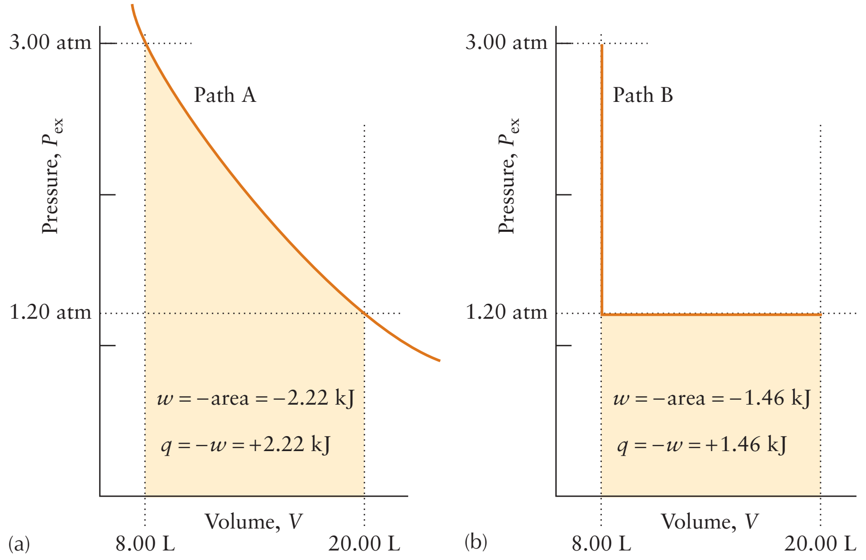

FIGURE 7.16 (a) On the reversible path, the work done in Example 7.5 is relatively large ($w = -2.22$ kJ); because the change in internal energy is zero, heat flows in to maintain constant temperature and constant internal energy. Therefore, $q = +2.22$ kJ. (b) On the irreversible path, the work done is also equal to the negative of the area beneath the curve and, for this path, is relatively small ($w = -1.46$ kJ). The net heat input, allowing for outflow of heat in the cooling step and influx of heat in the expansion, is $q = +1.46$ kJ.

Living Graph 7.16

EXAMPLE 7.5 Calculating the work, heat, and change in internal energy for the expansion of an ideal gas

Suppose that 1.00 mol of ideal gas molecules maintained at 292 K and 3.00 atm expands from 8.00 L to 20.00 L and a final pressure of 1.20 atm by two different paths. (a) Path A is an isothermal, reversible expansion. (b) Path B has two parts. In step 1, the gas is cooled at constant volume until its pressure has fallen to 1.20 atm. In step 2, it is heated and allowed to expand against a constant pressure of 1.20 atm until its volume is 20.00 L and $T = 292$ K. Determine for each path the work done, the heat transferred, and the change in internal energy (w, q, and ΔU).

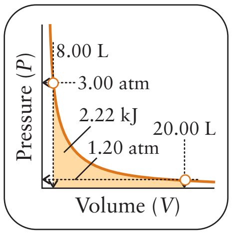
Anticipate Because internal energy is a state function and because the initial and final states are the same in both paths, ΔU for path B is the same as for path A. Because the process is isothermal, the change in internal energy (of this ideal gas) is zero. We should expect the value of w to be less negative (less energy lost as work) in the irreversible path and therefore q to be less positive as less heat is needed to maintain the temperature.

PLAN It is a good idea to begin by sketching a plot of each process (Fig. 7.16). (a) For an isothermal, reversible expansion, we use Eq. 4 to calculate w. (b) In step 1, the volume does not change, and so no work is done ($w = 0$). Step 2 is a constant-pressure process, so we use Eq. 3 to calculate w. Because $\Delta U = 0$ for an isothermal expansion of an ideal gas, in each case, we find q for the overall path from $\Delta U = q + w$ with $\Delta U = 0$. Use 1 L·atm = 101.325 J to convert liter-atmospheres into joules.

SOLVE

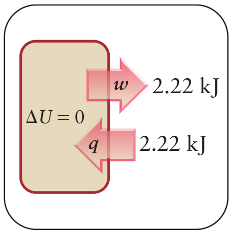
(a) From $w = -nRT \ln(V_{\text{final}}/V_{\text{initial}})$,

$$w = -(1.00\text{ mol}) \times (8.3145\text{ J·K}^{-1}\text{·mol}^{-1}) \times (292\text{ K}) \times \ln\frac{20.00\text{ L}}{8.0\text{ L}} = -2.22 \times 10^3\text{ J} = -2.22\text{ kJ}$$



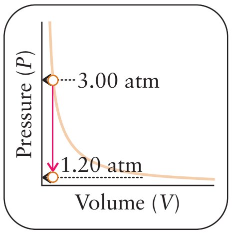
From $\Delta U = q + w = 0$,

$$q = -w = +2.22\text{ kJ}$$



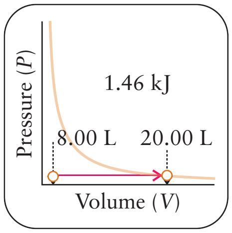
(b) **Step 1** Cool at constant volume, so no work is done.

$w = 0$



Step 2 From $w = -P_{ex}\Delta V$,

$w = -(1.20 \text{ atm}) \times (20.00 - 8.00) \text{ L} = -14.4 \text{ L·atm}$

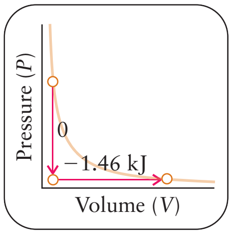


Convert liter-atmospheres to joules.

$$w = -(14.4 \text{ L·atm}) \times \left(\frac{101.325 \text{ J}}{1 \text{ L·atm}}\right) = -1.46 \times 10^3 \text{ J} = -1.46 \text{ kJ}$$

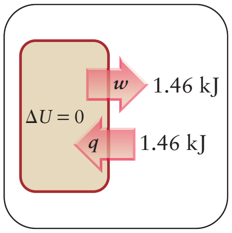
Calculate total work for path B.

$w = 0 + (-1.46) \text{ kJ} = -1.46 \text{ kJ}$



From $\Delta U = q + w = 0$,

$q = -w = +1.46 \text{ kJ}$



In summary,

	q	w	ΔU
For the reversible path:	+2.22 kJ	−2.22 kJ	0
For the irreversible path:	+1.46 kJ	−1.46 kJ	0

Evaluate As expected, less work is done in the irreversible path and less energy has to enter the system as heat to maintain its temperature.

Self-Test 7.6A Suppose that 2.00 mol CO_2 at 2.00 atm and 300. K is compressed isothermally and reversibly to half its original volume before being used to produce soda water. Calculate w, q, and ΔU by treating the CO_2 as an ideal gas.

[***Answer:*** $w = +3.46$ kJ, $q = -3.46$ kJ, $\Delta U = 0$]

Self-Test 7.6B Suppose that 1.00 kJ of energy is transferred as heat to oxygen in a cylinder fitted with a piston; the external pressure is 2.00 atm. The oxygen expands from 1.00 L to 3.00 L against this constant pressure. Calculate w and ΔU for the entire process by treating the O_2 as an ideal gas.

The first law of thermodynamics states that the internal energy of an isolated system is constant. A state function depends only on the current state of a system. The change in a state function between two states is independent of the path between them. Internal energy is a state function but work and heat are not.

7.7 A Molecular Interlude: The Origin of Internal Energy

Internal energy is energy stored in a system as kinetic energy and potential energy. We saw in Section A that kinetic energy is energy due to motion and that the faster a molecule travels, the greater is its translational kinetic energy. When we heat a gas, the average speed of the molecules increases. When we do work on a gas in an insulated container, the molecules are also stimulated to move faster. The increase in the average speed of the gas molecules corresponds to an increase in the total kinetic energy of the molecules and therefore to an increase in the internal energy of the gas. We have already seen (in Section 4.10) that the temperature is an indication of the average speed of gas molecules, and so this increase in internal energy also corresponds to an increase in temperature. It is always the case that *a system at high temperature has a greater internal energy than the same system at a lower temperature.*

Molecules in a gas can move in a variety of different ways, and each mode of motion can act as a store of energy (Fig. 7.17). The energy of an atom or molecule due to its motion through space is called its **translational energy** (this energy is kinetic energy). Molecules (in contrast to atoms) can also store energy as **rotational energy,** the energy due to their rotational motion (this energy is also kinetic). A third store of energy for molecules is in the oscillation of their atoms relative to one another: this contribution is called **vibrational energy** and is the sum of kinetic and potential contributions. Most molecules are not vibrationally excited at room temperature, and so we ignore that mode for now. The contribution of translational and rotational motion to the internal energy can be estimated from the temperature.

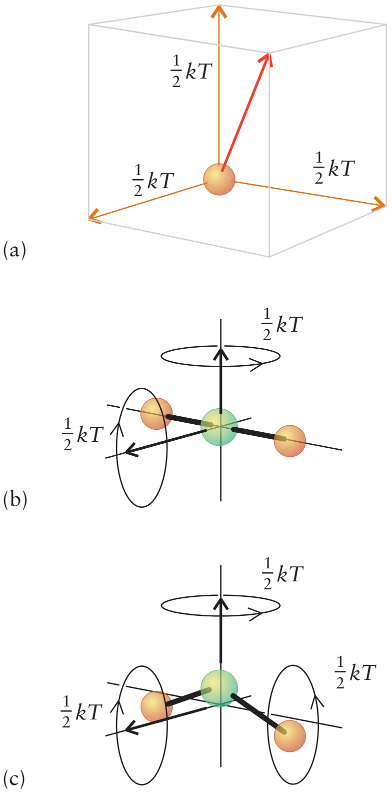


FIGURE 7.17 The translational and rotational modes of atoms and molecules and the corresponding average energies of each mode at a temperature T. (a) An atom or molecule can undergo translational motion in three dimensions. (b) A linear molecule can also rotate about two axes perpendicular to the line of atoms. (c) A nonlinear molecule can rotate about three perpendicular axes.

HOW DO WE DO THAT?

First, we need to know that a "quadratic contribution" to the energy is an expression that depends on the square of a velocity or a displacement, as in $\frac{1}{2}mv^2$ for translational kinetic energy. The **equipartition theorem** (which we shall not derive here) then states that *the average value of each quadratic contribution to the energy of a molecule in a sample at a temperature T is equal to $\frac{1}{2}kT$.* The name "equipartition" simply means that the available energy is shared (partitioned) equally over all the available modes. In this expression, k is Boltzmann's constant, a fundamental constant with the value 1.381×10^{-23} J·K^{-1}. Boltzmann's constant is related to the gas constant (8.314 J·K^{-1}·mol^{-1}) by $R = N_A k$, where N_A is Avogadro's constant. The equipartition theorem is a result from classical mechanics; so we can use it for translational and rotational motion of molecules at room temperature and above, where quantization is unimportant. We cannot use it reliably for vibrational motion, except at very high temperatures, because at ordinary temperatures only the lowest vibrational quantum state is occupied and the effects of quantization are very important. The following remarks therefore apply only to translational and rotational motion.

A molecule can move through space along any of three dimensions, so it has *three* translational modes of motion, each one giving a quadratic contribution to the energy. It follows from the equipartition theorem that the average translational kinetic energy of a molecule in a sample at a temperature T is $3 \times \frac{1}{2}kT = \frac{3}{2}kT$. The contribution to the molar internal energy (the energy per mole of molecules, U_m) is therefore N_A times this value, or

$$U_m(\text{translation}) = \tfrac{3}{2}N_A kT = \tfrac{3}{2}RT$$

Because $RT = 2.48$ kJ·mol^{-1} at 25°C, the translational motion of gas molecules contributes $\frac{3}{2} \times 2.48$ kJ·mol^{-1} to the internal energy of the sample at 25°C. Apart from the energy arising from the internal structures of the atoms themselves, this is the only motional contribution to the internal energy of a monatomic gas, such as argon or any other noble gas.

A *linear molecule*, such as any diatomic molecule, carbon dioxide, and ethyne (acetylene, HC≡CH), can rotate about two axes perpendicular to the line of atoms, and so it

has two rotational modes of motion. Its average rotational energy is therefore $2 \times \frac{1}{2}kT$ and the contribution to the molar internal energy is N_A times this value:

$$U_m(\text{rotation, linear}) = N_A kT = RT$$

or about 2.48 kJ·mol^{-1} at 25°C. The total motional contribution to the internal energy of a gas of linear molecules is the sum of the translational and rotational contributions, or $\frac{5}{2}RT$, which corresponds to 6.20 kJ·mol^{-1} at 25°C.

A *nonlinear molecule*, such as water, methane, or benzene, can rotate about any of three perpendicular axes, and so it has three rotational modes of motion. The average rotational energy of such a molecule is therefore $3 \times \frac{1}{2}kT = \frac{3}{2}kT$. The contribution of rotation to the molar internal energy of a gas of nonlinear molecules is therefore

$$U_m(\text{rotation, nonlinear}) = \tfrac{3}{2}RT$$

At 25°C, the contribution of rotation to the energy is 3.72 kJ·mol^{-1} (the same as for the translational motion), and the total motional contribution for nonlinear molecules is therefore $3RT$, or about 7.44 kJ·mol^{-1} at 25°C.

We have shown that the contribution to the molar internal energy of a monatomic ideal gas (such as argon) that arises from molecular motion is $\frac{3}{2}RT$. We can conclude that if the gas is heated through ΔT, then the change in its molar internal energy, ΔU_m, is $\Delta U_m = \frac{3}{2}R\Delta T$. For instance, if the gas is heated from 20.°C to 100.°C (so $\Delta T = +80.$ K), then its molar internal energy increases by $\frac{3}{2} \times (8.314\ \text{J·K}^{-1}\text{·mol}^{-1}) \times (80.\ \text{K})$, or 1.0 kJ·mol^{-1}.

Internal energy is stored as molecular kinetic and potential energy. The equipartition theorem can be used to estimate the translational and rotational contributions to the internal energy of an ideal gas. The vibrational contribution to the energy is insignificant at ordinary temperatures.

ENTHALPY

If the system has rigid walls, its volume remains the same even though other changes may take place, so it does no expansion work. Suppose also that it does no nonexpansion work (for instance, it is not an electric battery driving an electric motor). Then we can set $w = 0$ in Eq. 7 ($\Delta U = w + q$) and obtain

$$\text{At constant volume and no nonexpansion work: } \Delta U = q \qquad (8)^*$$

That is, in such a system, the change in the internal energy of the system is equal to the energy supplied to it as heat and we can monitor changes in internal energy simply by monitoring the flow of energy as heat into or out of the system. In chemistry, though, we are more concerned with heat transfers at constant pressure: most chemical reactions take place in containers open to the atmosphere and therefore take place at a constant pressure of about 1 atm. Such systems are free to expand or contract. If a gas is evolved, the expanding gas needs to drive back the surrounding atmosphere to make room for itself. Work is done, even though there is no actual piston. For example, if in some process we supply 100 J of heat to a system ($q = +100$ J) and the system does 20 J of work ($w = -20$ J) as it expands at constant pressure, the internal energy of the system rises by only 80 J. We need another state function, one that will allow us to keep track of energy changes at constant pressure by taking into account automatically losses of energy as expansion work.

7.8 Heat Transfers at Constant Pressure

The state function that allows us to keep track of energy changes at constant pressure is called the **enthalpy,** H:

$$H = U + PV \qquad (9)^*$$

where U, P, and V are the internal energy, pressure, and volume of the system. We can see that enthalpy is a state function by noting that U (from the first law), P, and V are

all state functions, and so $H = U + PV$ must be a state function, too. What we now need to show is that it follows from this definition that *a change in the enthalpy of a system is equal to the heat released or absorbed at constant pressure.*

HOW DO WE DO THAT?

Consider a process at constant pressure for which the change in internal energy is ΔU and the change in volume is ΔV. It then follows from the definition of enthalpy in Eq. 9 that the change in enthalpy is

$$\text{At constant pressure: } \Delta H = \Delta U + P\Delta V \qquad (10)$$

Now we use $\Delta U = q + w$, where q is the energy supplied to the system as heat and w is the energy supplied as work. Therefore,

$$\Delta H = q + w + P\Delta V$$

Next, suppose that the system can do no work other than expansion work. In that case, we can use Eq. 3 ($w = -P_{ex}\Delta V$) to write

$$\Delta H = q - P_{ex}\Delta V + P\Delta V$$

Finally, because the system is open to the atmosphere, the pressure of the system is the same as the external pressure; so $P_{ex} = P$, and the last two terms cancel to leave $\Delta H = q$.

We have shown that for a system that can do work only by expansion against a constant pressure,

$$\text{At constant pressure, and with no nonexpansion work: } \Delta H = q \qquad (11)^*$$

The implication of this equation is that, because chemical reactions typically take place at constant pressure in vessels open to the atmosphere, the heat that they release or require can be equated to the change in enthalpy of the system. It follows that if we study a reaction in a calorimeter that is open to the atmosphere (such as that depicted in Fig. 7.11), then the measurement of its temperature rise gives us the enthalpy change that accompanies the reaction. For instance, if a reaction releases 1.25 kJ of heat in this kind of calorimeter, then we can write $\Delta H = q = -1.25$ kJ.

It is important to realize that the enthalpy is not a measure of the energy that a system possesses in the same fundamental sense as the internal energy. It is really an accounting device that accounts for the effects of allowing the volume to change during heat transactions at constant pressure.

When we transfer energy to a constant-pressure system as heat, the enthalpy of the system *increases* by that amount. When energy leaves a constant-pressure system as heat, the enthalpy of the system *decreases* by that amount. For example, the formation of zinc iodide from its elements is an exothermic reaction that (at constant pressure) releases 208 kJ of heat to the surroundings for each mole of ZnI_2 formed:

$$Zn(s) + I_2(s) \longrightarrow ZnI_2(s)$$

We can therefore report that $\Delta H = -208$ kJ because the enthalpy of the reaction mixture decreases by 208 kJ in this reaction (Fig. 7.18). An endothermic process absorbs heat, and so when ammonium nitrate dissolves in water the enthalpy of the system increases (Fig. 7.19). Note that $\Delta H < 0$ for exothermic reactions, whereas $\Delta H > 0$ for endothermic reactions.

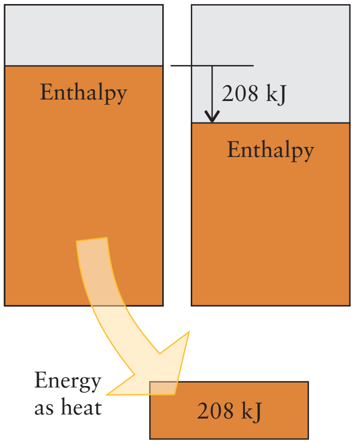

FIGURE 7.18 The enthalpy of a system is like a measure of the height of water in a reservoir. When an exothermic reaction releases 208 kJ of heat at constant pressure, the "reservoir" falls by 208 kJ and $\Delta H = -208$ kJ.

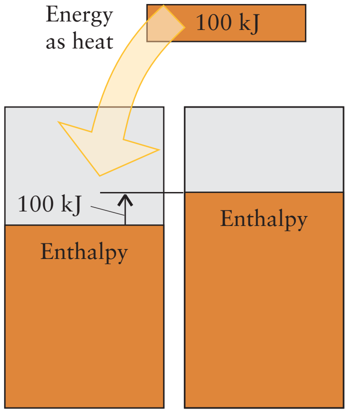

FIGURE 7.19 If an endothermic reaction absorbs 100 kJ of heat at constant pressure, the height of the enthalpy "reservoir" rises by 100 kJ and $\Delta H = +100$ kJ.

Self-Test 7.7A In an exothermic reaction at constant pressure, 50. kJ of energy left the system as heat and 20. kJ of energy left the system as expansion work. What are the values of (a) ΔH and (b) ΔU for this process?

[***Answer:*** (a) −50. kJ; (b) −70. kJ]

Self-Test 7.7B In an endothermic reaction at constant pressure, 30. kJ of energy entered the system as heat. The products took up less volume than the reactants, and 40. kJ of energy entered the system as work as the outside atmosphere pressed down on it. What are the values of (a) ΔH and (b) ΔU for this process?

The change in enthalpy of a system is equal to the heat supplied to the system at constant pressure. For an endothermic process, $\Delta H > 0$; for an exothermic process, $\Delta H < 0$.

7.9 Heat Capacities at Constant Volume and Constant Pressure

As explained in Section 7.5, the heat capacity C is the constant of proportionality between the heat supplied to a substance and the temperature rise that results ($q = C\Delta T$). However, the rise in temperature and therefore the heat capacity depend on the conditions under which the heating takes place because, at constant pressure, some of the heat is used to do expansion work rather than to raise the temperature of the system. We need to refine our definition of heat capacity.

Because heat transferred at constant volume can be identified with the change in internal energy, ΔU, we can combine Eq. 8 with $C = q/\Delta T$ and define the **heat capacity at constant volume,** C_V, as

$$C_V = \frac{\Delta U}{\Delta T} \tag{12a}$$

Similarly, because heat transferred at constant pressure can be identified with the change in enthalpy, ΔH, we can define the **heat capacity at constant pressure,** C_P, as

$$C_P = \frac{\Delta H}{\Delta T} \tag{12b}$$

The corresponding molar heat capacities are these quantities divided by the amount of substance and are denoted $C_{V,\text{m}}$ and $C_{P,\text{m}}$.

Thinking point: Which would you expect to be larger, $C_{V,\text{m}}$ or $C_{P,\text{m}}$?

The constant-volume and constant-pressure heat capacities of a solid substance are similar; the same is true of a liquid but not of a gas. The difference is a reflection of the fact that gases expand much more than solids and liquids when they are heated, so more energy is lost as work when a gas is heated at constant pressure than when a solid or a liquid is heated. We can use the definition of enthalpy and the ideal gas law to find a simple quantitative relation between C_P and C_V for an ideal gas.

HOW DO WE DO THAT?

For an ideal gas, the PV in the definition of enthalpy, $H = U + PV$, can be replaced by nRT, and so $H = U + nRT$. When a sample of an ideal gas is heated, the enthalpy, internal energy, and temperature all change, and it follows that

$$\Delta H = \Delta U + nR\Delta T$$

The heat capacity at constant pressure can therefore be expressed as

$$C_P = \frac{\Delta H}{\Delta T} = \frac{\Delta U + nR\Delta T}{\Delta T} = \frac{\Delta U}{\Delta T} + nR = C_V + nR$$

To obtain the relation between the two molar heat capacities, we divide this expression by n.

We have shown that the two molar heat capacities of an ideal gas are related by

$$C_{P,\text{m}} = C_{V,\text{m}} + R \tag{13}*$$

As an example, the molar constant-volume heat capacity of argon is 12.8 $\text{J·K}^{-1}\text{·mol}^{-1}$, and so the corresponding constant-pressure value is 12.8 + 8.3 $\text{J·K}^{-1}\text{·mol}^{-1}$ = 21.1 $\text{J·K}^{-1}\text{·mol}^{-1}$, a difference of 65%. The heat capacity at constant pressure is greater than that at constant volume because at constant pressure not all the heat supplied is used to raise the temperature: some returns to the surroundings as expansion

work and $C = q/\Delta T$ is larger (because ΔT is smaller) than at constant volume (when all the energy remains inside the system).

The molar heat capacity of an ideal gas at constant pressure is greater than that at constant volume; the two quantities are related by Eq. 13.

7.10 A Molecular Interlude: The Origin of the Heat Capacities of Gases

We can see how the values of heat capacities depend on molecular properties by using the relations in Section 7.7 and the equipartition theorem. We start with a simple system, a monatomic ideal gas such as argon. We saw in Section 7.7 that the molar internal energy of a monatomic ideal gas at a temperature T is $\frac{3}{2}RT$ and that the change in molar internal energy when the temperature is changed by ΔT is $\Delta U_m = \frac{3}{2}R\Delta T$. It follows from Eq. 12a that the molar heat capacity at constant volume is

$$\text{For a monatomic gas: } C_{V,m} = \frac{\Delta U_m}{\Delta T} = \frac{\frac{3}{2}R\Delta T}{\Delta T} = \tfrac{3}{2}R$$

or about 12.5 $J{\cdot}K^{-1}{\cdot}mol^{-1}$, in agreement with the value found experimentally. Note that the molar heat capacity of a monatomic ideal gas is independent of temperature and pressure. From Eq. 13 ($C_{P,m} = C_{V,m} + R$), the molar heat capacity of an ideal gas at constant pressure is $C_{P,m} = \frac{3}{2}R + R = \frac{5}{2}R$.

The molar heat capacities of gases composed of molecules (as distinct from atoms) are higher than those of monatomic gases because the molecules can store energy as rotational kinetic energy as well as translational kinetic energy. We saw in Section 7.7 that the rotational motion of linear molecules contributes another RT to the molar internal energy:

$$\text{For a linear molecule: } C_{V,m} = \frac{\Delta U_m}{\Delta T} = \frac{\frac{3}{2}R\Delta T + RT}{\Delta T} = \tfrac{5}{2}R$$

For nonlinear molecules, the rotational contribution is $\frac{3}{2}RT$, for a total (rotational + translational) contribution of $3RT$. Therefore, we have the following expressions:

	Atoms	Linear molecules	Nonlinear molecules
$C_{V,m}$	$\frac{3}{2}R$	$\frac{5}{2}R$	$3R$
$C_{P,m}$	$\frac{5}{2}R$	$\frac{7}{2}R$	$4R$

(In each case, $C_{P,m}$ has been calculated from $C_{P,m} = C_{V,m} + R$.) Note that the molar heat capacity increases with molecular complexity. The molar heat capacity of nonlinear molecules is higher than that of linear molecules because nonlinear molecules can rotate about three rather than only two axes (recall Fig. 7.17).

The graph in Fig. 7.20 shows how $C_{V,m}$ for iodine vapor, $I_2(g)$, varies with temperature. At very low temperatures $C_{V,m} = \frac{3}{2}R$, but rises to $\frac{5}{2}R$ as molecular rotation takes place. At still higher temperatures, molecular vibrations start to absorb energy and the heat capacity rises toward $\frac{7}{2}R$. At 298 K, the experimental value is equivalent to $3.4R$.

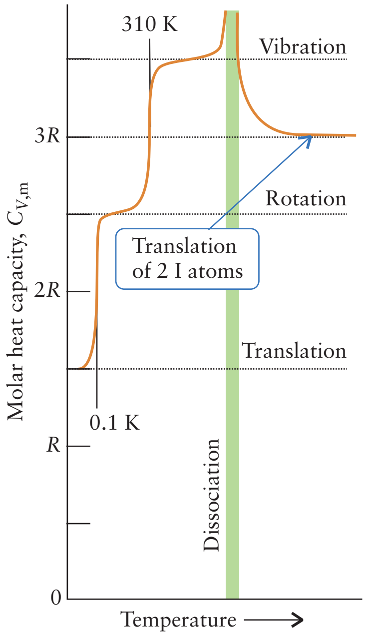

FIGURE 7.20 Variation in the molar heat capacity of iodine vapor at constant volume. The translational motion of the gaseous molecules contributes to the heat capacity even at very low temperatures. As the temperature rises past 0.05 K, rotation makes a significant contribution, but vibrations of the molecule contribute only at high temperatures (above about 310 K; for most other molecules the temperature must be much higher). When the molecules dissociate, the heat capacity becomes very large during dissociation, but then settles down to a value characteristic of 2 mol I atoms undergoing only translational motion.

EXAMPLE 7.6 Calculating the energy changes when heating an ideal gas

Calculate the final temperature and the change in internal energy when 500. J of energy is transferred as heat to 0.900 mol $O_2(g)$ at 298 K and 1.00 atm at (a) constant volume; (b) constant pressure. Treat the gas as ideal.

Anticipate We expect the temperature to rise more as a result of heating at constant volume than at constant pressure because at constant pressure some of the energy is used to expand the system.

PLAN Oxygen is a linear molecule and its heat capacities can be estimated from the equipartition theorem; then we can use $q = C\Delta T$, with $C = nC_m$, to find the final temperature. The internal energy change at constant volume is equal to the heat supplied. At constant pressure, find the internal energy change by regarding the process as taking place in two steps: heating to the final temperature at constant volume, followed by isothermal expansion.

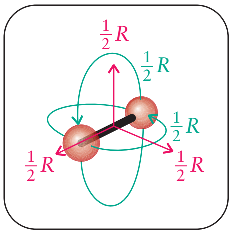
What should we assume? That oxygen behaves as an ideal gas and that there is no vibrational contribution to the heat capacity.

SOLVE

From $C_{V,m} = \frac{5}{2}R$ and $C_{P,m} = C_{V,m} + R$,

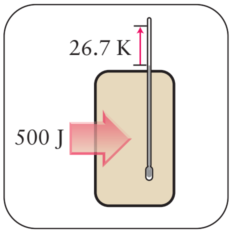
$$C_{V,m} = \tfrac{5}{2}(8.3145\ \text{J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}) = 20.79\ \text{J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}$$

$$C_{P,m} = \tfrac{7}{2}(8.3145\ \text{J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}) = 29.10\ \text{J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}$$



(a) From $\Delta T = q/nC_{V,m}$,

$$\Delta T = \frac{500.\ \text{J}}{(0.900\ \text{mol}) \times (20.79\ \text{J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1})} = +26.7\ \text{K}$$

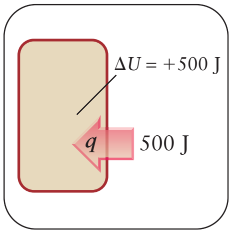


Find the final temperature.

$$T = 298 + 26.7\ \text{K} = 325\ \text{K}, \quad \text{or} \quad 52°\text{C}$$

From $\Delta U = q$ at constant volume,

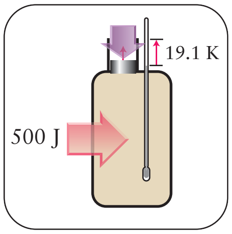
$$\Delta U = +500.\ \text{J}$$



(b) To find ΔU for heating at constant pressure, find the final temperature, then break down the overall process into two steps (heating at constant volume to the final temperature, then allowing the gas to expand isothermally):

From $\Delta T = q/nC_{P,m}$,

$$\Delta T = \frac{500.\ \text{J}}{(0.900\ \text{mol}) \times (29.10\ \text{J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1})} = +19.1\ \text{K}$$

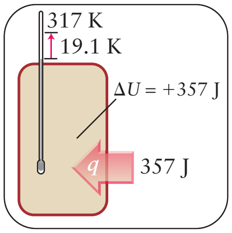


Find the final temperature.

$$T = 298 + 19.1\ \text{K} = 317\ \text{K}, \quad \text{or} \quad 44°\text{C}$$

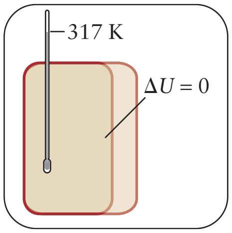
Heat: Transfer enough energy at constant volume to raise the temperature to its final value (317 K), and use $\Delta U = q$.

$$\Delta U = q = (0.900\ \text{mol}) \times (20.79\ \text{J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}) \times (19.1\ \text{K})$$
$$= +357\ \text{J}$$



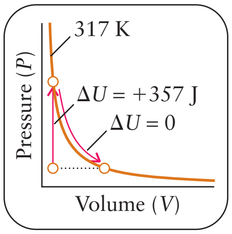
Expand: Allow the sample to expand isothermally to its final volume.

Because U is independent of volume for an ideal gas, $\Delta U_{\text{step 2}} = 0$



Now add the two changes in internal energy.

$\Delta U = +357\ \text{J}$



Evaluate The overall change is smaller than for the constant-volume case, as predicted.

Self-Test 7.8A Calculate the final temperature and the change in internal energy when 500. J of energy is transferred as heat to 0.900 mol Ne(g) at 298 K and 1.00 atm (a) at constant volume; (b) at constant pressure. Treat the gas as ideal.

[***Answer:*** (a) 343 K, 500. J; (b) 325 K, 300. J]

Self-Test 7.8B Calculate the final temperature and the change in internal energy when 1.20 kJ of energy is transferred as heat to 1.00 mol H_2(g) at 298 K and 1.00 atm (a) at constant volume; (b) at constant pressure. Treat the gas as ideal.

Rotation requires energy and leads to higher heat capacities for complex molecules; the equipartition theorem can be used to estimate the molar heat capacities of gas-phase molecules.

7.11 The Enthalpy of Physical Change

The molecules in a solid or liquid are held together by intermolecular attractions. A phase change in which the molecules become further separated, such as melting or vaporization, requires energy to overcome these intermolecular attractions and is therefore endothermic. Phase changes that increase molecular contact, such as condensation or freezing, are exothermic because energy is released when molecules come closer together and can interact with one another more strongly. When a phase transition takes place at constant pressure, as is most common, the heat transfer accompanying the phase change is equal to the change in enthalpy of the substance.

At a given temperature, the vapor phase of a substance has a higher energy and therefore a higher enthalpy than the liquid phase. The difference in molar enthalpy between the vapor and the liquid states is called the **enthalpy of vaporization,** ΔH_{vap}:

$$\Delta H_{\text{vap}} = H_{\text{m}}(\text{vapor}) - H_{\text{m}}(\text{liquid}) \qquad (14)$$

The enthalpy of vaporization of most substances changes little with temperature. For water at its boiling point, 100°C, $\Delta H_{\text{vap}} = 40.7\ \text{kJ}\cdot\text{mol}^{-1}$; but, at 25°C, $\Delta H_{\text{vap}} = 44.0\ \text{kJ}\cdot\text{mol}^{-1}$. The latter value means that to vaporize 1.00 mol H_2O(l), corresponding to 18.02 g of water, at 25°C and constant pressure, we have to supply 44.0 kJ of energy as heat.

Self-Test 7.9A A sample of benzene, C_6H_6, was heated to 80°C, its normal boiling point. The heating was continued until 15.4 kJ had been supplied; as a result, 39.1 g of boiling benzene was vaporized. What is the enthalpy of vaporization of benzene at its boiling point?

[***Answer:*** $30.8\ \text{kJ}\cdot\text{mol}^{-1}$]

Self-Test 7.9B The same heater was used to heat a sample of ethanol, C_2H_5OH, of mass 23 g to its boiling point. It was found that 22 kJ was required to vaporize all the ethanol. What is the enthalpy of vaporization of ethanol at its boiling point?

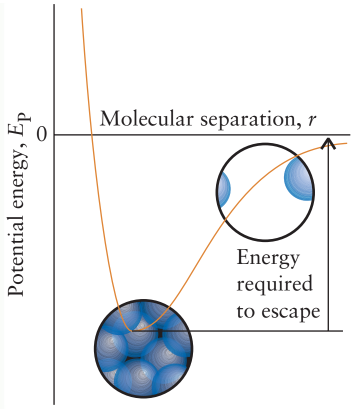


FIGURE 7.21 The potential energies of molecules decrease as they approach one another and experience intermolecular attractions, then rise again as the molecules are pressed closely together. The average intermolecular distance in a liquid is given by the position of the energy minimum. To vaporize a liquid, molecules must be raised from the bottom of the well to the energy of the horizontal part of the curve on the right.

Lab Video 7.21

TABLE 7.3 Standard Enthalpies of Physical Change*

Substance	Formula	Freezing point (K)	$\Delta H_{fus}°$ ($kJ \cdot mol^{-1}$)	Boiling point (K)	$\Delta H_{vap}°$ ($kJ \cdot mol^{-1}$)
acetone	CH_3COCH_3	177.8	5.72	329.4	29.1
ammonia	NH_3	195.4	5.65	239.7	23.4
argon	Ar	83.8	1.2	87.3	6.5
benzene	C_6H_6	278.6	10.59	353.2	30.8
ethanol	C_2H_5OH	158.7	4.60	351.5	43.5
helium	He	3.5	0.021	4.22	0.084
mercury	Hg	234.3	2.292	629.7	59.3
methane	CH_4	90.7	0.94	111.7	8.2
methanol	CH_3OH	175.2	3.16	337.8	35.3
water	H_2O	273.2	6.01	373.2	40.7 (44.0 at 25°C)

*Values correspond to the temperature of the phase change. The superscript ° signifies that the change takes place at 1 bar and that the substance is pure (that is, the values are for standard states; see Section 7.15).

Table 7.3 lists the enthalpies of vaporization of various substances. All enthalpies of vaporization are positive, and so it is conventional to report them without their sign. Notice that compounds with strong intermolecular forces, such as hydrogen bonds, tend to have the highest enthalpies of vaporization. That correlation is easy to explain, because the enthalpy of vaporization is a measure of the energy needed to separate molecules from their attractions in the liquid state into a free state in the vapor. In plots of the potential energy arising from intermolecular interactions, like that shown in Fig. 7.21, the enthalpy of the substance in the liquid state, where molecular interactions are strong, is related to the depth of the bottom of the well in the curve. The enthalpy of the vapor state, where the interactions are almost insignificant, corresponds to the horizontal part of the curve to the right. A substance with a high molar enthalpy of vaporization has a deep intermolecular potential well, indicating strong intermolecular attractions.

The molar enthalpy change that accompanies melting (fusion) is called the **enthalpy of fusion**, ΔH_{fus}, of the substance:

$$\Delta H_{fus} = H_m(\text{liquid}) - H_m(\text{solid}) \quad \textbf{(15)}$$

Melting, with only one known exception (helium), is endothermic, and so all enthalpies of fusion (with the exception of that special case) are positive and are reported without their sign (see Table 7.3). The enthalpy of fusion of water at 0°C is $6.0\ kJ \cdot mol^{-1}$: to melt 1.0 mol $H_2O(s)$ (18 g of ice) at 0°C, we have to supply 6.0 kJ of heat. Vaporizing the same amount of water takes much more energy (more than 40 kJ) because, when water is vaporized to a gas, its molecules must be separated completely. When a solid melts, the molecules can move more freely, but because they stay nearly as close together in the liquid as in the solid, the interactions between them remain nearly as strong (Fig. 7.22).

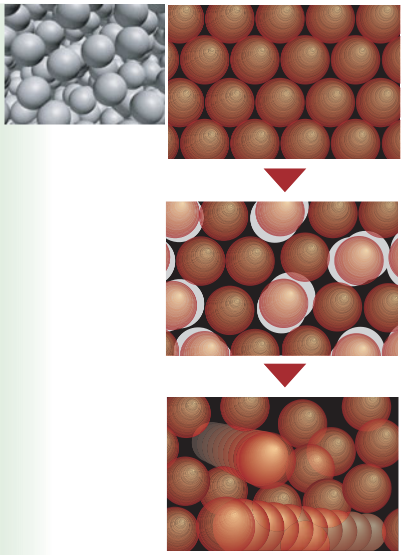

FIGURE 7.22 Melting (fusion) is an endothermic process. Molecules in a solid sample vibrate about ordered positions (top) but, as molecules acquire more energy, they begin to be able to struggle past their neighbors (center). Finally, the solid changes completely into a liquid with disordered, mobile molecules (bottom).

Animation 7.22

The **enthalpy of freezing** is the change in molar enthalpy of a liquid when it solidifies. Because enthalpy is a state property, the enthalpy of a sample of water must be the same after being frozen and then melted as it was before it was frozen. Therefore, the enthalpy of freezing of a substance is the negative of its enthalpy of fusion. For water at 0°C, the enthalpy of freezing is $-6.0\ kJ \cdot mol^{-1}$, because 6.0 kJ of heat is *released* when 1 mol $H_2O(l)$ freezes. In general, to obtain the enthalpy change for the reverse of any process, we just take the negative of the enthalpy change for the original process:

$$\Delta H_{\text{reverse process}} = -\Delta H_{\text{forward process}} \quad \textbf{(16)*}$$

This relation is illustrated in Fig. 7.23.

Sublimation is the direct conversion of a solid into its vapor. Frost disappears on a cold, dry morning as the ice sublimes directly into water vapor. Solid carbon dioxide also sublimes, which is why it is called "dry ice." Each winter on Mars, solid carbon dioxide is deposited as polar frost, which sublimes when the feeble summer arrives (Fig. 7.24). The **enthalpy of sublimation,** ΔH_{sub}, is the molar enthalpy change when a solid sublimes:

$$\Delta H_{sub} = H_m(\text{vapor}) - H_m(\text{solid}) \quad (17)$$

Because enthalpy is a state function, the enthalpy of sublimation of a substance is the same whether the transition takes place in one step, directly from solid to gas, or we imagine it as taking place in two steps, first from solid to liquid and then from liquid to gas. The enthalpy of sublimation of a substance must therefore be equal to the sum of the enthalpies of fusion and vaporization, provided that they are measured at the same temperature (Fig. 7.25):

$$\Delta H_{sub} = \Delta H_{fus} + \Delta H_{vap} \quad (18)^*$$

Self-Test 7.10A The enthalpy of fusion of sodium metal is 2.6 $kJ \cdot mol^{-1}$ at 25°C, and the enthalpy of sublimation of solid sodium at that temperature is 101 $kJ \cdot mol^{-1}$. What is the enthalpy of vaporization of sodium at 25°C?

[***Answer:*** 98 $kJ \cdot mol^{-1}$]

Self-Test 7.10B The enthalpy of vaporization of methanol is 38 $kJ \cdot mol^{-1}$ at 25°C, and the enthalpy of fusion is 3 $kJ \cdot mol^{-1}$ at the same temperature. What is the enthalpy of sublimation of methanol at that temperature?

The enthalpy change for a reverse reaction is the negative of the enthalpy change for the forward reaction. Enthalpy changes can be added to obtain the value for an overall process.

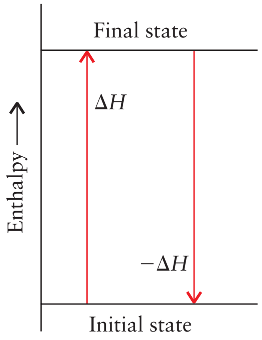

FIGURE 7.23 The enthalpy change for a reverse process has the same value but the opposite sign of the enthalpy change for the forward process at the same temperature.

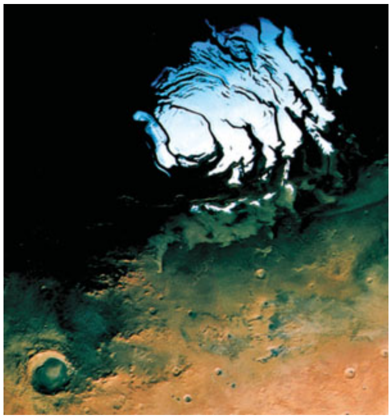

FIGURE 7.24 The polar ice caps on Mars extend and recede with the seasons. They are mostly solid carbon dioxide and form by direct conversion of the gas into a solid. They disappear by sublimation. Although some water ice is also present in the polar caps, the temperature on Mars never becomes high enough to melt it. On Mars, ice is just another rock.

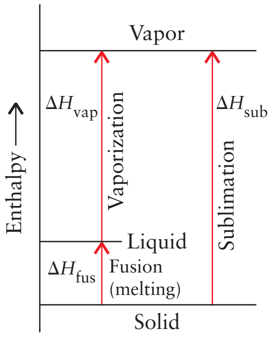

FIGURE 7.25 Because enthalpy is a state property, the enthalpy of sublimation can be expressed as the sum of the enthalpies of fusion and vaporization measured at the same temperature.

7.12 Heating Curves

The enthalpies of fusion and vaporization affect the appearance of the *heating curve* of a substance. A **heating curve** is the graph showing the variation in the temperature of a sample as it is heated at a constant rate at constant pressure and therefore at a constant rate of increase in enthalpy (Box 7.1).

Consider what happens when we heat a sample of very cold ice. As we see in Fig. 7.26, at first its temperature rises steadily. Although the molecules are still locked in a solid mass, they are oscillating more and more vigorously around their mean positions. However, once the temperature has reached the melting point, the molecules have enough energy to move past one another. At this temperature, all the added energy is used to overcome the attractive forces between molecules. Thus, although heating continues, the temperature remains constant at the melting point until all the ice has melted. Only then does the temperature rise again, and the rise continues right up to the boiling point. At the boiling point, the temperature rise again comes to a halt. Now the water molecules have enough energy to escape into the vapor state, and all the heat supplied is used to form the vapor. After the sample has evaporated and heating continues, the temperature of the vapor rises again.

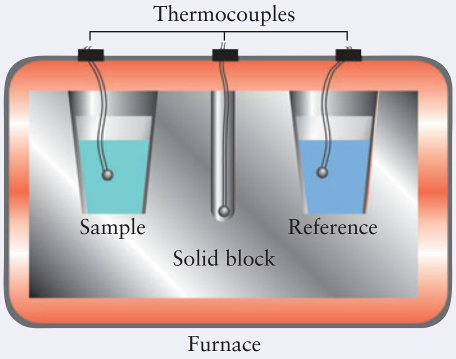
Thinking point: What is the molar heat capacity of water at its boiling point?

The steeper the slope of a heating curve, the lower the heat capacity. In the heating curve for water, for instance, the heating curves of the solid and vapor phases have steeper slopes than the liquid; therefore, we know that the liquid has a greater heat capacity than either the solid or the gas phase does. The high heat capacity of liquid water is due largely to the extensive hydrogen-bonding network that survives in the liquid. The molecules are linked to one another by loose intermolecular hydrogen bonds

BOX 7.1 HOW DO WE KNOW . . . THE SHAPE OF A HEATING CURVE?

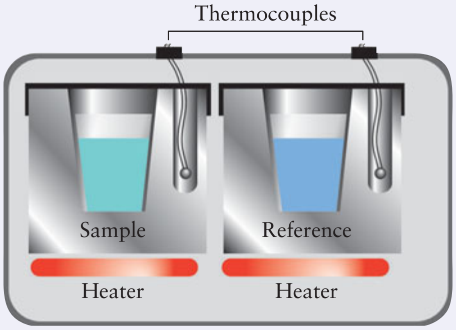
The heating curve of a substance shows how its temperature changes as heat is supplied at a constant rate, usually at constant pressure. How are these curves produced? Simple laboratory heaters can be used to obtain a crude estimate of a heating curve. However, for accuracy, one of two related techniques is normally used.

In *differential thermal analysis* (DTA), equal masses of a sample and a reference material that will not undergo any phase changes, such as Al_2O_3 (which melts at a very high temperature), are inserted into two separate sample wells in a large steel block that acts as a heat sink (see the following illustration). Because the steel block is so large, it is possible to heat the sample and reference at the same slow and accurately monitored rate. Thermocouples are placed in each well and in the block itself. Then the block is gradually heated and the temperatures of the sample and the reference are compared. An electrical signal is generated if the temperature of the sample suddenly stops rising while that of the reference continues to rise. Such an event signals an endothermic process in the sample, such as a phase change. The output of a DTA analysis is a *thermogram*, which shows the temperatures of phase changes as heat absorption peaks at the transition temperatures.



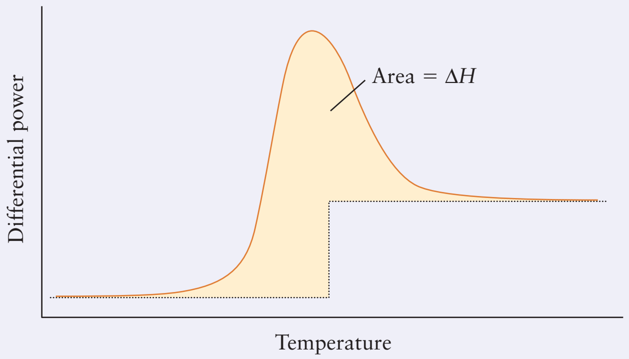
In differential thermal analysis, a sample and reference material are placed in the same large metal heat sink. Changes in the heat capacity of the sample are measured by noting differences in temperature between the sample and the reference materials as they are heated at the same rate.

In *differential scanning calorimetry* (DSC), higher precision can be obtained and heat capacities can be measured. The apparatus is similar to that for a DTA analysis, with the primary difference being that the sample and reference are in separate heat sinks that are heated by individual heaters (see the following illustration). The temperatures of the two samples are kept the same by differential heating. Even slight temperature differences between the reference and the sample will trigger a switch that sends more or less power to the sample to maintain the constant temperature. If the heat capacity of the sample is higher than the heat capacity of the reference, energy must be supplied at a greater rate to the sample cell. If a phase transition occurs in the sample, a great deal of energy must be supplied to the sample until the phase transition is complete and the temperature begins to rise again.



In a differential scanning calorimeter, a sample and reference material are heated in separate, but identical, metal heat sinks. The temperatures of the sample and reference material are kept the same by varying the power supplied to the two heaters. The output is the difference in power as a function of heat added.

The output of a differential scanning calorimeter is a measure of the power (the rate of energy supply) supplied to the sample cell. The thermogram in the third illustration shows a peak that signals a phase change. The thermogram does not look much like a heating curve, but it contains all the necessary information and is easily transformed into the familiar shape.



A thermogram from a differential scanning calorimeter. The peak indicates a phase change in the sample, and the difference in base line before and after the phase transition is due to the difference in heat capacities of the two phases.

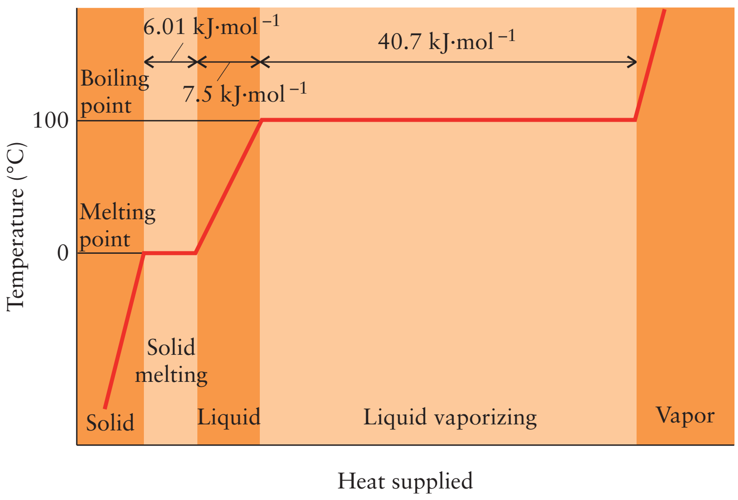


FIGURE 7.26 The heating curve of water. The temperature of the solid rises as heat is supplied. At the melting point, the temperature remains constant, because all the heat is used to melt the sample. When enough heat has been supplied to melt all the solid, the temperature begins to rise again. The heating curve for the liquid is not as steep as for the solid because the liquid has the higher heat capacity. A similar pause occurs at the boiling point.

and the vibrations of these "bonds" can take up energy more readily than can the stiff chemical bonds between atoms.

> ***The temperature of a sample is constant at its melting and boiling points, even though heat is being supplied. The slope of a heating curve is steeper for a phase with a low heat capacity than for one with a high heat capacity.***

THE ENTHALPY OF CHEMICAL CHANGE

We have seen that enthalpy changes accompany physical changes, such as vaporization. The same principles apply to the energy and enthalpy changes that accompany chemical changes. Enthalpies of chemical change are important in many areas of chemistry, such as the selection of materials that make good fuels, the design of chemical plants, and the study of biochemical processes.

7.13 Reaction Enthalpies

Every chemical reaction is accompanied by a change in energy, and commonly that energy is released as heat. For example, complete reaction with oxygen is called **combustion** and the combustion of methane, the major component of natural gas, is the following reaction:

$$CH_4(g) + 2\,O_2(g) \longrightarrow CO_2(g) + 2\,H_2O(l)$$

Calorimetry shows that burning 1.00 mol $CH_4(g)$ produces 890. kJ of heat at 298 K and 1 bar. To report this value, we write

$$CH_4(g) + 2\,O_2(g) \longrightarrow CO_2(g) + 2\,H_2O(l) \qquad \Delta H = -890.\text{ kJ} \qquad \textbf{(A)}$$

Note that, although burning takes place at much higher temperatures than 298 K, the value of ΔH is determined by the difference in enthalpies of the products and reactants, both measured at 298 K.

This entire expression is called a **thermochemical equation,** and consists of a chemical equation together with a statement of the **reaction enthalpy,** the corresponding enthalpy change. The stoichiometric coefficients indicate the number of moles that react to give the reported change in enthalpy. Therefore, in this case, the enthalpy change is that resulting from the complete reaction of 1 mol $CH_4(g)$ and 2 mol $O_2(g)$. If the same reaction is written with the coefficients all multiplied by 2, then the change in enthalpy will be twice as great:

$$2\,CH_4(g) + 4\,O_2(g) \longrightarrow 2\,CO_2(g) + 4\,H_2O(l) \qquad \Delta H = -1780\text{ kJ}$$

This result makes sense because the equation now represents the burning of twice as much methane.

We saw in Section 7.11 that the first law of thermodynamics implies that, because enthalpy is a state function, the enthalpy change for the reverse of a process is the negative of the enthalpy change of the forward process. The same relation applies to forward and reverse chemical reactions. For the reverse of reaction A, for instance, we can write

$$CO_2(g) + 2\,H_2O(l) \longrightarrow CH_4(g) + 2\,O_2(g) \qquad \Delta H = +890.\text{ kJ}$$

Once we know the reaction enthalpy, we can calculate the enthalpy change, and therefore the heat released or required, for any amount, mass, or volume of reactant consumed or product formed. As shown in the following example, we carry out a stoichiometry calculation like those described in Section L but with heat treated as a reactant or a product.

EXAMPLE 7.7 Determining a reaction enthalpy from experimental data

When 0.113 g of benzene, C_6H_6, burns in excess oxygen in a calibrated constant-pressure calorimeter with a heat capacity of 551 J·(°C)$^{-1}$, the temperature of the calorimeter rises by 8.60°C. Write the thermochemical equation for

$$2\ C_6H_6(l) + 15\ O_2(g) \longrightarrow 12\ CO_2(g) + 6\ H_2O(l)$$

Anticipate Because the temperature rises, the reaction is exothermic and therefore we should expect ΔH to be negative. All combustions are exothermic.

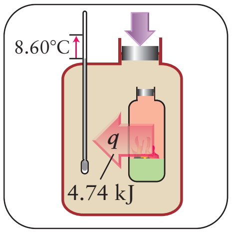
PLAN The heat released by the reaction at constant pressure is calculated from the temperature change multiplied by the heat capacity of the calorimeter. Use the molar mass of one species (the benzene) to convert the heat released into the reaction enthalpy corresponding to the thermochemical equation as written (for 2 mol C_6H_6). From Appendix 2A, the molar mass of benzene is 78.12 g·mol^{-1}.

What should we assume? That all the heat released by the reaction is absorbed by the calorimeter, with none lost to the rest of the surroundings.

SOLVE

Find the heat transferred to the calorimeter from $q_{cal} = C_{cal}\Delta T$.

$$q_{cal} = [551\ \text{J}\cdot(°\text{C})^{-1}] \times (8.60°\text{C}) = 8.60 \times 551\ \text{J}\ (4.74\ \text{kJ})$$



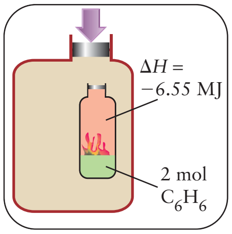
Calculate the amount of C_6H_6 that reacts from $n = m/M$.

$$n = \frac{0.113\ \text{g}}{78.12\ \text{g}\cdot\text{mol}^{-1}} = \frac{0.113}{78.12}\ \text{mol}$$

Because the stoichiometric coefficient of C_6H_6 in the chemical equation is 2, calculate ΔH for 2 mol C_6H_6 from $\Delta H = q \times (2\ \text{mol})/n$. Because the reaction is exothermic, ΔH is negative.

$$\Delta H = -\frac{(2\ \text{mol}) \times (8.60 \times 551\ \text{J})}{(0.113/78.12)\ \text{mol}}$$

$$= -6.55 \times 10^6\ \text{J}\ (-6.55\ \text{MJ})$$



We can therefore write the thermochemical equation as

$$2\ C_6H_6(l) + 15\ O_2(g) \longrightarrow 12\ CO_2(g) + 6\ H_2O(l) \qquad \Delta H = -6.55\ \text{MJ}$$

Evaluate As expected, the enthalpy is negative, indicating an exothermic reaction.

Self-Test 7.11A When 0.231 g of phosphorus reacts with chlorine to form phosphorus trichloride, PCl_3, in a constant-pressure calorimeter of heat capacity 216 J·(°C)$^{-1}$, the temperature of the calorimeter rises by 11.06°C. Write the thermochemical equation for the reaction.

[***Answer:*** $2\ P(s) + 3\ Cl_2(g) \longrightarrow 2\ PCl_3(l)$, $\Delta H = -641$ kJ]

Self-Test 7.11B When 0.338 g of pentane, C_5H_{12}, burns in an excess of oxygen to form carbon dioxide and liquid water in the same calorimeter as that used in Self-Test 7.11A, the temperature rises by 76.7°C. Write the thermochemical equation for the reaction.

A thermochemical equation is a statement of a chemical equation and the corresponding reaction enthalpy, the enthalpy change for the stoichiometric amounts of substances in the chemical equation.

7.14 The Relation Between ΔH and ΔU

We have seen that a constant-pressure calorimeter and a constant-volume bomb calorimeter measure changes in different state functions: at constant volume, the heat transfer is interpreted as ΔU; at constant pressure, it is interpreted as ΔH. However, it is sometimes necessary to convert the measured value of ΔU into ΔH. For example, it is easy to measure the heat released by the combustion of glucose in a bomb calorimeter, but to use that information in assessing energy changes in metabolism, which take place at constant pressure, we need the enthalpy of reaction.

For reactions in which no gas is generated or consumed, little expansion work is done as the reaction proceeds and the difference between ΔH and ΔU is negligible; so we can set $\Delta H = \Delta U$. However, if a gas is formed in the reaction, so much expansion work is done to make room for the gaseous products that the difference can be significant. We can use the ideal gas law to relate the values of ΔH and ΔU for gases that behave ideally.

HOW DO WE DO THAT?

To calculate the relation between ΔH and ΔU for a chemical reaction, we suppose that the amount of ideal gas reactant molecules is n_{initial}. Because for an ideal gas $PV = nRT$, the initial enthalpy is

$$H_{\text{initial}} = U_{\text{initial}} + PV_{\text{initial}} = U_{\text{initial}} + n_{\text{initial}}RT$$

After the reaction is complete, the amount of ideal gas product molecules is n_{final}. The enthalpy is then

$$H_{\text{final}} = U_{\text{final}} + PV_{\text{final}} = U_{\text{final}} + n_{\text{final}}RT$$

The difference is

$$\Delta H = H_{\text{final}} - H_{\text{initial}} = \Delta U + (n_{\text{final}} - n_{\text{initial}})RT$$

We have deduced that

$$\Delta H = \Delta U + \Delta n_{\text{gas}}RT \qquad \textbf{(19)*}$$

where $\Delta n_{\text{gas}} = n_{\text{final}} - n_{\text{initial}}$ is the change in the amount of gas molecules in the reaction (positive for net gas formation, negative for net gas consumption). Notice that ΔH is less negative (more positive) than ΔU for reactions that generate gases: less energy can be obtained from a reaction as heat at constant pressure than at constant volume because the system must use some energy to expand to make room for the reaction products. For reactions with no change in the amount of gas, the two quantities are about the same.

EXAMPLE 7.8 Relating the enthalpy change and internal energy change for a chemical reaction

A constant-volume calorimeter showed that the heat generated by the combustion of 1.000 mol glucose molecules in the reaction $C_6H_{12}O_6(s) + 6\,O_2(g) \longrightarrow 6\,CO_2(g) + 6\,H_2O(g)$ is 2559 kJ at 298 K, and so $\Delta U = -2559$ kJ. What is the change in enthalpy for the same reaction?

Anticipate Because there is a net formation of gas (from 6 mol to 12 mol), we expect ΔH to be less negative than ΔU.

What should we assume? That each gas is ideal.

FIGURE 7.27 In this preparation of rocket fuel for the space shuttle, powdered aluminum is mixed with an oxidizing agent in a liquid polymer base that hardens inside the booster rocket shell.

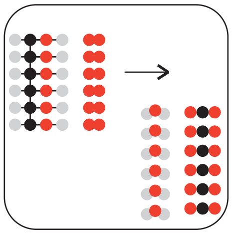
SOLVE

From $\Delta n_{gas} = n_{final} - n_{initial}$,

$$\Delta n_{gas} = 12 - 6 \text{ mol} = +6 \text{ mol}$$

From $\Delta H = \Delta U + \Delta n_{gas}RT$,

$$\Delta H = -2559 \text{ kJ} + [(6 \text{ mol}) \times (8.3145 \text{ J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}) \times (298 \text{ K})]$$
$$= -2559 \text{ kJ} + 14.9 \text{ kJ} = -2544 \text{ kJ}$$



Evaluate As we anticipated, the reaction enthalpy is less negative than the reaction internal energy.

Self-Test 7.12A The thermochemical equation for the combustion of cyclohexane, C_6H_{12}, is $C_6H_{12}(l) + 9\ O_2(g) \longrightarrow 6\ CO_2(g) + 6\ H_2O(l)$, $\Delta H = -3920$ kJ at 298 K. What is the change in internal energy for the combustion of 1.00 mol $C_6H_{12}(l)$ at 298 K?

[***Answer:*** -3.91×10^3 kJ]

Self-Test 7.12B The reaction $4\ Al(s) + 3\ O_2(g) \longrightarrow 2\ Al_2O_3(s)$ was investigated as part of a study on using aluminum powder as a rocket fuel (Fig. 7.27). It was found that 1.000 mol Al produced 3378 kJ of heat in this reaction under constant-pressure conditions at 1000.°C. What is the change in internal energy for the combustion of 1.000 mol Al at 1000.°C?

The reaction enthalpy is less negative (more positive) than the reaction internal energy for reactions that generate gases; for reactions with no change in the amount of gas, the two quantities are almost the same.

7.15 Standard Reaction Enthalpies

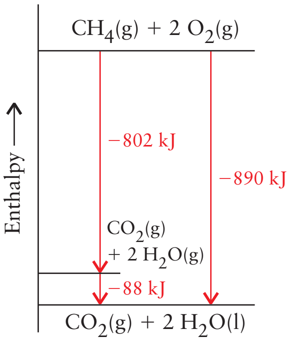


FIGURE 7.28 The enthalpy changes for the reactions in which 1 mol $CH_4(g)$ burns to give carbon dioxide and water in either the gaseous (left) or the liquid (right) state. The difference in enthalpy is equal to 88 kJ, the enthalpy of vaporization of 2 mol $H_2O(l)$.

You may see some tables reporting data at 1 atm, the former standard. The small change in standard pressure makes a negligible difference to most numerical values, and except in very precise work it is normally safe to use data compiled for 1 atm instead of 1 bar.

Because the heat released or absorbed by a reaction depends on the physical states of the reactants and products, when calculating the reaction enthalpy we need to specify the state of each substance. For example, when describing the combustion of methane, we can write two different thermochemical equations for two different sets of products:

$$CH_4(g) + 2\ O_2(g) \longrightarrow CO_2(g) + 2\ H_2O(g) \qquad \Delta H = -802 \text{ kJ} \qquad \textbf{(B)}$$
$$CH_4(g) + 2\ O_2(g) \longrightarrow CO_2(g) + 2\ H_2O(l) \qquad \Delta H = -890. \text{ kJ} \qquad \textbf{(C)}$$

In the first reaction, the water is produced as a vapor; in the second, it is produced as a liquid. The heat generated is different in each case. We have already seen that the enthalpy of water vapor is 44 $\text{kJ}\cdot\text{mol}^{-1}$ higher than that of liquid water at 25°C (see Table 7.3). As a result, an additional 88 kJ (for 2 mol H_2O) remains stored in the system if water vapor is formed (Fig. 7.28). If the 2 mol $H_2O(g)$ subsequently condenses, an additional 88 kJ is given off as heat.

An enthalpy of reaction also depends on the conditions (such as the pressure). All the tables in this book list data for reactions in which each reactant and product is in its **standard state,** its pure form at exactly 1 bar. The standard state of liquid water is pure water at 1 bar. The standard state of ice is pure ice at 1 bar. A solute in a liquid solution is in its standard state when its concentration is 1 $\text{mol}\cdot\text{L}^{-1}$. The standard value of a property X (that is, the value of X for the standard state of the substance) is denoted $X°$.

The **standard reaction enthalpy,** $\Delta H°$, is the reaction enthalpy when reactants in their standard states change into products in their standard states. For example, for reaction C, the value $\Delta H° = -890.$ kJ signifies that the heat output is 890. kJ when 1 mol $CH_4(g)$ as pure methane gas at 1 bar is allowed to react with pure oxygen gas at 1 bar, giving pure carbon dioxide gas and pure liquid water, both at 1 bar (Fig. 7.29). Reaction enthalpies do not change very much with pressure over the small ranges normally encountered, so the standard value gives a good indication of the change in enthalpy for pressures near 1 bar.

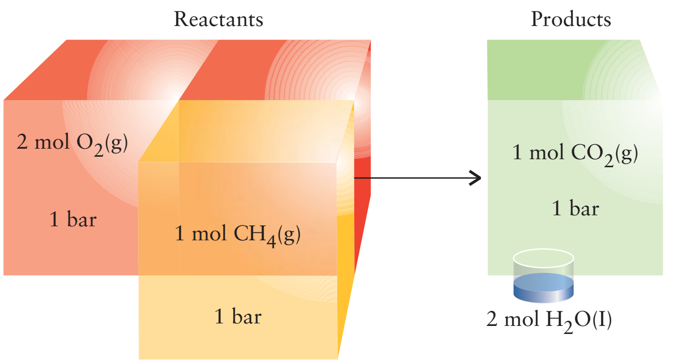

FIGURE 7.29 The standard reaction enthalpy is the difference in enthalpy between the pure products and the pure reactants, each at 1 bar and the specified temperature (which is commonly but not necessarily 298 K). The scheme here is for the combustion of methane gas to carbon dioxide gas and liquid water.

Most thermochemical data are reported for 25°C (more precisely, for 298.15 K). Temperature is not part of the definition of standard states: we can have a standard state at any temperature; 298.15 K is simply the most common temperature used in tables of data. All reaction enthalpies used in this text are for 298.15 K unless another temperature is indicated.

Standard reaction enthalpies refer to reactions in which the reactants and products are in their standard state, the pure form at 1 bar; they are usually reported for a temperature of 298.15 K.

7.16 Combining Reaction Enthalpies: Hess's Law

Enthalpy is a state function; therefore, the value of ΔH is independent of the path between given initial and final states. We saw an application of this approach in Section 7.11, when we calculated the enthalpy change for an overall physical process as the sum of the enthalpy changes for a series of two individual steps. The same rule applied to chemical reactions is known as **Hess's law:** *the overall reaction enthalpy is the sum of the reaction enthalpies of the steps into which the reaction can be divided.* Hess's law applies even if the intermediate reactions or the overall reaction cannot actually be carried out. Provided that the equation for each step balances and the individual equations add up to the equation for the reaction of interest, a reaction enthalpy can be calculated from any convenient sequence of reactions (Fig. 7.30).

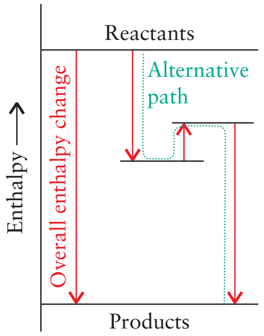

FIGURE 7.30 If an overall reaction can be broken down into a series of steps, then the corresponding overall reaction enthalpy is the sum of the reaction enthalpies of those steps. None of the steps need be a reaction that can actually be carried out.

As an example of Hess's law, let's consider the oxidation of carbon as graphite, denoted C(gr), to carbon dioxide:

$$C(gr) + O_2(g) \longrightarrow CO_2(g)$$

This reaction can be thought of as the outcome of two steps. One step is the oxidation of carbon to carbon monoxide:

$$C(gr) + \tfrac{1}{2}O_2(g) \longrightarrow CO(g) \qquad \Delta H° = -110.5\ \text{kJ}$$

The second step is the oxidation of carbon monoxide to carbon dioxide:

$$CO(g) + \tfrac{1}{2}O_2(g) \longrightarrow CO_2(g) \qquad \Delta H° = -283.0\ \text{kJ}$$

This two-step process is an example of a **reaction sequence,** a series of reactions in which the products of one reaction take part as reactants in another reaction. The equation for the overall reaction, the net outcome of the sequence, is the sum of the equations for the intermediate steps:

$$C(gr) + \tfrac{1}{2}O_2(g) \longrightarrow CO(g) \qquad \Delta H° = -110.5\ \text{kJ} \qquad \text{(a)}$$

$$CO(g) + \tfrac{1}{2}O_2(g) \longrightarrow CO_2(g) \qquad \Delta H° = -283.0\ \text{kJ} \qquad \text{(b)}$$

$$C(gr) + O_2(g) \longrightarrow CO_2(g) \qquad \Delta H° = -393.5\ \text{kJ} \qquad \text{(a + b)}$$

The same procedure is used to predict the enthalpies of reactions that we cannot measure directly in the laboratory. The procedure is described in Toolbox 7.1.

TOOLBOX 7.1 HOW TO USE HESS'S LAW

CONCEPTUAL BASIS

Because enthalpy is a state function, the enthalpy change of a system depends only on its initial and final states. Therefore, we can carry out a reaction in one step or, if that is not convenient, visualize it as the sum of several steps; the reaction enthalpy is the same in each case.

PROCEDURE

To use Hess's law to find the enthalpy of a given reaction, we find a sequence of reactions with known reaction enthalpies that adds up to the reaction of interest.

Step 1 Select one of the reactants in the overall reaction and write down a chemical equation in which it also appears as a reactant.
Step 2 Select one of the products in the overall reaction and write down a chemical equation in which it also appears as a product. Add this equation to the equation written in step 1 and cancel species that appear on both sides of the equation.
Step 3 Cancel unwanted species in the sum obtained in step 2 by adding an equation that has the same substance or substances on the opposite side of the arrow.
Step 4 Once the sequence is complete, combine the standard reaction enthalpies.

In each step, we may need to reverse the equation or multiply it by a factor. Recall from Eq. 16 that, if we want to reverse a chemical equation, we have to change the sign of the reaction enthalpy. If we multiply the stoichiometric coefficients by a factor, we must multiply the reaction enthalpy by the same factor.

This procedure is illustrated in Example 7.9.

EXAMPLE 7.9 Using Hess's law

Consider the synthesis of propane, C_3H_8, a gas used as camping fuel:

$$3\,C(gr) + 4\,H_2(g) \longrightarrow C_3H_8(g)$$

It is difficult to measure the enthalpy change of this reaction directly. However, standard enthalpies of combustion reactions are easy to measure. Calculate the standard enthalpy of this reaction from the following experimental data:

(a) $C_3H_8(g) + 5\,O_2(g) \longrightarrow 3\,CO_2(g) + 4\,H_2O(l) \qquad \Delta H° = -2220.\ kJ$

(b) $C(gr) + O_2(g) \longrightarrow CO_2(g) \qquad \Delta H° = -394\ kJ$

(c) $H_2(g) + \frac{1}{2}O_2(g) \longrightarrow H_2O(l) \qquad \Delta H° = -286\ kJ$

PLAN Use the procedure in Toolbox 7.1 to combine the chemical equations in a way that yields the desired equation.

SOLVE

Step 1 To treat carbon as a reactant, select (b) and multiply it through by 3.

$$3\,C(gr) + 3\,O_2(g) \longrightarrow 3\,CO_2(g) \qquad \Delta H° = 3 \times (-394\ kJ) = -1182\ kJ$$

Step 2 Reverse equation (a), changing the sign of its reaction enthalpy.

$$3\,CO_2(g) + 4\,H_2O(l) \longrightarrow C_3H_8(g) + 5\,O_2(g) \qquad \Delta H° = +2220.\ kJ$$

Add the two preceding equations and their enthalpies.

$$3\,C(gr) + 3\,O_2(g) + 3\,CO_2(g) + 4\,H_2O(l) \longrightarrow C_3H_8(g) + 5\,O_2(g) + 3\,CO_2(g)$$
$$\Delta H° = (-1182) + (2200)\ kJ = +1038\ kJ$$

Simplify the equation.

$$3\,C(gr) + 4\,H_2O(l) \longrightarrow C_3H_8(g) + 2\,O_2(g) \qquad \Delta H° = +1038\ kJ$$

Step 3 To cancel the unwanted H_2O and O_2, multiply equation (c) by 4.

$$4\,H_2(g) + 2\,O_2(g) \longrightarrow 4\,H_2O(l) \qquad \Delta H° = 4 \times (-286\ kJ) = -1144\ kJ$$

Step 4 Add the equations in steps 2 and 3.

$$3\,C(gr) + 4\,H_2(g) + 4\,H_2O(l) + 2\,O_2(g) \longrightarrow C_3H_8(g) + 2\,O_2(g) + 4\,H_2O(l)$$
$$\Delta H° = 1038 + (-1144)\text{ kJ} = -106\text{ kJ}$$

Simplify the equation by canceling species that appear on both sides.

$$3\,C(gr) + 4\,H_2(g) \longrightarrow C_3H_8(g) \qquad \Delta H° = -106\text{ kJ}$$

Self-Test 7.13A Gasoline, which contains octane, may burn to carbon monoxide if the air supply is restricted. Determine the standard reaction enthalpy for the incomplete combustion of liquid octane to carbon monoxide gas and liquid water from the standard reaction enthalpies for the combustions of octane and carbon monoxide:

$$2\,C_8H_{18}(l) + 25\,O_2(g) \longrightarrow 16\,CO_2(g) + 18\,H_2O(l) \qquad \Delta H° = -10\,942\text{ kJ}$$
$$2\,CO(g) + O_2(g) \longrightarrow 2\,CO_2(g) \qquad \Delta H° = -566.0\text{ kJ}$$

[***Answer:*** $2\,C_8H_{18}(l) + 17\,O_2(g) \longrightarrow 16\,CO(g) + 18\,H_2O(l)$, $\Delta H° = -6414$ kJ]

Self-Test 7.13B Methanol is a clean-burning liquid fuel proposed as a replacement for gasoline. Suppose it could be produced by the controlled reaction of the oxygen in air with methane. Find the standard reaction enthalpy for the formation of 1 mol $CH_3OH(l)$ from methane and oxygen, given the following information:

$$CH_4(g) + H_2O(g) \longrightarrow CO(g) + 3\,H_2(g) \qquad \Delta H° = +206.10\text{ kJ}$$
$$2\,H_2(g) + CO(g) \longrightarrow CH_3OH(l) \qquad \Delta H° = -128.33\text{ kJ}$$
$$2\,H_2(g) + O_2(g) \longrightarrow 2\,H_2O(g) \qquad \Delta H° = -483.64\text{ kJ}$$

According to Hess's law, thermochemical equations for the individual steps of a reaction sequence may be combined to give the thermochemical equation for the overall reaction.

7.17 The Heat Output of Reactions

Most of our energy comes from the Sun, either directly or indirectly. The energy of all the solar radiation absorbed by the vegetation on Earth is enough to build about 6×10^{14} kg of glucose a year. Most of this glucose is converted to starches and cellulose. As long as these compounds do not decay completely back to carbon dioxide and water, dead vegetation remains a store of energy. If losses through forest fires are ignored, this store, called the *biomass*, increases by about 10^{19} kJ each year, which is about 20 times the current annual global industrial demand for energy. However, because biomass is bulky and widely dispersed, most of our fuels are fossil fuels, energy-rich decomposition products of ancient vegetation that have been kept from oxidizing by favorable geological formations. Coal, for example, originated as matter that collected at the bottoms of swamps (see Section 18.10). It has been estimated that less than 0.07% of all vegetation has avoided oxidation to be stored in this way. The rate at which biomass energy is stored in a useful form is therefore only about 10^{11} kJ per year. Yet we are using it at the rate of 5×10^{17} kJ per year, which is 5 million times more rapidly than it is being stored. Therefore, conservation of existing energy resources has grown in importance, along with research into alternative fuels (Box 7.2).

The **standard enthalpy of combustion**, $\Delta H_c°$, is the change in enthalpy per mole of a substance that is burned in a combustion reaction under standard conditions. The products of the combustion of an organic compound are carbon dioxide gas and liquid water; any nitrogen present is released as N_2, unless other products are specified. Standard enthalpies of combustion are listed in Table 7.4 and Appendix 2A (for organic compounds). One practical measure of a fuel's value, also shown in Table 7.4, is its **specific enthalpy**, the enthalpy of combustion per gram. Fuels with a high specific

BOX 7.2 WHAT HAS THIS TO DO WITH . . . THE ENVIRONMENT?

Alternative Fuels

Our complex modern life style was made possible by the discovery and refining of fossil fuels, fuels that are the result of the decay of organic matter laid down millions of years ago. The natural gas that heats our homes, the gasoline that powers our automobiles, and the coal, gas, and oil that provide much of our electrical power are fossil fuels. Vast reserves of petroleum, the source of liquid hydrocarbon fuels such as gasoline and coal, exist in many areas of the world. However, although large, these reserves are limited and essentially irreplaceable. Yet we are using them up rapidly.

Alternative and sustainable power generation methods, such as hydroelectric power, wind power, geothermal power, solar power, and alternative fuels are being sought to reduce the demand for fossil fuels. Four of the most promising alternative fuels are hydrogen, ethanol, methane, and biodiesel. Hydrogen is extracted from ocean water by electrolysis. Ethanol is obtained by fermenting biomass, the name given to plant materials that can be burned or reacted to produce fuels. Methane is generated by bacterial digestion of wastes such as sewage and agricultural wastes. In each case, the fuel is renewable. That means the source of the fuel is replenished every year by the Sun. The use of hydrogen as a fuel is discussed in Section 15.3. Here, we look at ethanol, methane, and biodiesel.

Ethanol, CH_3CH_2OH, is produced from the biological fermentation of the starches in grains, mainly corn. It is used as an additive in gasoline or as "E85," which is 85% ethanol and 15% gasoline by volume. Ethanol currently makes up about 10% by volume of gasoline in the United States, thereby reducing pollution as well as the use of petroleum. The 2005 U.S. Energy Policy Act required that, by 2012, 7.5 billion gallons (2.8×10^{10} L) of renewable fuel be used per year. The 2007 Energy Independence and Security Act requires that by 2022 the annual usage of renewable fuels increase to 36 billion gallons (1.4×10^{11} L, about 23% of the total annual volume of liquid fuels used in the United States).

The oxygen atom in the ethanol molecule reduces emissions of carbon monoxide and hydrocarbons by helping to ensure complete combustion. However, because ethanol is already partly oxygenated, it can provide less energy per liter; currently mileage for a car burning E85 is 15% lower than for pure gasoline. One bushel of corn (about 30 L) can produce nearly 10 L of ethanol. A problem with ethanol as a fuel is that the sugars and starches fermented to produce it are expensive. However, the cellulose in straw and cornstalks left behind as stubble when grains

The cellulose-based waste biomass in this reactor is being digested by special enzymes that break it down into ethanol. These enzymes are being intensively studied to improve the efficiency of conversion.

enthalpy release a lot of heat per gram when they burn. Hence, specific enthalpy is an important criterion when mass is important, as it is in airplanes and spacecraft. Notice that fuels that have already been partially oxygenated, such as glucose and ethanol, have lower specific enthalpies than the hydrocarbons.

TABLE 7.4 Standard Enthalpies of Combustion at 25°C*

Substance	Formula	$\Delta H_c°$ (kJ·mol^{-1})	Specific enthalpy (kJ·g^{-1})
benzene	C_6H_6(l)	−3268	41.8
carbon	C(s, graphite)	−394	32.8
ethanol	C_2H_5OH(l)	−1368	29.7
ethyne (acetylene)	C_2H_2(g)	−1300.	49.9
glucose	$C_6H_{12}O_6$(s)	−2808	15.59
hydrogen	H_2(g)	−286	142
methane	CH_4(g)	−890.	55
octane	C_8H_{18}(l)	−5471	48
propane	C_3H_8(g)	−2220.	50.35
urea	$CO(NH_2)_2$(s)	−632	10.52

*In a combustion, carbon is converted into carbon dioxide, hydrogen into liquid water, and nitrogen into nitrogen gas. More values are given in Appendix 2A.

These tanks at a water treatment facility are used to generate a mixture of methane and carbon dioxide by anaerobic digestion of sewage. The methane produced provides much of the power needed to run the facility.

are harvested is now attracting attention. Cellulose is the structural material in plants (see Section 19.14). It is made up of simple sugars, just as starches are, but the bacteria that ferment starches cannot digest cellulose. Research is now being conducted on enzymes that break down cellulose into sugars that can be digested. This process would greatly increase the biomass available for fuel production, because straw, wood, grasses, and in fact, nearly any plant materials, could be used for fuel. It would also partly avoid the problem of the production of fuel being in competition with the production of food.

Methane, CH_4, is found in underground reserves as the primary component of natural gas, but it is also obtained from biological materials. The "digestion" of the biomaterials by bacteria is anaerobic, which means that it takes place in the absence of oxygen. Currently, many sewage treatment plants have anaerobic digesters that produce the methane used to operate the plants. To generate methane by anaerobic digestion on a large-scale basis, additional materials, such as sugars from the enzymatic breakdown of biomass, would need to be used. Methane would be less useful than ethanol as a transportation fuel, because it is a gas and so has a low *enthalpy density*, the enthalpy of combustion per liter. However, it can be used wherever natural gas is used.

Biodiesel is the term used for diesel fuel that comes from renewable, biological sources, such as vegetable oil. Even used oils, such as those discarded from restaurant deep fryers, can be filtered and used as biodiesel. Biodiesel engines are more efficient than gasoline engines, as the fuel has a high energy density (enthalpy of combustion per liter). A problem with biodiesel is that it is more viscous than gasoline and can solidify at low temperatures.

These alternative fuels do produce carbon dioxide when burned and thus contribute to the greenhouse effect and global warming (Box 15.1). However, they can be renewed every year, as long as the Sun shines and produces green plants.

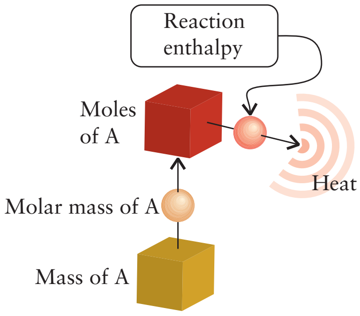
Allen, "Crunching the Numbers on Alternative Fuels," *Popular Mechanics,* May, 2006, http://www.popularmechanics.com/science/earth/2690341.html.

A great advantage of hydrogen over hydrocarbon fuels is that it produces no carbon dioxide when it burns. Carbon dioxide is potentially harmful, because it contributes to the greenhouse effect (see Box 15.1). However, although hydrogen forms only water when it burns, its use is limited by the high volume required for a gas. Chemists are working to synthesize solid compounds that concentrate hydrogen and release it as needed. Candidates include the hydrides formed when titanium, copper, and other metals are heated in hydrogen. These compounds occupy a much smaller volume than the equivalent amount of hydrogen gas and release hydrogen when heated or treated with acid. One example is an iron titanium hydride of approximate formula $FeTiH_2$. Another promising low-density storage medium for hydrogen is offered by carbon nanotubes (see Section 6.19).

We have seen in Toolbox 7.1 how to use enthalpies of combustion to obtain the standard enthalpies of reactions. Here we consider another practical application—the choice of a fuel. For example, suppose we want to know the heat output from the combustion of 150. g of methane. The thermochemical equation allows us to write the following relation

$$1 \text{ mol } CH_4 \simeq 890. \text{ kJ}$$

and to use it as a conversion factor in the usual way (**1**).



1

EXAMPLE 7.10 Calculating the heat output of a fuel

How much butane should a backpacker carry? Calculate the mass of butane that you would need to burn to obtain 350. kJ of heat, which is just enough energy to heat 1 L of water from 17°C to boiling at sea level (if we ignore all heat losses). The thermochemical equation is

$$2\ C_4H_{10}(g) + 13\ O_2(g) \longrightarrow 8\ CO_2(g) + 10\ H_2O(l) \qquad \Delta H° = -5756\ kJ$$

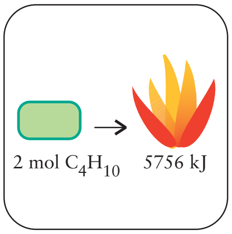
Anticipate From experience, you might suspect that only a few grams of fuel will be sufficient.

PLAN The first step is to convert heat output required into moles of fuel molecules by using the thermochemical equation. Then use the molar mass of the fuel to convert from moles of fuel molecules into grams.

What should we assume? That no heat is lost to the surroundings, so that all the heat generated by the reaction is available to boil the water.

Find the relation of the enthalpy change to amount of fuel molecules from the thermochemical equation.

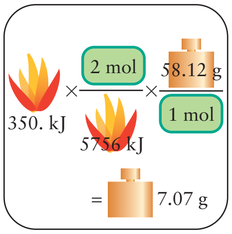
$$5756\ kJ \simeq 2\ mol\ C_4H_{10}$$



Convert heat output into moles of fuel molecules.

$$n(C_4H_{10}) = (350.\ kJ) \times \frac{2\ mol\ C_4H_{10}}{5756\ kJ}$$

$$= \frac{350. \times 2}{5756} mol\ C_4H_{10}\ \ (0.122\ mol\ C_4H_{10})$$



Use $m = nM$ and the molar mass of butane, $58.12\ g{\cdot}mol^{-1}$, to find the mass of reactant.

$$m(C_4H_{10}) = \left(\frac{350. \times 2}{5756} mol\ C_4H_{10}\right) \times (58.12\ g{\cdot}mol^{-1})$$

$$= 7.07\ g\ C_4H_{10}$$

Evaluate The mass needed, just over 7 g, is consistent with our anticipation that only a few grams need be carried.

Self-Test 7.14A The thermochemical equation for the combustion of propane is

$$C_3H_8(g) + 5\ O_2(g) \longrightarrow 3\ CO_2(g) + 4\ H_2O(l) \qquad \Delta H° = -2220.\ kJ$$

What mass of propane must be burned to supply 350. kJ as heat? Would it be easier to pack propane rather than butane?

[***Answer:*** 6.95 g. Yes, propane would be very slightly lighter to carry.]

Self-Test 7.14B Ethanol trapped in a gel is another common camping fuel. What mass of ethanol must be burned to supply 350. kJ as heat? The thermochemical equation for the combustion of ethanol is

$$C_2H_5OH(l) + 3\ O_2(g) \longrightarrow 2\ CO_2(g) + 3\ H_2O(l) \qquad \Delta H° = -1368\ kJ$$

The heat absorbed or released by a reaction can be treated like a reactant or product in a stoichiometric calculation.

7.18 Standard Enthalpies of Formation

There are millions of possible reactions, and it is impractical to list every one with its standard reaction enthalpy. However, chemists have devised an ingenious alternative. First, they report the "standard enthalpies of formation" of substances. Then they combine these quantities to obtain the standard enthalpy of any reaction. Let's look at these two stages in turn.

The **standard enthalpy of formation,** $\Delta H_f°$, of a substance is the standard reaction enthalpy per mole of formula units for the formation of a substance from its elements in their *most stable form*, as in the reaction for the formation of ethanol:

Phosphorus is an exception: white phosphorus is used because it is much easier to obtain pure than the other, more stable allotropes.

$$2\,C(gr) + 3\,H_2(g) + \tfrac{1}{2}O_2(g) \longrightarrow C_2H_5OH(l) \qquad \Delta H° = -277.69\text{ kJ}$$

where gr denotes graphite, the most stable form of carbon at normal temperatures. The chemical equation that corresponds to the standard enthalpy of formation of a substance has the substance as the sole product with a stoichiometric coefficient of 1 (implying the formation of 1 mol of the substance). Sometimes, as here, fractional coefficients are required for the reactants. Because standard enthalpies of formation are expressed in kilojoules per mole of the substance of interest, we report that $\Delta H_f°(C_2H_5OH, l) = -277.69\text{ kJ·mol}^{-1}$. Note also how the substance and its state are used to label the enthalpy change so that we know which species and which form of that species (liquid, in this case) we are talking about.

A note on good practice: You should always be alert to the difference between a quantity per mole of molecules and the same quantity for or of a mole of molecules. Standard enthalpies of formation are expressed per mole of molecules, as in $-277.69\text{ kJ·mol}^{-1}$; the standard enthalpy of forming 1 mol $C_2H_5OH(l)$ is -277.69 kJ. The point might seem picky, but it will help you to keep units straight.

It follows from the definition just given that the standard enthalpy of formation of an element in its most stable form is zero. For instance, the standard enthalpy of formation of C(gr) is zero because C(gr) $\longrightarrow$ C(gr) is a "null reaction" (that is, nothing changes). We write, for instance, $\Delta H_f°(C, gr) = 0$. However, the enthalpy of formation of an element in a form other than its most stable one is nonzero. For example, the conversion of carbon from graphite (its most stable form) into diamond is endothermic:

$$C(gr) \longrightarrow C(diamond) \qquad \Delta H° = +1.9\text{ kJ}$$

The standard enthalpy of formation of diamond is therefore reported as $\Delta H_f°$ (C, diamond) $= +1.9\text{ kJ·mol}^{-1}$. Values for a selection of other substances are listed in Table 7.5 and Appendix 2A.

Now let's see how to combine standard enthalpies of formation to calculate a standard reaction enthalpy. To do so, we imagine that to carry out the reaction we convert

TABLE 7.5 Standard Enthalpies of Formation at 25°C (kJ·mol^{-1})*

Substance	Formula	$\Delta H_f°$	Substance	Formula	$\Delta H_f°$
Inorganic compounds			**Organic compounds**		
ammonia	$NH_3(g)$	−46.11	benzene	$C_6H_6(l)$	+49.0
carbon dioxide	$CO_2(g)$	−393.51	ethanol	$C_2H_5OH(l)$	−277.69
carbon monoxide	$CO(g)$	−110.53	ethyne (acetylene)	$C_2H_2(g)$	+226.73
dinitrogen tetroxide	$N_2O_4(g)$	+9.16			
hydrogen chloride	$HCl(g)$	−92.31	glucose	$C_6H_{12}O_6(s)$	−1268
hydrogen fluoride	$HF(g)$	−271.1	methane	$CH_4(g)$	−74.81
nitrogen dioxide	$NO_2(g)$	+33.18			
nitric oxide	$NO(g)$	+90.25			
sodium chloride	$NaCl(s)$	−411.15			
water	$H_2O(l)$	−285.83			
	$H_2O(g)$	−241.82			

*A much longer list is given in Appendix 2A.

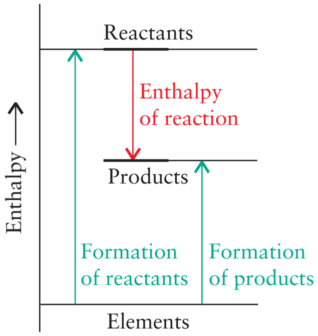


FIGURE 7.31 The reaction enthalpy can be constructed from standard enthalpies of formation by imagining forming the reactants and products from their elements. Then the reaction enthalpy is the difference between the standard enthalpies of formation of products and reactants.

the reactants into the elements in their most stable form, then form the products from those elements. The first step is usually to calculate the reaction enthalpy for the formation of all the products from their elements. For this step, we use the enthalpies of formation of the products. Then, we calculate the reaction enthalpy for the formation of all the reactants from their elements. The difference between these two totals is the standard enthalpy of the reaction (Fig. 7.31):

$$\Delta H° = \sum n\Delta H_f°\,(\text{products}) - \sum n\Delta H_f°(\text{reactants}) \qquad (20)^*$$

In this expression, the n are the stoichiometric coefficients in the chemical equation and the symbol Σ (sigma) means a sum. The first sum is the total standard enthalpy of formation of the products. The second sum is the similar total for the reactants.

EXAMPLE 7.11 Using standard enthalpies of formation to calculate a standard enthalpy of reaction

Amino acids are the building blocks of proteins, which have long chainlike molecules. They are oxidized in the body to urea, carbon dioxide, and liquid water. Is this reaction a source of heat for the body? Use the information in Appendix 2A to predict the standard enthalpy of reaction for the oxidation of the simplest amino acid, glycine (NH_2CH_2COOH), a solid, to solid urea (H_2NCONH_2), carbon dioxide gas, and liquid water:

$$2\ NH_2CH_2COOH(s) + 3\ O_2(g) \longrightarrow H_2NCONH_2(s) + 3\ CO_2(g) + 3\ H_2O(l)$$

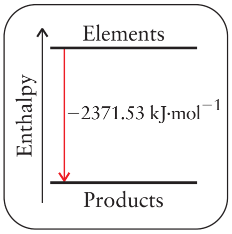
Anticipate We expect a strongly negative value because all combustions are exothermic and this oxidation is like an incomplete combustion.

PLAN First, add together the standard enthalpies of formation of the products, multiplying each value by the appropriate number of moles from the balanced equation. Remember that the standard enthalpy of formation of an element in its most stable form is zero. Then, calculate the total standard enthalpy of formation of the reactants in the same way and use Eq. 20 to calculate the standard reaction enthalpy.

SOLVE

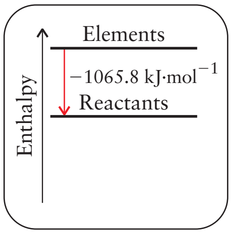
Calculate the total enthalpy of formation of the products.

$$\begin{aligned}\sum n\Delta H_f°(\text{products}) &= (1\text{ mol})\Delta H_f°(H_2NCONH_2, s) + (3\text{ mol})\Delta H_f°(CO_2, g)\\ &\quad + (3\text{ mol})\Delta H_f°(H_2O, l)\\ &= (1\text{ mol})(-333.51\text{ kJ·mol}^{-1}) + (3\text{ mol})(-393.51\text{ kJ·mol}^{-1})\\ &\quad + (3\text{ mol})(-285.83\text{ kJ·mol}^{-1})\\ &= -333.51 + (-1180.53) + (-857.49)\text{ kJ}\\ &= -2371.53\text{ kJ}\end{aligned}$$



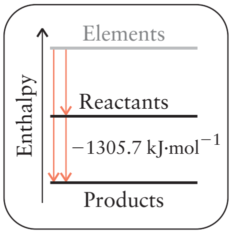
Calculate the total enthalpy of formation of the reactants.

$$\begin{aligned}\sum nH_f°(\text{reactants}) &= (2\text{ mol})\Delta H_f°(NH_2CH_2COOH, s)\\ &\quad + (3\text{ mol})\Delta H_f°(O_2, g)\\ &= (2\text{ mol})(-532.9\text{ kJ·mol}^{-1}) + (3\text{ mol})(0)\\ &= -1065.8\text{ kJ}\end{aligned}$$



From $\Delta H° = \sum n\Delta H_f°(\text{products}) - \sum n\Delta H_f°(\text{reactants})$,

$$\begin{aligned}\Delta H° &= -2371.53 - (-1065.8)\text{ kJ}\\ &= -1305.7\text{ kJ}\end{aligned}$$



Evaluate The thermochemical equation is therefore

$$2\ NH_2CH_2COOH(s) + 3\ O_2(g) \longrightarrow H_2NCONH_2(s) + 3\ CO_2(g) + 3\ H_2O(l) \qquad \Delta H° = -1305.7\ kJ$$

As we anticipated, the reaction is strongly exothermic. Because reactions in the body take place in aqueous solution, this value is not the same as the enthalpy change for the reaction in the body. However, the two values are fairly close. Therefore, the oxidation of glycine, which we have found to be exothermic, is a potential source of energy in the body.

A note on good practice: Enthalpies of formation are expressed in kilojoules per mole and enthalpies of reaction in kilojoules for the reaction as written. Note how the stoichiometric coefficients are interpreted as numbers of moles, and that an unwritten coefficient of 1 for urea is included as 1 mol in the calculation.

Self-Test 7.15A Calculate the standard enthalpy of combustion of glucose from the standard enthalpies of formation in Table 7.5 and Appendix 2A.

[***Answer:*** $-2808\ kJ\cdot mol^{-1}$]

Self-Test 7.15B You have an inspiration: maybe diamonds would make a great fuel! Calculate the standard enthalpy of combustion of diamonds from the information in Appendix 2A.

Standard enthalpies of formation are commonly determined from combustion data by using Eq. 20. The procedure is the same, but the standard reaction enthalpy is known and the unknown value is one of the standard enthalpies of formation.

EXAMPLE 7.12 Using the enthalpy of combustion to calculate an enthalpy of formation

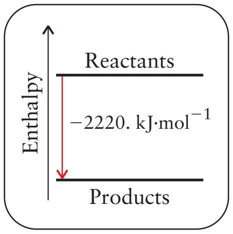
Use the information in Table 7.5 and the enthalpy of combustion of propane gas to calculate the enthalpy of formation of propane, a gas commonly used for camping stoves and outdoor barbecues.

PLAN Use Eq. 20 and the procedure set out in Example 7.11, but solve for the standard enthalpy of formation of propane.

SOLVE

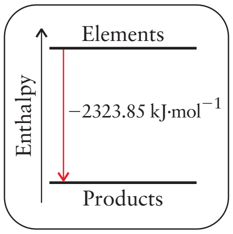
Write the thermochemical equation for the combustion of 1 mol C_3H_8.

$$C_3H_8(g) + 5\ O_2(g) \longrightarrow 3\ CO_2(g) + 4\ H_2O(l) \qquad \Delta H° = -2220.\ kJ$$



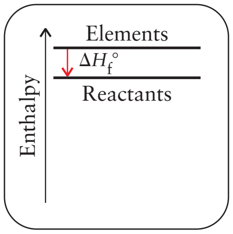
Find the total enthalpy of formation of the products.

$$\begin{aligned}\sum n\Delta H_f°(\text{products}) &= (3\ \text{mol})\Delta H_f°(CO_2, g) + (4\ \text{mol})\Delta H_f°(H_2O, l)\\ &= (3\ \text{mol})(-393.51\ kJ\cdot mol^{-1}) + (4\ \text{mol})(-285.83\ kJ\cdot mol^{-1})\\ &= -1180.53 - 1143.32\ kJ\\ &= -2323.85\ kJ\end{aligned}$$



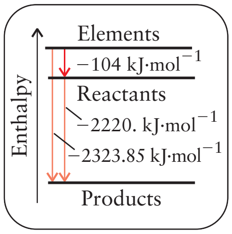
Find the total enthalpy of formation of the reactants.

$$\begin{aligned}\sum n\Delta H_f°(\text{reactants}) &= (1\ \text{mol})\Delta H_f°(C_3H_8, g) + (5\ \text{mol})\Delta H_f°(O_2, g)\\ &= (1\ \text{mol})\Delta H_f°(C_3H_8, g)\end{aligned}$$



From $\Delta H_r° = \sum n\Delta H_f°$ (products) $- \sum n\Delta H_f°$ (reactants),

$$-2220.\ \text{kJ} = -2323.85\ \text{kJ} - (1\ \text{mol})\Delta H_f°(\text{C}_3\text{H}_8, \text{g})$$



Solve for $\Delta H_f°(\text{C}_3\text{H}_8, \text{g})$.

$$\Delta H_f°(\text{C}_3\text{H}_8, \text{g}) = -2323.85 - (-2220.)\ \text{kJ·mol}^{-1} = -104\ \text{kJ·mol}^{-1}$$

Self-Test 7.16A Calculate the standard enthalpy of formation of ethyne, the fuel used in oxyacetylene welding torches, from the information in Tables 7.4 and 7.5.

[***Answer:*** +227 kJ·mol^{-1}]

Self-Test 7.16B Calculate the standard enthalpy of formation of urea, $CO(NH_2)_2$, a by-product of the metabolism of proteins, from the information in Tables 7.4 and 7.5.

Standard enthalpies of formation can be combined to obtain the standard enthalpy of any reaction.

7.19 The Born–Haber Cycle

We saw in Section 2.4 that the energy changes accompanying the formation of a solid could be estimated on the basis of a model—the ionic model—in which the principal contribution to the lattice energy was the Coulomb interaction between ions. However, a model can give only an estimate: we need a way to *measure* the energy change. If the measured and calculated energies are similar, we can conclude that the ionic model is reliable for the particular substance. If the two energies are markedly different, then we know that the ionic model must be improved or even discarded.

For a given solid, the difference in molar enthalpy between the solid and a gas of widely separated ions is called the **lattice enthalpy** of the solid, ΔH_L:

$$\Delta H_L = H_m(\text{ions, g}) - H_m(\text{solid}) \qquad (21)$$

The lattice enthalpy can be identified with the heat required to vaporize the solid at constant pressure. The greater the lattice enthalpy, the greater is the heat required. Heat equal to the lattice enthalpy is released when the solid forms from gaseous ions. In Section 2.4 we calculated the lattice *energy* and discussed how it depended on the attractions between the ions. The lattice enthalpy differs from the lattice energy by only a few kilojoules per mole and can be interpreted in a similar way.

The lattice enthalpy of a solid cannot normally be measured directly. However, we can obtain it indirectly by combining other measurements in an application of Hess's law. This approach takes advantage of the first law of thermodynamics and, in particular, the fact that enthalpy is a state function. The procedure uses a **Born–Haber cycle,** a closed path of steps, one of which is the formation of a solid lattice from the gaseous ions. The enthalpy change for this step is the negative of the lattice enthalpy. Table 7.6 lists some lattice enthalpies found in this way.

In a Born–Haber cycle, we imagine that we break apart the bulk elements into atoms, ionize the atoms, combine the gaseous ions to form the ionic solid, then form the elements again from the ionic solid (Fig. 7.32). Only the lattice enthalpy, the negative of the enthalpy of the step in which the ionic solid is formed from the gaseous ions, is unknown. The sum of the enthalpy changes for a complete Born–Haber cycle is zero, because the enthalpy of the system must be the same at the start and finish.

TABLE 7.6 Lattice Enthalpies at 25°C ($kJ\cdot mol^{-1}$)

Halides							
LiF	1046	LiCl	861	LiBr	818	LiI	759
NaF	929	NaCl	787	NaBr	751	NaI	700.

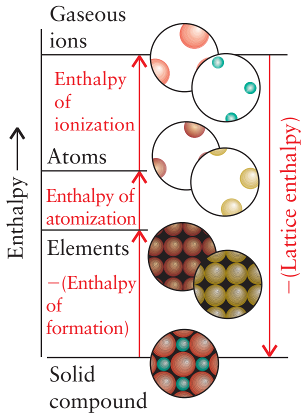

FIGURE 7.32 In a Born–Haber cycle, we select a sequence of steps that starts and ends at the same point (the solid compound, for instance). The lattice enthalpy is the enthalpy change accompanying the reverse of the step in which the solid is formed from a gas of ions. The sum of enthalpy changes around the complete cycle is 0 because enthalpy is a state function.

EXAMPLE 7.13 Using a Born–Haber cycle to calculate a lattice enthalpy

Devise and use a Born–Haber cycle to calculate the lattice enthalpy of potassium chloride.

Anticipate Typical lattice enthalpies are close to 1000 $kJ\cdot mol^{-1}$.

PLAN A Born–Haber cycle combines the enthalpy changes that take place when we begin with the pure elements, atomize them to form gaseous atoms, ionize the atoms to form gaseous ions, allow the ions to form an ionic solid, and then convert the solid back into the pure elements. The only unknown enthalpy change is that of the step in which the ionic solid forms from gaseous ions ($-\Delta H_L$). Because the sum of the enthalpy changes for the complete cycle is zero, we can solve for the lattice enthalpy, ΔH_L.

SOLVE The Born–Haber cycle for KCl is shown in Fig. 7.33.

Find ΔH_f(K, atoms) in Appendix 2A.

$$K(s) \longrightarrow K(g) \qquad +89\ kJ\cdot mol^{-1}$$

Find ΔH_f(Cl, atoms) in Appendix 2A.

$$\tfrac{1}{2}Cl_2(g) \longrightarrow Cl(g) \qquad +122\ kJ\cdot mol^{-1}$$

Find the ionization energy of K in Fig. 1.50 or Appendix 2D.

$$K(g) \longrightarrow K^+(g) + e^-(g) \qquad +418\ kJ\cdot mol^{-1}$$

Write the electron gain enthalpy of Cl as the negative of the electron affinity (Fig. 1.54 or Appendix 2D).

$$Cl(g) + e^-(g) \longrightarrow Cl^-(g) \qquad -349\ kJ\cdot mol^{-1}$$

Use Appendix 2A to write the negative of the standard enthalpy of formation of KCl, $-\Delta H_f$(KCl).

$$KCl(s) \longrightarrow K(s) + \tfrac{1}{2}Cl_2(g) \qquad -(-437\ kJ\cdot mol^{-1})$$

Set up the cycle, with a sum of zero.

$$\{89 + 122 + 418 - 349 - (-437)\}\ kJ\cdot mol^{-1} - \Delta H_L = 0$$

Solve for ΔH_L, the enthalpy of the reaction $KCl(s) \longrightarrow K^+(g) + Cl^-(g)$,

$$\Delta H_L = (89 + 122 + 418 - 349 + 437)\ kJ\cdot mol^{-1} = +717\ kJ\cdot mol^{-1}$$

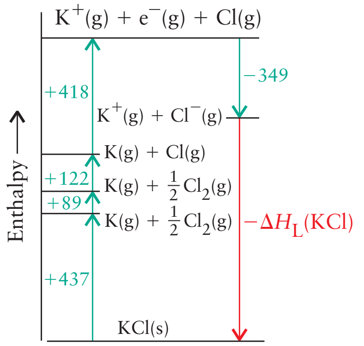

FIGURE 7.33 The Born–Haber cycle used to determine the lattice enthalpy of potassium chloride (see Example 7.13). The enthalpy changes are in kilojoules per mole.

TABLE 7.7 Bond Enthalpies of Diatomic Molecules ($kJ\cdot mol^{-1}$)

Molecule	ΔH_B
H_2	436
N_2	944
O_2	496
CO	1074
F_2	158
Cl_2	242
Br_2	193
I_2	151
HF	565
HCl	431
HBr	366
HI	299

Evaluate The lattice enthalpy of potassium chloride is 717 $kJ\cdot mol^{-1}$, of the order of magnitude expected.

Self-Test 7.17A Calculate the lattice enthalpy of calcium chloride, $CaCl_2$, by using the data in Appendices 2A and 2D.

[***Answer:*** 2259 $kJ\cdot mol^{-1}$]

Self-Test 7.17B Calculate the lattice enthalpy of magnesium bromide, $MgBr_2$, by using the data in Appendices 2A and 2D.

The strength of interaction between ions in a solid is measured by the lattice enthalpy, which can be determined by using a Born–Haber cycle.

7.20 Bond Enthalpies

In a chemical reaction, old bonds are broken and new ones formed. We can estimate reaction enthalpies if we know the enthalpy changes that accompany the breaking and making of bonds. The strength of a chemical bond is measured by the **bond enthalpy,** ΔH_B, the difference between the standard molar enthalpies of a molecule, X—Y (for instance, H_3C—OH), and its fragments X and Y (such as CH_3 and OH) in the gas phase:

A bond dissociation energy (Section 2.14) is strictly the *energy* required to break the bond at $T = 0$; a bond enthalpy is the change in *enthalpy* at the temperature of dissociation (typically 298 K). The two quantities differ by a few kilojoules per mole.

$$\Delta H_B(X - Y) = \{H_m°(X, g) + H_m°(Y, g)\} - H_m°(XY, g) \quad (22)$$

Whereas a lattice enthalpy is equal to the heat required (at constant pressure) to break up an ionic substance, a bond enthalpy is the heat required to break a specific type of bond at constant pressure. For example, the bond enthalpy of H_2 is derived from the thermochemical equation

$$H_2(g) \longrightarrow 2\,H(g) \qquad \Delta H° = +436\ kJ$$

We write ΔH_B(H—H) = 436 $kJ\cdot mol^{-1}$ to report this value and conclude that 436 kJ of heat is needed to dissociate 1 mol H_2(g) into atoms. All bond enthalpies are positive because heat must be supplied to break a bond. In other words, *bond breaking is always endothermic and bond formation is always exothermic*. Table 7.7 lists bond enthalpies of some diatomic molecules.

In a polyatomic molecule, all the atoms in the molecule exert a pull—through their electronegativities (recall Section 2.12)—on all the electrons in the molecule (Fig. 7.34). As a result, the bond strength between a given pair of atoms varies to a small extent from one compound to another. For example, the O—H bond enthalpy in water, HO—H (492 $kJ\cdot mol^{-1}$), is somewhat different from that of the same bond in CH_3O—H (437 $kJ\cdot mol^{-1}$). However, these variations in bond enthalpy are not very great, and so the **mean bond enthalpy,** which we also denote ΔH_B, is a guide to the strength of a bond in any molecule containing the bond (Table 7.8). A bond enthalpy refers to the dissociation of a species in the gas phase; to find the enthalpy change accompanying the dissociation of a liquid or solid sample, we must add the enthalpy of vaporization or sublimation of the sample:

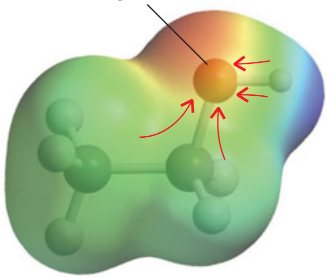

FIGURE 7.34 An electrostatic potential diagram of ethanol, C_2H_5OH. An electronegative atom (here, the O atom) can pull electrons toward itself from more distant parts of the molecule, as shown by the red tint over the O atom. Hence it can influence the strengths of bonds even between atoms to which it is not directly attached.

$$X_2(l) \longrightarrow 2\,X(g) \qquad \Delta H° = \Delta H_{vap}°(X_2, l) + \Delta H_B°(X - X)$$

Reaction enthalpies can be estimated by using mean bond enthalpies to determine the total energy required to break the reactant bonds and form the product bonds. In practice, only the bonds that change are treated. Because bond enthalpies refer to gaseous substances, to use the tabulated values, all substances must be gases or converted into the gas phase.

TABLE 7.8 Mean Bond Enthalpies ($kJ \cdot mol^{-1}$)

Bond	Mean bond enthalpy	Bond	Mean bond enthalpy
C—H	412	C—I	238
C—C	348	N—H	388
C═C	612	N—N	163
C┅C*	518	N═N	409

C—N	305	N—Cl	381
C—F	484	O—H	463
C—Cl	338	O—O	157
C—Br	276		

*In benzene.

EXAMPLE 7.14 Using mean bond enthalpies to estimate the enthalpy of a reaction

Estimate the enthalpy of the reaction between gaseous iodoethane and water vapor:

$$CH_3CH_2I(g) + H_2O(g) \longrightarrow CH_3CH_2OH(g) + HI(g)$$

Anticipate The H—I bond is weak and the H—O bonds in water are strong, so it would not be surprising if this reaction turned out to be endothermic.

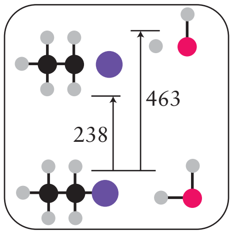
PLAN Decide which bonds are broken and which bonds are formed. Use the mean bond enthalpies in Table 7.8 to estimate the change in enthalpy when the reactant bonds break and the change in enthalpy when the new product bonds form. For diatomic molecules, use the information in Table 7.7 for the specific molecule. Finally, add the enthalpy change required to break the reactant bonds (a positive value) to the enthalpy change that occurs when the product bonds form (a negative value).

What should we assume? That the mean bond enthalpies in the table are close to the actual bond enthalpies in the reactants and products.

SOLVE

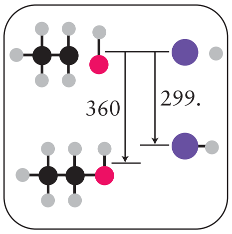
Reactants: Break 1 mol C—I bonds in CH_3CH_2I (average value 238 $kJ \cdot mol^{-1}$) and 1 mol O—H bonds in H_2O (average value 463 $kJ \cdot mol^{-1}$).

$$\Delta H° = 238 + 463 \text{ kJ} = +701 \text{ kJ}$$



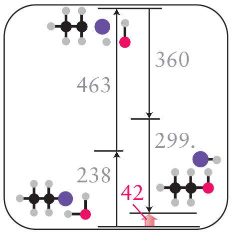
Products: Form 1 mol C—O bonds (average value 360 $kJ \cdot mol^{-1}$) and 1 mol H—I bonds (299 $kJ \cdot mol^{-1}$). The enthalpy change when the product bonds *form* are the negative of the bond formation enthalpy.

$$\Delta H° = -(360 + 299) \text{ kJ} = -659 \text{ kJ}$$



The overall enthalpy change is the sum of the bond enthalpy changes.

$$\Delta H° = 701 + (-659) \text{ kJ} = +42 \text{ kJ}$$



Evaluate The reaction is endothermic, as we suspected might be the case, primarily because a relatively large energy is needed to break an O—H bond and not much is recovered from the formation of an H—I bond.

Self-Test 7.18A Use bond enthalpies to estimate the standard enthalpy of the reaction $CCl_3CHCl_2(g) + 2\,HF(g) \longrightarrow CCl_3CHF_2(g) + 2\,HCl(g)$.

[***Answer:*** $-24\ kJ\cdot mol^{-1}$]

Self-Test 7.18B Use bond enthalpies to estimate the standard enthalpy of the reaction in which 1.00 mol of gaseous CH_4 reacts with gaseous F_2 to form gaseous CH_2F_2 and HF.

A note on good practice. The use of mean bond enthalpies is hazardous because actual bond enthalpies may differ considerably from mean values. The modern procedure for estimating a reaction enthalpy is to use commercial software to calculate the enthalpies of formation of the reactants and products and then to take the difference, as in Section 7.18.

A mean bond enthalpy is the average molar enthalpy change accompanying the dissociation of a given type of bond.

7.21 The Variation of Reaction Enthalpy with Temperature

Suppose we know the reaction enthalpy for one temperature but require it for another temperature. For instance, the temperature of the human body is about 37°C, but the data in Appendix 2A are for 25°C. How can we find out whether an increase of 12°C makes much difference to the reaction enthalpy of a metabolic process?

The enthalpies of both reactants and products increase with temperature. If the total enthalpy of the reactants increases more than that of the products when the temperature is raised, then the reaction enthalpy of an exothermic reaction becomes more negative (Fig. 7.35). On the other hand, if the enthalpy of the products increases more than that of the reactants, then the reaction enthalpy will become less negative. The increase in enthalpy of a substance when the temperature is raised depends on its heat capacity at constant pressure (Eq. 12b), and it is easy to deduce **Kirchhoff's law** (see Exercise 7.89) that

$$\Delta H°(T_2) = \Delta H°(T_1) + (T_2 - T_1)\Delta C_P \qquad (23)^*$$

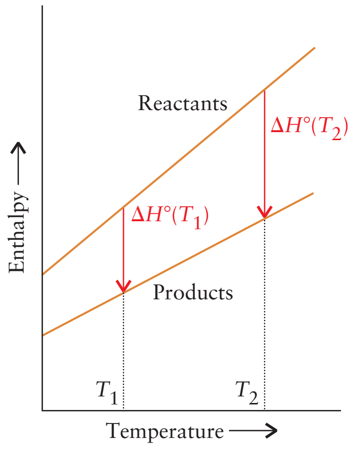


FIGURE 7.35 If the heat capacity of the reactants is larger than that of the products, the enthalpy of the reactants will increase more sharply with increasing temperature. If the reaction is exothermic, the reaction enthalpy will become more negative, as shown here. If the reaction is endothermic, the reaction enthalpy will become less positive and may even become negative.

To use this expression, we need to know ΔC_P, the difference between the constant-pressure heat capacities of the products and reactants:

$$\Delta C_P = \sum nC_{P,m}(\text{products}) - \sum nC_{P,m}(\text{reactants}) \qquad (24)$$

These values can be found in Appendix 2A. Because the difference between $\Delta H°(T_2)$ and $\Delta H°(T_1)$ depends on the *difference* in the heat capacities of the reactants and products—a difference that is normally small—in most cases, the reaction enthalpy depends only weakly on the temperature and, for small ranges of temperature, can be treated as a constant.

EXAMPLE 7.15 Predicting the reaction enthalpy at a different temperature

The standard enthalpy of reaction of $N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g)$ is $-92.22\ kJ\cdot mol^{-1}$ at 298 K. The industrial synthesis takes place at 450.°C. What is the standard reaction enthalpy at the latter temperature?

Anticipate There are more reactant molecules than product molecules, so we should suspect that the heat capacity of the products is less than that of the reactants, and therefore that ΔC_P is negative. If that is so, an increase in temperature will make ΔH more negative and therefore the reaction more exothermic.

What should we assume? That the heat capacities of reactants and products are constant over the temperature range of interest.

SOLVE

Calculate the difference in heat capacities.

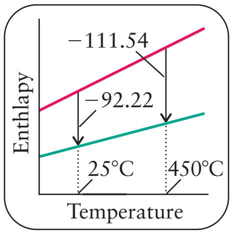
$$\Delta C_P = (2\text{ mol})C_{P,\text{m}}(\text{NH}_3, \text{g}) - \{(1\text{ mol})C_{P,\text{m}}(\text{N}_2, \text{g}) + (3\text{ mol})C_{P,\text{m}}(\text{H}_2, \text{g})\}$$
$$= (2\text{ mol})(35.06\text{ J·K}^{-1}\text{·mol}^{-1}) - \{(1\text{ mol})(29.12\text{ J·K}^{-1}\text{·mol}^{-1}) + (3\text{ mol})(28.82\text{ J·K}^{-1}\text{·mol}^{-1})\}$$
$$= -45.46\text{ J·K}^{-1}$$

Evaluate $T_2 - T_1$.

$$T_2 - T_1 = (450 + 273\text{ K}) - 298\text{ K} = 425\text{ K}$$

Calculate the enthalpy change at the final temperature from $\Delta H°(T_2) = \Delta H°(T_1) + (T_2 - T_1)\Delta C_P$

$$\Delta H°(450\text{ K}) = -92.22\text{ kJ} + (425\text{ K}) \times (-45.46\text{ J·K}^{-1})$$
$$= -92.22\text{ kJ} - 1.932 \times 10^4\text{ J}$$
$$= -92.22\text{ kJ} - 19.32\text{ kJ} = -111.54\text{ kJ}$$



Evaluate The individual contributions of the changes in enthalpy of the reactants and products are depicted in Fig. 7.36. As we anticipated, ΔC_P is negative and the reaction is more exothermic at the higher temperature.

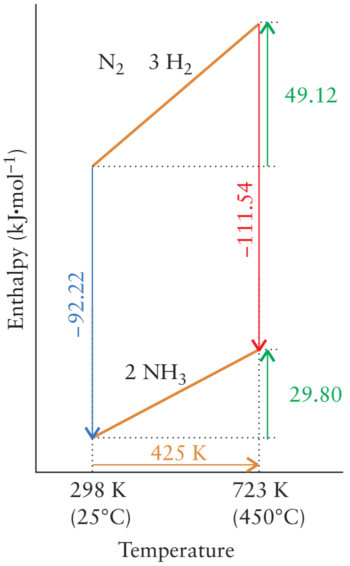


FIGURE 7.36 A depiction of the individual contributions to the change in standard reaction enthalpy for the reaction treated in Example 7.15.

Self-Test 7.19A The reaction enthalpy of $4\,\text{Al(s)} + 3\,\text{O}_2\text{(g)} \longrightarrow 2\,\text{Al}_2\text{O}_3\text{(s)}$ is −3351 kJ at 298 K. Estimate its value at 1000.°C.

[*Answer:* −3378 kJ]

Self-Test 7.19B The standard enthalpy of formation of ammonium nitrate is −365.56 kJ·mol^{-1} at 298 K. Estimate its value at 250.°C.

The temperature variation of the standard reaction enthalpy is given by Kirchhoff's law, Eq. 23, in terms of the difference in molar heat capacities at constant pressure between the products and the reactants.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Calculate the work done by a gas due to expansion (Examples 7.1 and 7.2).

❑ 2 Use the heat capacity of a substance to calculate the heat required to raise its temperature by a given amount (Example 7.3).

❑ 3 Calculate energy changes from calorimetry data and write a thermochemical equation (Examples 7.4 and 7.7).

❑ 4 State, and explain the implications of, the first law of thermodynamics (Sections 7.6–7.7).

❑ 5 Calculate the change in internal energy due to heat and work (Self-Test 7.5).

❑ 6 Calculate the work, heat, and change in internal energy when an ideal gas undergoes an isothermal expansion (Example 7.5).

❑ 7 Calculate the change in internal energy when an ideal gas is heated (Example 7.6).

❑ 8 Determine the enthalpy of vaporization (Self-Test 7.9).

❑ 9 Interpret the heating curve of a substance (Section 7.12).

❑ 10 Distinguish between the internal energy and the enthalpy of a process and describe how each is measured (Sections 7.8 and 7.14).

❑ 11 Determine the enthalpy change of a reaction, given the change in internal energy, and vice versa (Example 7.8).

❑ 12 Calculate an overall reaction enthalpy from the enthalpies of the reactions in a reaction sequence by using Hess's law (Toolbox 7.1 and Example 7.9).

❑ 13 Calculate the heat output of a fuel (Example 7.10).

❑ 14 Use standard enthalpies of formation to calculate the standard enthalpy of a reaction, and vice versa (Examples 7.11 and 7.12).

❑ 15 Calculate a lattice enthalpy by using the Born–Haber cycle (Example 7.13).

❑ 16 Use average bond enthalpies to estimate the standard enthalpy of a reaction, (Example 7.14).

❑ 17 Predict the reaction enthalpy at a temperature different from that of the data (Example 7.15).

EXERCISES

Systems

7.1 Identify the following systems as open, closed, or isolated: (a) coffee in a very high quality thermos bottle; (b) coolant in a refrigerator coil; (c) a bomb calorimeter in which benzene is burned; (d) gasoline burning in an automobile engine; (e) mercury in a thermometer; (f) a living plant.

7.2 (a) Describe three ways in which you could increase the internal energy of an open system. (b) Which of these methods could you use to increase the internal energy of a closed system? (c) Which, if any, of these methods could you use to increase the internal energy of an isolated system?

The First Law

7.3 Air in a bicycle pump is compressed by pushing in the handle. If the inner diameter of the pump is 3.0 cm and the pump is depressed 20. cm with a pressure of 2.00 atm, (a) how much work is done in the compression? (b) Is the work positive or negative with respect to the air in the pump?

7.4 Each of the four cylinders of a new type of combustion engine has a displacement of 3.60 L. (The volume of the cylinder expands 3.60 L each time the fuel is ignited.) (a) If each piston in the four cylinders is displaced against a pressure of 1.80 kbar and each cylinder is ignited once per second, how much work can the engine do in 1.00 minute? (b) Is the work positive or negative with respect to the engine and its contents?

7.5 A gas sample in a cylinder is supplied with 524 kJ of energy as heat. At the same time, a piston compresses the gas, doing 340 kJ of work. What is the change in internal energy of the gas during this process?

7.6 A gas sample in a piston assembly expands, doing 536 kJ of work on its surroundings at the same time that 214 kJ of heat is added to the gas. (a) What is the change in internal energy of the gas during this process? (b) Will the pressure of the gas be higher or lower when these changes are completed?

7.7 The internal energy of a system increased by 982 J when it absorbed 492 J of heat. (a) Was work done by or on the system? (b) How much work was done?

7.8 (a) Calculate the value of w for a system that releases 216 kJ of heat in a process for which the decrease in internal energy is 184 kJ. (b) Is work done on or by the system during this process?

7.9 A gas in a cylinder was placed in a heater and gained 5500 kJ of energy as heat. If the cylinder increased in volume from 345 mL to 1846 mL against an atmospheric pressure of 750. Torr during this process, what is the change in internal energy of the gas in the cylinder?

7.10 A 100.-W electric heater ($1\ \mathrm{W} = 1\ \mathrm{J \cdot s^{-1}}$) operates for 10.0 min to heat the gas in a cylinder. At the same time, the gas expands from 2.00 L to 10.00 L against a constant atmospheric pressure of 0.975 atm. What is the change in internal energy of the gas?

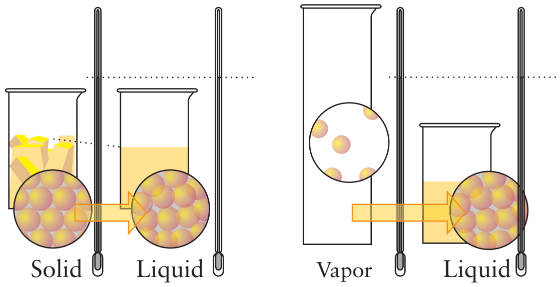
7.11 In a combustion cylinder, the total internal energy change produced from the burning of a fuel is –2573 kJ. The cooling system that surrounds the cylinder absorbs 947 kJ as heat. How much work can be done by the fuel in the cylinder?

7.12 A laboratory animal exercised on a treadmill that was connected to a weight with a mass of 250 g through a pulley. The work done by the animal raised the weight through 1.32 m. At the same time the animal gave off 8.0 J of energy as heat. Disregarding any other losses and treating the animal as a closed system, what was the change in internal energy of the animal?

7.13 In an adiabatic process, no energy is transferred as heat. Indicate whether each of the following statements about an adiabatic process in a closed system is always true, always false, or true in certain conditions (specify the conditions): (a) $\Delta U = 0$; (b) $q = 0$; (c) $q < 0$; (d) $\Delta U = q$; (e) $\Delta U = w$.

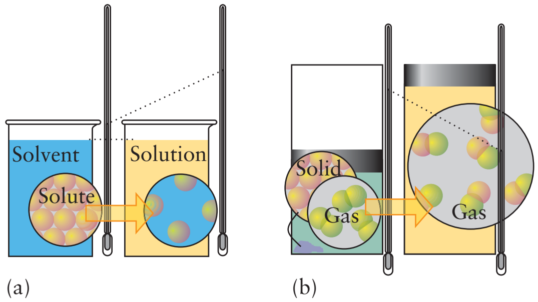
7.14 Indicate whether each of the following statements about a process in a closed system with a constant volume is always true, always false, or true in certain conditions (specify the conditions): (a) $\Delta U = 0$; (b) $w = 0$; (c) $w < 0$; (d) $\Delta U = q$; (e) $\Delta U = w$.

7.15 Each of the pictures below shows a molecular view of a system undergoing a change at constant temperature. In each case, indicate whether heat is absorbed or given off by the system, whether expansion work is done on or by the system, and predict the signs of q and w for the process.



(a) (b)

7.16 Each of the pictures below shows a molecular view of a system undergoing a change. In each case, indicate whether heat is absorbed or given off by the system, whether expansion work is done on or by the system, and predict the signs of q and w for the process.



(a) (b)

7.17 (a) Calculate the heat that must be supplied to a 500.0-g copper kettle containing 400.0 g of water to raise its temperature from 22.0°C to the boiling point of water, 100.0°C. (b) What percentage of the heat is used to raise the temperature of the water? (See Table 7.2.)

7.18 (a) Calculate the heat that must be supplied to a 500.0-g stainless steel vessel containing 400.0 g of water to raise its temperature from 22.0°C to the boiling point of water, 100.0°C. (b) What percentage of the heat is used to raise the temperature of the water? (c) Compare these answers with those of Exercise 7.17. (See Table 7.2.)

7.19 A piece of copper of mass 20.0 g at 100.0°C is placed in a vessel of negligible heat capacity but containing 50.7 g of water at 22.0°C. Calculate the final temperature of the water. Assume that there is no energy lost to the surroundings.

7.20 A piece of metal of mass 20.0 g at 100.0°C is placed in a calorimeter containing 50.7 g of water at 22.0°C. The final temperature of the mixture is 25.7°C. What is the specific heat capacity of the metal? Assume that there is no energy lost to the surroundings.

7.21 A calorimeter was calibrated with an electric heater, which supplied 22.5 kJ of energy as heat to the calorimeter and increased the temperature of the calorimeter and its water bath from 22.45°C to 23.97°C. What is the heat capacity of the calorimeter?

7.22 The enthalpy of combustion of benzoic acid, C_6H_5COOH, which is often used to calibrate calorimeters, is $-3227\ kJ\cdot mol^{-1}$. When 1.453 g of benzoic acid was burned in a calorimeter, the temperature increased by 2.265°C. What is the heat capacity of the calorimeter?

7.23 Calculate the work for each of the following processes beginning with a gas sample in a piston assembly with $T = 305$ K, $P = 1.79$ atm, and $V = 4.29$ L: (a) irreversible expansion against a constant external pressure of 1.00 atm to a final volume of 6.52 L; (b) isothermal, reversible expansion to a final volume of 6.52 L.

7.24 A sample of gas in a cylinder of volume 3.42 L at 298 K and 2.57 atm expands to 7.39 L by two different pathways. Path A is an isothermal, reversible expansion. Path B has two steps. In the first step, the gas is cooled at constant volume to 1.19 atm. In the second step, the gas is heated and allowed to expand against a constant external pressure of 1.19 atm until the final volume is 7.39 L. Calculate the work for each path.

Enthalpy

7.25 Which molecular substance do you expect to have the higher molar heat capacity, NO or NO_2? Why?

7.26 Explain why the heat capacities of methane and ethane differ from the values expected for an ideal monatomic gas and from each other. The values of C_P are $35.31\ J\cdot K^{-1}\cdot mol^{-1}$ for CH_4 and $52.63\ J\cdot K^{-1}\cdot mol^{-1}$ for C_2H_6.

7.27 Calculate the heat released by 5.025 g of Kr(g) at 0.400 atm as it cools from 97.6°C to 25.0°C at (a) constant pressure and (b) constant volume. Assume that krypton behaves as an ideal gas.

7.28 Calculate the heat that must be supplied to 0.104 g of Ne(g) at 0.250 atm to raise its temperature from 22.0°C to 60.0°C at (a) constant pressure and (b) constant volume. Assume that neon behaves as an ideal gas.

7.29 Predict the contribution to the heat capacity $C_{V,m}$ made by molecular motions for each of the following atoms and molecules: (a) HCN; (b) C_2H_6; (c) Ar; (d) HBr.

7.30 Predict the contribution to the heat capacity $C_{V,m}$ made by molecular motions for each of the following molecules: (a) NO; (b) NH_3; (c) HClO; (d) SO_2.

7.31 In a microwave oven, radiation is absorbed by water in the food and the food is heated. How many photons of wavelength 4.50 mm are required to heat 350. g of water from 25.0°C to 100.0°C, assuming all the energy is used to raise the temperature?

7.32 Samples consisting of 1 mol N_2 and 1 mol CH_4 are in identical but separate containers, with initial temperatures of 500. K. Both gases gain 1200. J of heat at constant volume. Do the gases have the same final temperature? If not, which gas has the higher final temperature? Justify your reasoning.

7.33 The high-temperature contribution of vibrational modes to the molar heat capacity of a solid at constant volume is R for each mode of vibrational motion. Hence, for a monatomic solid, the molar heat capacity at constant volume is approximately $3R$. (a) The specific heat capacity of a certain monatomic solid is $0.392\ J\cdot K^{-1}\cdot g^{-1}$. The chloride of this element (XCl_2) is 52.7% chlorine by mass. Identify the element. (b) This element crystallizes in a face-centered cubic unit cell and its atomic radius is 128 pm. What is the density of this solid?

7.34 Estimate the molar heat capacity (at constant volume) of sulfur dioxide gas. In addition to translational and rotational motion, there is vibrational motion. Each vibrational degree of freedom contributes R to the molar heat capacity. The temperature needed for the vibrational modes to be accessible can be approximated by $\theta = h\nu_{vib}/k$, where k is Boltzmann's constant. The vibrational modes have frequencies 3.5×10^{13} Hz, 4.1×10^{13} Hz, and 1.6×10^{13} Hz. (a) What is the high-temperature limit of the molar heat capacity at constant volume? (b) What is the molar heat capacity at constant volume at 1000. K? (c) What is the molar heat capacity at constant volume at room temperature?

7.35 (a) At its boiling point, the vaporization of 0.579 mol CH_4(l) requires 4.76 kJ of heat. What is the enthalpy of vaporization of methane? (b) An electric heater was immersed in a flask of boiling ethanol, C_2H_5OH, and 22.45 g of ethanol was vaporized when 21.2 kJ of energy was supplied. What is the enthalpy of vaporization of ethanol?

7.36 (a) When 25.23 g of methanol, CH_3OH, froze, 4.01 kJ of heat was released. What is the enthalpy of fusion of methanol? (b) A sample of benzene was vaporized at 25°C. When 37.5 kJ of heat was supplied, 95 g of the liquid benzene vaporized. What is the enthalpy of vaporization of benzene at 25°C?

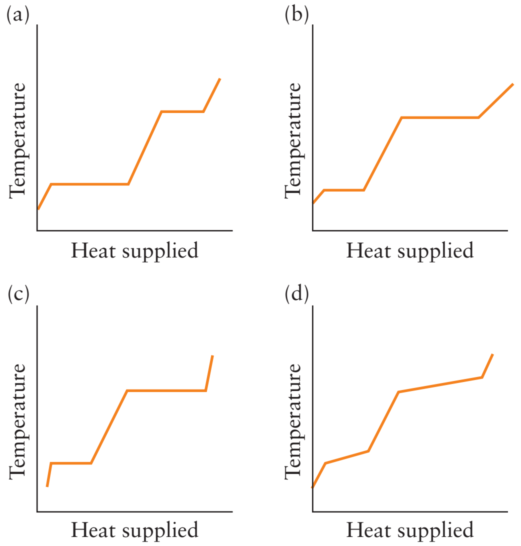
7.37 How much heat is needed to convert 80.0 g of ice at 0.0°C into liquid water at 20.0°C (see Tables 7.2 and 7.3)?

7.38 If we start with 325 g of water at 30.°C, how much heat must we add to convert all the liquid into vapor at 100.°C (see Tables 7.2 and 7.3)?

7.39 A 50.0-g ice cube at 0.0°C is added to a glass containing 400.0 g of water at 45.0°C. What is the final temperature of the system (see Tables 7.2 and 7.3)? Assume that no heat is lost to the surroundings.

7.40 When 25.0 g of a metal at 90.0°C is added to 50.0 g of water at 25.0°C, the temperature of the water rises to 29.8°C. What is the specific heat capacity of the metal (see Table 7.2)?

7.41 The following data were collected for a new compound used in cosmetics: $\Delta H_{fus} = 10.0\ kJ\cdot mol^{-1}$, $\Delta H_{vap} = 20.0\ kJ\cdot mol^{-1}$; heat capacities: $30\ J\cdot mol^{-1}$ for the solid; $60\ J\cdot mol^{-1}$ for the liquid; $30\ J\cdot mol^{-1}$ for the gas. Which heating curve below best matches the data for this compound?



7.42 Use the following information to construct a heating curve for bromine from −7.2°C to 70.0°C. The molar heat capacity of liquid bromine is $75.69\ J\cdot K^{-1}\cdot mol^{-1}$ and that of bromine vapor is $36.02\ J\cdot K^{-1}\cdot mol^{-1}$. The enthalpy of vaporization of liquid bromine is $30.91\ kJ\cdot mol^{-1}$. Bromine melts at −7.2°C and boils at 58.78°C.

Reaction Enthalpies

7.43 Carbon disulfide can be prepared from coke (an impure form of carbon) and elemental sulfur:

$$4\ C(s) + S_8(s) \longrightarrow 4\ CS_2(l) \qquad \Delta H° = +358.8\ kJ$$

How much heat is absorbed in the reaction of 1.25 mol S_8? (b) Calculate the heat absorbed in the reaction of 197 g of carbon with an excess of sulfur. (c) If the heat absorbed in the reaction was 415 kJ, how much CS_2 was produced?

7.44 The oxidation of nitrogen in the hot exhaust of jet engines and automobiles occurs by the reaction

$$N_2(g) + O_2(g) \longrightarrow 2\ NO(g) \qquad \Delta H° = +180.6\ kJ$$

How much heat is absorbed in the formation of 1.55 mol NO? (b) How much heat is absorbed in the oxidation of 5.45 L of nitrogen measured at 1.00 atm and 273 K? (c) When the oxidation of N_2 to NO was completed in a bomb calorimeter, the heat absorbed was measured as 492 J. What mass of nitrogen gas was oxidized?

7.45 The combustion of octane is expressed by the thermochemical equation

$$C_8H_{18}(l) + \tfrac{25}{2}O_2(g) \longrightarrow 8\ CO_2(g) + 9\ H_2O(l) \qquad \Delta H° = -5471\ kJ$$

Estimate the mass of octane that would need to be burned to produce enough heat to raise the temperature of the air in a 12 ft × 12 ft × 8.0 ft room from 40.°F to 78°F on a mild winter's day. Use the normal composition of air to determine its density and assume a pressure of 1.00 atm. (b) How much heat will be evolved from the combustion of 1.0 gal of gasoline (assumed to be exclusively octane)? The density of octane is $0.70\ g\cdot mL^{-1}$.

7.46 Coal-fired steam engines get their power by using the heat from burning coal to boil water. Suppose that coal of density $1.5\ g\cdot cm^{-3}$ is carbon (it is, in fact, much more complicated, but this is a reasonable first approximation). The combustion of carbon is described by the equation

$$C(s) + O_2(g) \longrightarrow CO_2(g) \qquad \Delta H° = -394\ kJ$$

Calculate the heat produced when a lump of coal of size 7.0 cm × 6.0 cm × 5.0 cm is burned. (b) Estimate the mass of water that can be heated from 25°C to 100.°C by burning this piece of coal.

7.47 A student rides a bicycle to class every day, a 10.-mile round trip that takes 30. minutes in each direction. The student burns $1250\ kJ\cdot h^{-1}$ cycling. The same round trip in an automobile would require 0.40 gallons of gasoline. Assume that the student goes to class 150 days per year and that the enthalpy of combustion of gasoline can be approximated by that of octane, which has a density of $0.702\ g\cdot cm^{-3}$ (3.785 L = 1.000 gal). What is the yearly energy requirement of this journey by (a) bicycle and (b) automobile?

7.48 Calculate the heat generated by a reaction mixture of 13.4 L of sulfur dioxide at 1.00 atm and 273 K and 15.0 g of oxygen in the reaction

$$2\ SO_2(g) + O_2(g) \longrightarrow 2\ SO_3(g) \qquad \Delta H° = -198\ kJ$$

7.49 For a certain reaction at constant pressure, $\Delta H = -15$ kJ, and 22 kJ of expansion work is done on the system. What is ΔU for this process?

7.50 For a certain reaction at constant pressure, $\Delta U = -72$ kJ, and 35 kJ of expansion work is done by the system. What is ΔH for this process?

7.51 Oxygen difluoride is a colorless, very poisonous gas that reacts rapidly with water vapor to produce O_2, HF, and heat:

$$OF_2(g) + H_2O(g) \longrightarrow O_2(g) + 2HF(g) \qquad \Delta H = -318\ kJ$$

What is the change in internal energy for the reaction of 1.00 mol OF_2?

7.52 One step in the production of hydrogen as a fuel is the reaction of methane with water vapor:

$$CH_4(g) + H_2O(g) \xrightarrow{Ni} CO_2(g) + 3\ H_2(g) \qquad \Delta H = -318\ kJ$$

What is the change in internal energy for the production of 1.00 mol H_2?

7.53 Hydrochloric acid oxidizes zinc metal in a reaction that produces hydrogen gas and chloride ions. A piece of zinc metal of mass 8.5 g is dropped into an apparatus containing 800.0 mL of 0.500 M HCl(aq). If the initial temperature of the hydrochloric acid solution is 25°C, what is the final temperature of this solution? Assume that the density and molar heat capacity of the hydrochloric acid solution are the same as those of water and that all the heat is used to raise the temperature of the solution.

7.54 "Synthesis gas" is a mixture of carbon monoxide, hydrogen, methane, and some noncombustible gases. A certain synthesis gas is 40.0% by volume carbon monoxide, 25.0% hydrogen gas, 10.0% noncombustible gases, and the rest methane. What volume of this gas must be burned to raise the temperature of 5.5 L of water by 5°C? Assume the gas is at 1.0 atm and 298 K and that all three gases are completely oxidized in the combustion.

7.55 The enthalpy of formation of trinitrotoluene (TNT) is -67 kJ·mol^{-1}, and the density of TNT is 1.65 g·cm^{-3}. In principle, it could be used as a rocket fuel, with the gases resulting from its decomposition streaming out of the rocket to give the required thrust. In practice, of course, it would be extremely dangerous as a fuel because it is sensitive to shock. Explore its potential as a rocket fuel by calculating its enthalpy density (enthalpy released per liter) for the reaction

$$4\ C_7H_5N_3O_6(s) + 21\ O_2(g) \longrightarrow 28\ CO_2(g) + 10\ H_2O(g) + 6\ N_2(g)$$

7.56 A natural gas mixture is burned in a furnace at a power-generating station at a rate of 13.0 mol per minute. (a) If the fuel consists of 9.3 mol CH_4, 3.1 mol C_2H_6, 0.40 mol C_3H_8, and 0.20 mol C_4H_{10}, what mass of CO_2(g) is produced per minute? (b) How much heat is released per minute?

7.57 The reaction of 1.40 g of carbon monoxide with excess water vapor to produce carbon dioxide and hydrogen gases in a bomb calorimeter causes the temperature of the calorimeter assembly to rise from 22.113°C to 22.799°C. The calorimeter assembly is known to have a total heat capacity of 3.00 kJ·(°C)$^{-1}$. (a) Write a balanced equation for the reaction. (b) Calculate the internal energy change, ΔU, for the reaction of 1.00 mol CO(g).

7.58 Benzoic acid has a known internal energy of combustion (-3251 kJ·mol^{-1}). When a bomb calorimeter was calibrated by burning 0.825 g of benzoic acid in oxygen, the temperature rose 1.94°C. A 0.727-g sample of the sugar D-ribose ($C_5H_{10}O_5$) was then burned in excess oxygen in the same calorimeter, forming gaseous CO_2 and liquid H_2O. The temperature of the calorimeter rose from 21.81°C to 22.72°C. (a) Write a balanced equation for the combustion. (b) Calculate the internal energy change, ΔU, for the combustion of 1.00 mol ribose molecules.

Hess's Law

7.59 The standard enthalpies of combustion of graphite and diamond are -393.51 kJ·mol^{-1} and -395.41 kJ·mol^{-1}, respectively. Calculate the enthalpy of the graphite $\longrightarrow$ diamond transition.

7.60 Elemental sulfur exists in several forms, with rhombic sulfur the most stable under normal conditions and monoclinic sulfur slightly less stable. The standard enthalpies of combustion of the two forms (to sulfur dioxide) are -296.83 kJ·mol^{-1} and -297.16 kJ·mol^{-1}, respectively. Calculate the enthalpy of the rhombic $\longrightarrow$ monoclinic transition.

7.61 Barium metal is produced by the reaction of aluminum metal with barium oxide. From the standard reaction enthalpies

$$2\ Ba(s) + O_2(g) \longrightarrow 2\ BaO(s) \qquad \Delta H° = -1107\ kJ$$
$$2\ Al(s) + \tfrac{3}{2}\ O_2(g) \longrightarrow Al_2O_3(s) \qquad \Delta H° = -1676\ kJ$$

calculate the reaction enthalpy for the production of metallic barium in the reaction:

$$3\ BaO(s) + 2\ Al(s) \xrightarrow{\Delta} Al_2O_3(s) + 3\ Ba(s)$$

7.62 In the manufacture of nitric acid by the oxidation of ammonia, the first product is nitric oxide, which is then oxidized to nitrogen dioxide. From the standard reaction enthalpies

$$N_2(g) + O_2(g) \longrightarrow 2\ NO(g) \qquad \Delta H° = +180.5\ kJ$$
$$N_2(g) + 2\ O_2(g) \longrightarrow 2\ NO_2(g) \qquad \Delta H° = +66.4\ kJ$$

calculate the standard reaction enthalpy for the oxidation of nitric oxide to nitrogen dioxide:

$$2\ NO(g) + O_2(g) \longrightarrow 2\ NO_2(g)$$

7.63 Determine the reaction enthalpy for the hydrogenation of ethyne to ethane, $C_2H_2(g) + 2\ H_2(g) \longrightarrow C_2H_6(g)$, from the following data: $\Delta H_c°(C_2H_2, g) = -1300.$ kJ·mol^{-1}, $\Delta H_c°(C_2H_6, g) = -1560.$ kJ·mol^{-1}, $\Delta H_c°(H_2, g) = -286$ kJ·mol^{-1}.

7.64 Determine the enthalpy for the partial combustion of methane to carbon monoxide, $2\ CH_4(g) + 3\ O_2(g) \longrightarrow 2\ CO(g) + 4\ H_2O(l)$, from $\Delta H_c°(CH_4, g) = -890.$ kJ·mol^{-1} and $\Delta H_c°(CO, g) = -283.0$ kJ·mol^{-1}.

7.65 Use the data provided in Appendix 2A to calculate the standard reaction enthalpy for the reaction of pure nitric acid with hydrazine:

$$4\ HNO_3(l) + 5\ N_2H_4(l) \longrightarrow 7\ N_2(g) + 12\ H_2O(l)$$

7.66 Use the data provided in Appendix 2A to calculate the standard reaction enthalpy for the reaction of calcite with hydrochloric acid:

$$CaCO_3(s) + 2\ HCl(aq) \longrightarrow CaCl_2(aq) + H_2O(l) + CO_2(g)$$

7.67 Calculate the reaction enthalpy for the synthesis of hydrogen chloride gas, $H_2(g) + Cl_2(g) \longrightarrow 2\ HCl(g)$, from the following data:

$$NH_3(g) + HCl(g) \longrightarrow NH_4Cl(s) \qquad \Delta H° = -176.0\ kJ$$
$$N_2(g) + 3\ H_2(g) \longrightarrow 2\ NH_3(g) \qquad \Delta H° = -92.22\ kJ$$
$$N_2(g) + 4\ H_2(g) + Cl_2(g) \longrightarrow 2\ NH_4Cl(s) \qquad \Delta H° = -628.86\ kJ$$

7.68 Calculate the reaction enthalpy for the formation of anhydrous aluminum chloride, $2\ Al(s) + 3\ Cl_2(g) \longrightarrow 2\ AlCl_3(s)$, from the following data:

$$2\ Al(s) + 6\ HCl(aq) \longrightarrow 2\ AlCl_3(aq) + 3\ H_2(g) \qquad \Delta H° = -1049\ kJ$$
$$HCl(g) \longrightarrow HCl(aq) \qquad \Delta H° = -74.8\ kJ$$
$$H_2(g) + Cl_2(g) \longrightarrow 2\ HCl(g) \qquad \Delta H° = -185\ kJ$$
$$AlCl_3(s) \longrightarrow AlCl_3(aq) \qquad \Delta H° = -323\ kJ$$

7.69 Calculate the reaction enthalpy for the synthesis of hydrogen bromide gas, $H_2(g) + Br_2(l) \longrightarrow 2\ HBr(g)$, from the following data:

$$NH_3(g) + HBr(g) \longrightarrow NH_4Br(s) \qquad \Delta H° = -188.32\ kJ$$
$$N_2(g) + 3\ H_2(g) \longrightarrow 2\ NH_3(g) \qquad \Delta H° = -92.22\ kJ$$
$$N_2(g) + 4\ H_2(g) + Br_2(l) \longrightarrow 2\ NH_4Br(s) \qquad \Delta H° = -541.66\ kJ$$

7.70 Calculate the reaction enthalpy for the formation of anhydrous aluminum bromide, $2\ Al(s) + 3\ Br_2(l) \longrightarrow 2\ AlBr_3(s)$, from the following data:

$$2\ Al(s) + 6\ HBr(aq) \longrightarrow 2\ AlBr_3(aq) + 3\ H_2(g) \qquad \Delta H° = -1061\ kJ$$
$$HBr(g) \longrightarrow HBr(aq) \qquad \Delta H° = -81.15\ kJ$$
$$H_2(g) + Br_2(l) \longrightarrow 2\ HBr(g) \qquad \Delta H° = -72.80\ kJ$$
$$AlBr_3(s) \longrightarrow AlBr_3(aq) \qquad \Delta H° = -368\ kJ$$

Standard Enthalpies of Formation

7.71 Calculate the standard enthalpy of formation of dinitrogen pentoxide from the following data

$$2\,NO(g) + O_2(g) \longrightarrow 2\,NO_2(g) \qquad \Delta H° = -114.1\text{ kJ}$$
$$4\,NO_2(g) + O_2(g) \longrightarrow 2\,N_2O_5(g) \qquad \Delta H° = -110.2\text{ kJ}$$

and from the standard enthalpy of formation of nitric oxide, NO (see Appendix 2A).

7.72 An important reaction that takes place in the atmosphere is $NO_2(g) \longrightarrow NO(g) + O(g)$, which is brought about by sunlight. How much energy must be supplied by the Sun to cause it? Calculate the standard enthalpy of the reaction from the following information

$$O_2(g) \longrightarrow 2\,O(g) \qquad \Delta H° = +498.4\text{ kJ}$$
$$NO(g) + O_3(g) \longrightarrow NO_2(g) + O_2(g) \qquad \Delta H° = -200.\text{ kJ}$$

and from additional information in Appendix 2A.

7.73 Calculate the standard enthalpy of formation of $PCl_5(s)$ from the standard enthalpy of formation of $PCl_3(l)$ (see Appendix 2A) and $PCl_3(l) + Cl_2(g) \longrightarrow PCl_5(s)$, $\Delta H° = -124$ kJ.

7.74 Using standard enthalpies of formation from Appendix 2A, calculate the standard reaction enthalpy for each of the following reactions:

(a) the final stage in the production of nitric acid:

$$3\,NO_2(g) + H_2O(l) \longrightarrow 2\,HNO_3(aq) + NO(g)$$

(b) the industrial synthesis of boron trifluoride:

$$B_2O_3(s) + 3\,CaF_2(s) \longrightarrow 2\,BF_3(g) + 3\,CaO(s)$$

(c) the formation of a sulfide by the action of hydrogen sulfide on an aqueous solution of a base:

$$H_2S(aq) + 2\,KOH(aq) \longrightarrow K_2S(aq) + 2\,H_2O(l)$$

7.75 Use the information in Tables 7.3, 7.7, and 7.8 to estimate the enthalpy of formation of each of the following compounds in the *liquid* state. The standard enthalpy of sublimation of carbon is $+717\text{ kJ·mol}^{-1}$. (a) H_2O; (b) methanol, CH_3OH; (c) benzene, C_6H_6 (without resonance); (d) benzene, C_6H_6 (with resonance).

7.76 Use the information in Tables 7.3, 7.7, and 7.8 to estimate the enthalpy of formation of each of the following compounds in the *liquid* state. The standard enthalpy of sublimation of carbon is $+717\text{ kJ·mol}^{-1}$. (a) NH_3; (b) ethanol, CH_3CH_2OH; (c) acetone, CH_3COCH_3.

The Born–Haber Cycle

7.77 Use Fig. 1.54, Appendix 2A, Appendix 2D, and the following data to calculate the lattice enthalpy of Na_2O: $\Delta H_f°(Na_2O) = -409\text{ kJ·mol}^{-1}$; $\Delta H_f°(O, g) = +249\text{ kJ·mol}^{-1}$.

7.78 Use Fig. 1.54, Appendix 2A, Appendix 2D, and the following data to calculate the lattice enthalpy of $AlCl_3$: $\Delta H_f°(Al, g) = +326\text{ kJ·mol}^{-1}$.

7.79 Complete the following table (all values are in kilojoules per mole).

Compound MX	$\Delta H_f°$ M(g)	Ionization energy M	$\Delta H_f°$ X(g)	Electron affinity X	ΔH_L MX	$\Delta H_f°$ MX(s)
(a) NaCl	108	494	122	+349	787	?
(b) KBr	89	418	97	+325	?	–394
(c) RbF	?	402	79	+328	774	–558

7.80 By assuming that the lattice enthalpy of $NaCl_2$ is the same as that of $MgCl_2$, use enthalpy arguments based on data in Appendix 2A, Appendix 2D, and Fig. 1.54 to explain why $NaCl_2$ is an unlikely compound.

Bond Enthalpies

7.81 Use the bond enthalpies in Tables 7.7 and 7.8 to estimate the reaction enthalpy for

(a) $3\,C_2H_2(g) \longrightarrow C_6H_6(g)$

(b) $CH_4(g) + 4\,Cl_2(g) \longrightarrow CCl_4(g) + 4\,HCl(g)$

(c) $CH_4(g) + CCl_4(g) \longrightarrow CHCl_3(g) + CH_3Cl(g)$

7.82 Use the bond enthalpies in Tables 7.7 and 7.8 to estimate the reaction enthalpy for

(a) $HCl(g) + F_2(g) \longrightarrow HF(g) + ClF(g)$, given that $\Delta H_B(Cl{-}F) = -256\text{ kJ·mol}^{-1}$

(b) $C_2H_4(g) + HCl(g) \longrightarrow CH_3CH_2Cl(g)$

(c) $C_2H_4(g) + H_2(g) \longrightarrow CH_3CH_3(g)$

7.83 Use the bond enthalpies in Tables 7.7 and 7.8 to estimate the reaction enthalpy for

(a) $N_2(g) + 3\,F_2(g) \longrightarrow 2\,NF_3(g)$

(b) $CH_3CH{=}CH_2(g) + H_2O(g) \longrightarrow CH_3CH(OH)CH_3(g)$

(c) $CH_4(g) + Cl_2(g) \longrightarrow CH_3Cl(g) + HCl(g)$

7.84 The bond enthalpy in NO is 632 kJ·mol^{-1} and that of each N—O bond in NO_2 is 469 kJ·mol^{-1}. Using Lewis structures and the mean bond enthalpies given in Table 7.8, explain (a) the difference in bond enthalpies between the two molecules; (b) the fact that the bond enthalpies of the two bonds in NO_2 are the same.

7.85 Benzene is more stable and less reactive than would be predicted from its Kekulé structures. Use the mean bond enthalpies in Table 7.8 to calculate the lowering in molar energy when resonance is allowed between the Kekulé structures of benzene.

7.86 Investigate whether the replacement of a carbon–carbon double bond by single bonds is energetically favored by using Tables 7.7 and 7.8 to calculate the reaction enthalpy for the conversion of ethene, C_2H_4, to ethane, C_2H_6. The reaction is $H_2C{=}CH_2(g) + H_2(g) \longrightarrow CH_3{-}CH_3(g)$.

The Variation of Reaction Enthalpy with Temperature

7.87 (a) From the data in Appendix 2A, calculate the enthalpy of vaporization of benzene (C_6H_6) at 298.2 K. The standard enthalpy of formation of gaseous benzene is $+82.93\text{ kJ·mol}^{-1}$. (b) Given that, for liquid benzene, $C_{P,m} = 136.1\text{ J·mol}^{-1}\text{·K}^{-1}$ and that, for gaseous benzene, $C_{P,m} = 81.67\text{ J·mol}^{-1}\text{·K}^{-1}$, calculate the enthalpy of vaporization of benzene at its boiling point (353.2 K). (c) Compare the value obtained in part (b) with that found in Table 7.3. What is the source of difference between these numbers?

7.88 (a) From the data in Appendix 2A, calculate the enthalpy required to vaporize 1 mol $CH_3OH(l)$ at 298.2 K. (b) Given that the molar heat capacity, $C_{P,m}$, of liquid methanol is 81.6 $J{\cdot}K^{-1}{\cdot}mol^{-1}$ and that of gaseous methanol is 43.89 $J{\cdot}K^{-1}{\cdot}mol^{-1}$, calculate the enthalpy of vaporization of methanol at its boiling point (64.7°C). (c) Compare the value obtained in part (b) with that found in Table 7.3. What is the source of difference between these values?

7.89 Derive Kirchhoff's law for a reaction of the form $A + 2\,B \longrightarrow 3\,C + D$ by considering the change in molar enthalpy of each substance when the temperature is increased from T_1 to T_2.

7.90 Use the estimates of molar constant-volume heat capacities given in the text (as multiples of R) to estimate the change in reaction enthalpy of $N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g)$ when the temperature is increased from 300. K to 500. K. Ignore the vibrational contributions to heat capacity. Is the reaction more or less exothermic at the higher temperature?

Integrated Exercises

7.91 How much heat is required to convert a 42.30-g block of ice at −5.042°C into water vapor at 150.35°C?

7.92 A 155.7-g piece of stainless steel was heated to 475°C and quickly added to 25.34 g of ice at −24°C in a well-insulated flask that was immediately sealed. (a) If there is no loss of energy to the surroundings, what will be the final temperature of this system? (b) What phases of water will be present and in what quantities when the system reaches its final temperature?

7.93 Crude petroleum is often contaminated by poisonous hydrogen sulfide gas. The Claus process for the extraction of sulfur from petroleum has two steps:

$$2\,H_2S(g) + 3\,O_2(g) \longrightarrow 2\,SO_2(g) + 2\,H_2O(l)$$
$$2\,H_2S(g) + SO_2(g) \longrightarrow 3\,S(s) + 2\,H_2O(l)$$

(a) Write a thermochemical equation for the overall reaction that does not contain SO_2. (b) What enthalpy change would be associated with the production of 60.0 kg of sulfur? (c) Would the reactor need to be cooled or heated to maintain a constant temperature?

7.94 A reaction being studied to regenerate oxygen from carbon dioxide on long spaceflights takes place in the following two steps:

$$CO_2(g) + 2\,H_2(g) \longrightarrow C(s) + 2\,H_2O(l)$$
$$2\,H_2O(l) \longrightarrow 2\,H_2(g) + O_2(g)$$

(a) Write the thermochemical equation for the overall reaction. (b) What enthalpy change would be associated with the production of 45.0 L of oxygen at 0.80 atm and 300 K? (c) Would the reactor need to be cooled or heated to maintain a constant temperature?

7.95 The heat capacity of liquid iodine is 80.7 $J{\cdot}K^{-1}{\cdot}mol^{-1}$, and the enthalpy of vaporization of iodine is 41.96 $kJ{\cdot}mol^{-1}$ at its boiling point (184.3°C). Using these facts and information in Appendix 2A, calculate the enthalpy of fusion of iodine at 25°C.

7.96 A typical bathtub can hold 100. gallons of water. (a) Calculate the mass of natural gas that would need to be burned to heat the water for a tub of this size from 65°F to 108°F. Assume that the natural gas is pure methane, CH_4. (b) What volume of natural gas does this correspond to at 25°C and 1.00 atm? See Table 7.4.

7.97 In 1750 Joseph Black performed an experiment that eventually led to the discovery of enthalpies of fusion. He placed two 150.-g samples of water at 0.00°C (one ice and one liquid) in a room kept at a constant temperature of 5.00°C. He then observed how long it took for each sample to warm to its final temperature. The liquid sample reached 5.00°C after 30.0 min. However, the ice took 10.5 h to reach 5.00°C. He concluded that the difference in time that the two samples required to reach the same final temperature represented the difference in heat required to raise the temperatures of the samples. Use Black's data to calculate the enthalpy of fusion of ice in $kJ{\cdot}mol^{-1}$. Use the known heat capacity of liquid water.

7.98 (a) Calculate the work associated with the isothermal, reversible expansion of 1.000 mol of an ideal gas from 7.00 L to 15.50 L at 25.0°C. (b) Calculate the work associated with the irreversible adiabatic expansion of the sample of gas described in part (a) against a constant atmospheric pressure of 760. Torr. (c) How will the temperature of the gas in part (b) compare with that in part (a) after the expansion?

7.99 Aniline, $C_6H_5NH_2(l)$, is a derivative of benzene in which a hydrogen atom has been replaced by an NH_2 group. (a) Write the balanced equation for the combustion of aniline. (b) What is the mass of each product when 0.1754 g of aniline is burned in excess oxygen? (c) If the bomb calorimeter in which this reaction was carried out had a volume of 355 mL, what minimum pressure of oxygen at 23°C must have been used to ensure complete combustion? Assume that the volume of the aniline is negligible.

7.100 Calculate the work done by the reaction described in Exercise 7.53 and report it with the correct sign. Assume reaction is open to the surroundings at a constant external pressure of 1.0 atm and 25°C.

7.101 (a) Is the production of water gas (a cheap, low-grade industrial fuel) exothermic or endothermic? The reaction is

$$C(s) + H_2O(g) \longrightarrow CO(g) + H_2(g).$$

(b) Calculate the enthalpy change for the production of 200. L of hydrogen at 500. Torr and 65°C by this reaction.

7.102 The ABC cereal company is developing a new type of breakfast cereal to compete with a rival product that they call Brand X. You are asked to compare the energy content of the two cereals to see if the new ABC product is lower in calories; so you burn 1.00-g samples of the cereals in oxygen in a calorimeter with a heat capacity of 600. $J{\cdot}(°C)^{-1}$. When the Brand X cereal sample burned, the temperature rose from 300.2 K to 309.0 K. When the ABC cereal sample burned, the temperature rose from 299.0 K to 307.5 K. (a) What is the heat output of each sample? (b) One serving of each cereal is 30.0 g. How would you label the packages of the two cereals to indicate the fuel value per 30.0-g serving in joules? in nutritional Calories (kilocalories)?

7.103 An experimental automobile burns hydrogen for fuel. At the beginning of a test drive, the rigid 30.0-L tank was filled with hydrogen at 16.0 atm and 298 K. At the end of the drive, the temperature of the tank was still 298 K, but its pressure was 4.0 atm. (a) How many moles of H_2 were burned during the drive? (b) How much heat, in kilojoules, was given off by the combustion of that amount of hydrogen?

7.104 In hot, dry climates an inexpensive alternative to air conditioning is the swamp cooler. In this device water continuously wets porous pads through which fans blow the hot air. The air is cooled as the water evaporates. Use the information in Tables 7.2 and 7.3 to determine how much water must be evaporated to cool the air in a room of dimensions 4.0 m × 5.0 m × 3.0 m by 20.°C. Assume that the enthalpy of vaporization of water is the same as it is at 25°C.

7.105 (a) Calculate the work that must be done against the atmosphere for the expansion of the gaseous products in the combustion of 1.00 mol $C_6H_6(l)$ at 25°C and 1.00 bar. (b) Using data in Appendix 2A, calculate the standard enthalpy of the reaction. (c) Calculate the change in internal energy, $\Delta U°$, of the system.

7.106 A system undergoes a two-step process. In step 1, it absorbs 50. J of heat at constant volume. In step 2, it releases 5 J of heat at 1.00 atm as it is returned to its original internal energy. Find the change in the volume of the system during the second step and identify it as an expansion or compression.

7.107 Consider the hydrogenation of benzene to cyclohexane, which takes place by the step-by-step addition of two H atoms per step:

(1) $C_6H_6(l) + H_2(g) \longrightarrow C_6H_8(l)$ $\quad \Delta H° = ?$

(2) $C_6H_8(l) + H_2(g) \longrightarrow C_6H_{10}(l)$ $\quad \Delta H° = ?$

(3) $C_6H_{10}(l) + H_2(g) \longrightarrow C_6H_{12}(l)$ $\quad \Delta H° = ?$

Draw Lewis structures for the products of the hydrogenation of benzene. If resonance is possible, show only one resonance structure. (b) Use bond enthalpies to estimate the enthalpy changes of each step and the total hydrogenation. Ignore the delocalization of electrons in this calculation and the fact that the compounds are liquids. (c) Use data from Appendix 2A to calculate the enthalpy of the complete hydrogenation of benzene to cyclohexane.
(d) Compare the value obtained in part (c) with that obtained in part (b). Explain any difference.

7.108 Draw the Lewis structure for the hypothetical molecule N_6, consisting of a six-membered ring of nitrogen atoms. Using bond enthalpies, calculate the enthalpy of reaction for the decomposition of N_6 to $N_2(g)$. Do you expect N_6 to be a stable molecule?

7.109 Robert Curl, Richard Smalley, and Harold Kroto were awarded the Nobel prize in chemistry in 1996 for the discovery of the soccer-ball-shaped molecule C_{60}. This fundamental molecule was the first of a new series of *molecular* allotropes of carbon. The enthalpy of combustion of C_{60} is $-25\,937$ kJ·mol^{-1}, and its enthalpy of sublimation is +233 kJ·mol^{-1}. There are 90 bonds in C_{60}, of which 60 are single bonds and 30 are double bonds. Like benzene, C_{60} has a set of multiple bonds for which resonance structures may be drawn. (a) Determine the enthalpy of formation of C_{60} from its enthalpy of combustion. (b) Calculate the expected enthalpy of formation of C_{60} from bond enthalpies, assuming the bonds to be isolated double and single bonds. (c) Is C_{60} more or less stable than predicted on the basis of the isolated-bond model? (d) Quantify the answer to part (c) by dividing the difference between the enthalpy of formation calculated from the combustion data and that obtained from the bond enthalpy calculation by 60 to obtain a per carbon value. (e) How does the number in part (d) compare with the per carbon resonance stabilization energy of benzene (the total resonance stabilization energy of benzene is approximately 150 kJ·mol^{-1})? (f) Why might these values differ? The enthalpy of atomization of C(gr) is +717 kJ·mol^{-1}.

7.110 Normally, when sulfur is oxidized, the product is SO_2, but SO_3 may also be formed. When 0.6192 g of sulfur was burned, by using ultrapure oxygen in a bomb calorimeter with a heat capacity of 5.270 kJ·(°C)$^{-1}$, the temperature rose 1.140°C. Assuming that all the sulfur was consumed in the reaction, what was the ratio of sulfur dioxide to sulfur trioxide produced?

7.111 Speculate as to whether the combustion of 1,3,5-trinitrobenzene, $C_6H_3(NO_2)_3$, or the combustion of 1,3,5-triaminobenzene, $C_6H_3(NH_2)_3$, would be more exothermic. Support your answer with appropriate calculations.

7.112 Rank the following compounds in order of increasing enthalpy of vaporization: CH_4, H_2O, N_2, NaCl, C_6H_6, and H_2. Do not look up the enthalpy of vaporization. Explain your ordering.

7.113 A technician carries out the reaction $2\,SO_2(g) + O_2(g) \longrightarrow 2\,SO_3(g)$ at 25°C and 1.00 atm in a constant-pressure cylinder fitted with a piston. Initially, 0.030 mol SO_2 and 0.030 mol O_2 are present in the cylinder. The technician then adds a catalyst to initiate the reaction. (a) Calculate the volume of the cylinder containing the reactant gases before reaction begins. (b) What is the limiting reactant? (c) Assuming that the reaction goes to completion and that the temperature and pressure of the reaction remain constant, what is the final volume of the cylinder (include any excess reactant)? (d) How much work takes place, and is it done by the system or on the system? (e) How much enthalpy is exchanged, and does it leave or enter the system? (f) From your answers to parts (d) and (e), calculate the change in internal energy for the reaction.

7.114 In Section 7.3 we saw how to calculate the work of reversible, isothermal expansion of a perfect gas. Now suppose that the reversible expansion is not isothermal and that the temperature decreases during expansion. (a) Derive an expression for the work when $T = T_{initial} - c(V - V_{initial})$, with c a positive constant. (b) Is the work in this case greater or smaller than that of isothermal expansion? Explain your observation.

Chemistry Connections

7.115 Petroleum based fuels create large amounts of pollution, contribute to climate change, and are becoming scarce. Consequently, alternative fuels are being sought (see Box 7.2). Three compounds that could be produced biologically and used as fuels are methane, CH_4, which can be produced from the anaerobic digestion of sewage; dimethyl ether, $H_3C{-}O{-}CH_3$, a gas that can be produced from methanol and ethanol; and ethanol, CH_3CH_2OH, a liquid obtained from the fermentation of sugars.
(a) Draw the Lewis structure of each compound.
(b) Use bond enthalpies (and, for ethanol, its enthalpy of vaporization) to calculate the enthalpy of combustion of each fuel, assuming that they burn to produce gaseous CO_2 and gaseous H_2O. Explain any differences.
(c) Use the values for the enthalpies of combustion of organic compounds found in Appendix 2A to compare methane and ethanol with octane, a primary constituent of gasoline, as fuels by calculating the specific enthalpy (heat produced per gram) of each fuel. On the basis of this information, which would you choose as a fuel?
(d) What volume of methane gas at 10.00 atm and 298 K would you need to burn at constant pressure to produce the same amount of heat as 10.00 L of octane (the density of octane is 0.70 g·mL^{-1})?
(e) A problem with fuels containing carbon is that they produce carbon dioxide when they burn, and so a consideration governing the selection of a fuel could be the heat per mole of CO_2 produced. Calculate this quantity for methane, ethanol, and octane. Which process produces more carbon dioxide in the environment for each kilojoule generated?

THERMODYNAMICS: THE SECOND AND THIRD LAWS

8.13 Gibbs Free Energy of Reaction
8.14 The Gibbs Free Energy and Nonexpansion Work
8.15 The Effect of Temperature
8.16 Impact on Biology: Gibbs Free Energy Changes in Biological Systems

What Are the Key Ideas? The direction of natural change corresponds to the increasing disorder of energy and matter. Disorder is measured by the thermodynamic quantity called entropy. A related quantity—the Gibbs free energy—provides a link between thermodynamics and the description of chemical equilibrium.

Why Do We Need to Know This Material? The second law of thermodynamics is the key to understanding why one chemical reaction has a natural tendency to occur but another one does not. We apply the second law by using the very important concepts of entropy and Gibbs free energy. The third law of thermodynamics is the basis of the numerical values of these two quantities. The second and third laws jointly provide a way to predict the effects of changes in temperature and pressure on physical and chemical processes. They also lay the thermodynamic foundations for discussing chemical equilibrium, which the following chapters explore in detail.

What Do We Need to Know Already? The discussion draws on concepts related to the first law of thermodynamics, particularly enthalpy (Section 7.8) and work (Sections 7.2 and 7.3). We need to be aware that molecules can occupy only a series of discrete energy levels and so possess only certain energies (Section 1.7).

Some things happen naturally; some don't. Decay is natural; construction requires work. Water flows downhill naturally; we have to pump it uphill. A spark is enough to initiate a forest fire; the ceaseless input of energy from the Sun is required to rebuild the forest from carbon dioxide and water. Anyone who thinks about the world may wonder what determines the *natural* direction of change. What drives events forward? What drives a reaction toward products, and, on a larger scale, what drives the great and intricate network of reactions in biological systems forward in the extraordinary phenomenon we call life? As this chapter unfolds, we shall see that we can use a single quantity, "entropy," to provide an elegant and quantitative answer to all these questions: an increase in entropy accounts both for physical change and for the more intricate changes that accompany chemical reactions. We shall also see that, although entropy is a thermodynamic concept in the sense that it is a property of bulk samples of matter, it has a very straightforward molecular interpretation.

ENTROPY

The first law of thermodynamics tells us that, if a reaction takes place, then the total energy of the universe (the reaction system and its surroundings) remains unchanged. But the first law does not address the questions that lie behind the "if." Why do some reactions have a tendency to occur, whereas others do not? Why does anything happen at all? To answer these deeply important questions about the world around us, we need to take a further step into thermodynamics and learn more about energy beyond the fact that it is conserved.

8.1 Spontaneous Change

A **spontaneous change** is a change that has a tendency to occur without needing to be driven by an external influence. A simple example is the cooling of a block of hot metal to the temperature of its surroundings (Fig. 8.1). The reverse change, a block of metal spontaneously growing hotter than its surroundings, has never been observed. The expansion of a gas into a vacuum is spontaneous (Fig. 8.2): a gas has no tendency to contract spontaneously into one part of a container.

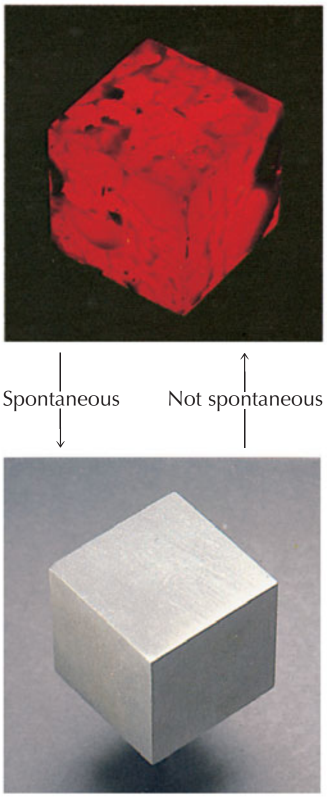

FIGURE 8.1 A hot block of metal (top) spontaneously cools to the temperature of its surroundings (bottom). The reverse process, in which a block at the same temperature as its surroundings spontaneously becomes hotter, does not occur.

A spontaneous change need not be fast and in some cases must be initiated. Molasses has a spontaneous tendency to flow out of an overturned can; but, at low temperatures, that flow may be very slow. Hydrogen and oxygen have a tendency to react to form water—the reaction is spontaneous in the thermodynamic sense—but a mixture of the two gases can be kept safely for centuries, provided it is not ignited with a spark. Diamonds have a natural tendency to turn into graphite, but diamonds last unchanged for countless years—on the human scale, diamonds are, in practice, forever. A spontaneous process has a natural *tendency* to occur; it does not necessarily take place rapidly. Throughout this chapter, and whenever we consider the thermodynamics of change, we must remember that we are exploring only the *tendency* of a process to occur. Whether that tendency is actually realized in practice depends on its rate: rates are outside the reach of thermodynamics and are considered in Chapter 14.

Changes can be made to happen in their "unnatural" direction. For example, we can force an electric current through a block of metal to heat it to a temperature higher than that of its surroundings. We can drive a gas into a smaller volume by pushing in a piston. In every case, though, to bring about a nonspontaneous change in a system, we have to contrive a way of *forcing* it to happen by applying an influence from outside the system. In short, *a nonspontaneous change can be brought about only by doing work*.

A process is spontaneous if it has a tendency to occur without being driven by an external influence; spontaneous changes need not be fast.

8.2 Entropy and Disorder

In science, we look for patterns to discover nature's laws. What is the pattern common to all spontaneous changes? To find a pattern, it is often best to start with very simple examples, because then the pattern is likely to be more obvious. So, let's think about two simple spontaneous changes—the cooling of a hot metal and the expansion of a gas—at a molecular level and search for their common feature.

A hot block of metal cools as the energy of its vigorously vibrating atoms spreads into the surroundings. The vigorously moving atoms of the metal collide with the slower atoms and molecules of the surroundings, transferring some of their energy in the collisions. The reverse change is very improbable, because it would require that energy migrate from the cooler surroundings and concentrate in a small hot block of metal. Such a process would require that collisions of the less vigorously moving atoms of the surroundings with the more vigorously moving atoms of the metal would cause the latter to move even more vigorously. The randomly moving molecules of a gas spread out all over their container; it is very unlikely that their random motion will bring them all simultaneously back into one corner. The pattern starting to emerge is that *energy and matter tend to disperse in a disorderly fashion*. As this chapter unfolds, we shall see how to use the idea of increasing disorder to account for any spontaneous change.

In the language of thermodynamics, this simple idea is expressed as the **entropy**, S, a measure of disorder. *Low entropy means little disorder; high entropy means great disorder*. It follows that we can express the pattern that we have identified as follows:

The entropy of an isolated system increases in the course of any spontaneous change.

Thus, the cooling of hot metal is accompanied by an increase in entropy as energy spreads into the surroundings. The "isolated system" in this case is taken to be the block and its immediate surroundings. Likewise, the expansion of a gas is accompanied

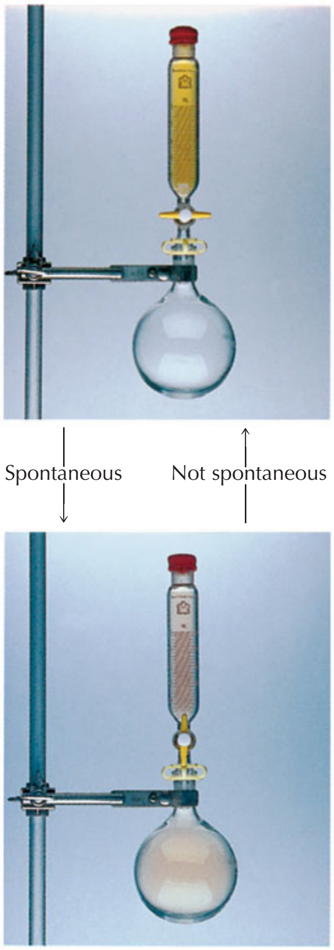

FIGURE 8.2 A gas spontaneously fills its container. A glass cylinder containing the brown gas nitrogen dioxide (upper piece of glassware in the top illustration) is attached to an evacuated flask. When the stopcock between them is opened, the gas spontaneously fills both upper and lower vessels (bottom illustration). The reverse process, in which the gas now in both vessels collects spontaneously back in the upper vessel, does not occur.

by an increase in entropy as the molecules spread through the container. The pattern we have identified is one version of the **second law of thermodynamics.** The natural progression of a system and its surroundings (which together make up "the universe") is from order to disorder, from organized to random, from lower to higher entropy. For practical measurements, a small isolated region, such as a thermally insulated, sealed flask or a calorimeter, is considered to represent the universe.

We need a quantitative definition of entropy to measure and make precise predictions about disorder. Provided that the temperature is constant, it turns out that a *change* in the entropy of a system can be calculated from the following expression:

$$\Delta S = \frac{q_{rev}}{T} \qquad \textbf{(1)*}$$

where q is the energy transferred as heat and T is the (absolute) temperature at which the transfer takes place. The subscript "rev" on q signifies that the energy must be transferred reversibly in the sense described in Section 7.3. For a reversible transfer of energy as heat, the temperatures of the surroundings and the system must be only infinitesimally different. With heat measured in joules and temperature in kelvins, the change in entropy (and entropy itself) is measured in joules per kelvin ($J\cdot K^{-1}$).

> ***What does this equation tell us?*** If a lot of energy is transferred as heat (large q_{rev}), a lot of disorder is stirred up in the system and we expect a correspondingly big increase in entropy. For a given transfer of energy, we expect a greater change in disorder when the temperature is low than when it is high. The arriving energy stirs up the molecules of a cool system, which have little thermal motion, more noticeably than those of a hot system, in which the molecules are already moving vigorously. (Think of how sneezing in a quiet library will attract attention, but sneezing in a noisy street may pass unnoticed.)

EXAMPLE 8.1 Calculating the change in entropy when a system is heated

A large flask of water is placed on a heater and 100. J of energy is transferred reversibly to the water at 25°C. What is the change in entropy of the water?

Anticipate Because the water is absorbing energy as heat, we expect its entropy to increase.

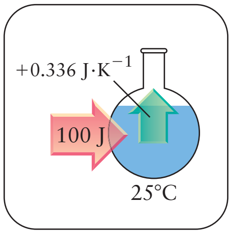
PLAN Use Eq. 1 to calculate the entropy change.

What should we assume? That the flask of water is so large that its temperature remains virtually constant as the heat is transferred: Eq. 1 applies only at constant temperature.

SOLVE

From $\Delta S = q_{rev}/T$,

$$\Delta S = \frac{100\ \text{J}}{\underbrace{(273.15 + 25)\ \text{K}}_{\text{Convert to kelvins}}} = \frac{1.00 \times 10^2}{298}\frac{\text{J}}{\text{K}} = +0.336\ \text{J}\cdot\text{K}^{-1}$$



Evaluate As predicted, the entropy of the water increases as a result of the flow of heat into it.

A note on good practice: Note the + sign on the answer: always show the sign explicitly for the change in a quantity, even if it is positive.

Self-Test 8.1A Calculate the change in entropy of a large block of ice when 50. J of energy is removed reversibly from it as heat at 0°C in a freezer.

[***Answer:*** $-0.18\ J\cdot K^{-1}$]

Self-Test 8.1B Calculate the change in entropy of a large vat of molten copper when 50. J of energy is removed reversibly from it as heat at 1100.°C.

A very important characteristic of entropy that is not immediately obvious from Eq. 1 but can be proved by using thermodynamics is that, like the enthalpy, *entropy is a state function*. This property is consistent with entropy being a measure of disorder, because the disorder of a system depends only on its current state and is independent of how that state was achieved.

Because entropy is a state function, the change in entropy of a system is independent of the path between its initial and final states. This independence means that, if we want to calculate the entropy difference between a pair of states joined by an *irreversible* path, we can look for a *reversible* path between the same two states and then use Eq. 1 for that path. For example, suppose an ideal gas undergoes free (irreversible) expansion at constant temperature. To calculate the change in entropy, we allow the gas to undergo reversible, isothermal expansion between the same initial and final volumes, calculate the heat absorbed in this process, and use it in Eq.1. Because entropy is a state function, the change in entropy calculated for this reversible path is also the change in entropy for the free expansion between the same two states.

Entropy is a measure of disorder; according to the second law of thermodynamics, the entropy of an isolated system increases in any spontaneous process. Entropy is a state function.

8.3 Changes in Entropy

We can expect disorder to increase when a system is heated because the supply of energy increases the thermal motion of the molecules. Heating increases the **thermal disorder,** the disorder arising from the thermal motion of the molecules. We can also expect the entropy to increase when a given amount of matter spreads into a greater volume or is mixed with another substance. These processes disperse the molecules of the substance over a greater volume and increase the **positional disorder,** the disorder related to the locations of the molecules.

Equation 1 allows us to express these changes quantitatively. First, let's calculate the entropy change that results when a system is heated and its temperature increases.

HOW DO WE DO THAT?

To derive an expression for the change in entropy when a system is heated, we first note that Eq. 1 applies only when the temperature remains constant as heat is supplied to a system. Except in special cases, that can be true only for infinitesimal transfers of heat; so we have to break down the calculation into an infinite number of infinitesimal steps, with each step taking place at a constant but slightly different temperature, and then add together the infinitesimal entropy changes for all the steps. To do this we use calculus. For an infinitesimal reversible transfer dq_{rev} at the temperature T, the increase in entropy is also infinitesimal; and, instead of Eq. 1, we write

These special cases include any isothermal process, such as isothermal expansion of a gas, and transfers of energy at freezing or boiling points (see Section 8.4).

$$dS = \frac{dq_{rev}}{T}$$

The energy supplied as heat is related to the resulting increase in temperature, dT, by the heat capacity, C, of the system:

$$dq_{rev} = CdT$$

(This equation is the infinitesimal form of Eq. 5b of Chapter 7, which also applies to reversible changes.) If the change in temperature is carried out at constant volume, we use the constant-volume heat capacity, C_V. If the change is carried out at constant pressure, we use the constant-pressure heat capacity, C_P. By combining the preceding two equations, we get

$$dS = \frac{CdT}{T}$$

Now suppose that the temperature of a sample is increased from T_1 to T_2. The overall change in entropy is the sum (integral) of all these infinitesimal changes:

$$\Delta S = \int_{T_1}^{T_2} \frac{CdT}{T}$$

Because an integral can be identified with an area, this expression for ΔS can be identified with the area under the graph of C/T plotted against T enclosed by vertical lines at T_1 and T_2 (see the following Example). Provided the heat capacity is independent of temperature in the temperature range of interest, C can be taken outside the integral and we obtain

$$\Delta S = C\int_{T_1}^{T_2} \frac{dT}{T} = C \ln \frac{T_2}{T_1}$$

To evaluate the integral, we have used the standard integral

$$\int \frac{dx}{x} = \ln x + \text{constant}$$

We have shown that, provided the heat capacity can be treated as constant in the temperature range of interest, the entropy change that occurs when a system is heated from T_1 to T_2 is given by

$$\Delta S = C \ln \frac{T_2}{T_1} \qquad (2)^*$$

where C is the heat capacity of the system (C_V if the volume is constant, C_P if the pressure is constant).

What does this equation tell us? If T_2 is higher than T_1, then $T_2/T_1 > 1$, the logarithm of this ratio is positive, and therefore ΔS is positive too, corresponding to the expected increase in entropy as the temperature is raised. The greater the heat capacity of the substance, the greater the increase in entropy for a given change in temperature.

Figure 8.3 shows how the entropy of a substance changes as it is heated through a temperature range in which it has a constant heat capacity.

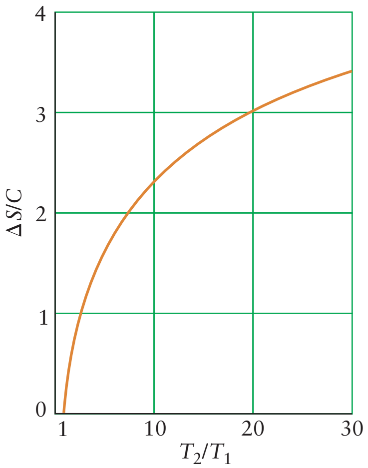


FIGURE 8.3 The change in entropy as a sample is heated for a system with a constant heat capacity (C) in the range of interest. Here we have plotted $\Delta S/C$ against the ratio of the final to the initial temperature. The entropy increases logarithmically with temperature.

EXAMPLE 8.2 Calculating the entropy change due to an increase in temperature

A sample of nitrogen gas of volume 20.0 L at 5.00 kPa is heated from 20.°C to 400.°C at constant volume. What is the change in the entropy of the nitrogen? The molar heat capacity of nitrogen at constant volume, $C_{V,m}$, is 20.81 $J\cdot K^{-1}\cdot mol^{-1}$.

Anticipate Because the thermal disorder in a system increases as the temperature rises, we should expect a positive entropy change.

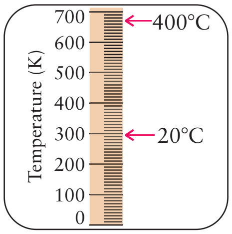
PLAN We use Eq. 2, with the heat capacity at constant volume, $C_V = nC_{V,m}$. Find the amount (in moles) of gas molecules by using the ideal gas law, $PV = nRT$ in the form $n = PV/RT$ and the initial conditions; remember to express temperature in kelvins. Because the data are liters and kilopascals, use R expressed in those units. As always, avoid rounding errors by delaying the numerical calculation to the last possible stage.

What should we assume? That nitrogen is an ideal gas (for the calculation of n) and that C_V is constant over the temperature range.

SOLVE

Convert temperatures into kelvins.

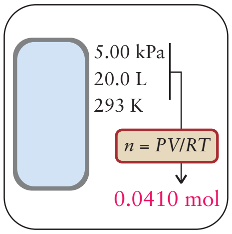
$$T_1 = 20. + 273.15\ K = 293\ K$$
$$T_2 = 400. + 273.15\ K = 673\ K$$



Find the amount of N_2 from $PV = nRT$ in the form $n = PV/RT$.

$$n = \frac{(5.00\ \text{kPa}) \times (20.0\ \text{L})}{(8.3145\ \text{L·kPa·K}^{-1}\text{·mol}^{-1}) \times (293\ \text{K})}$$

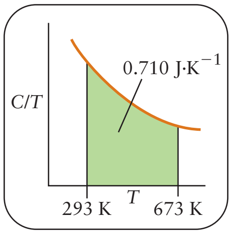
$$= \frac{5.00 \times 20.0}{8.3145 \times 293}\ \text{mol}\ (= 0.0410\ \text{mol})$$



Calculate the change in entropy from $\Delta S = C \ln(T_2/T_1)$ with $C = nC_{V,\text{m}}$.

$$\Delta S = \frac{5.00 \times 20.0}{8.3145 \times 293}\ \text{mol} \times (20.81\ \text{J·K}^{-1}\text{·mol}^{-1}) \times \ln\frac{673\ \text{K}}{293\ \text{K}}$$

$$= +0.710\ \text{J·K}^{-1}$$



Evaluate The change is positive (an increase), as expected. Note that, as remarked earlier, the change in entropy is equal to the area beneath the graph of C/T plotted against T.

Self-Test 8.2A The temperature of 1.00 mol He(g) is increased from 25°C to 300.°C at constant volume. What is the change in the entropy of the helium? Assume ideal behavior and use $C_{V,\text{m}} = \frac{3}{2}R$.

[***Answer:*** $+8.15\ \text{J·K}^{-1}$]

Self-Test 8.2B The temperature of 5.5 g of stainless steel is increased from 20.°C to 100.°C. What is the change in the entropy of the stainless steel? The specific heat capacity of stainless steel is $0.51\ \text{J·(°C)}^{-1}\text{·g}^{-1}$.

Some changes are accompanied by a change in volume. Because a larger volume provides a greater range of locations for the molecules, we can expect the positional disorder of a gas and therefore its entropy to increase as the volume it occupies is increased. Once again, we can use Eq. 1 to turn this intuitive idea into a quantitative expression of the entropy change for the isothermal expansion of an ideal gas. We choose an isothermal expansion because both temperature and volume affect the entropy of a substance; at this stage, we do not want to have to consider changes in both temperature and volume.

HOW DO WE DO THAT?

To derive an expression for the dependence of the entropy of an ideal gas on its volume, we note that, when the expansion is isothermal, implying that T is constant, we can use Eq. 1 directly. We then use the first law in the form $\Delta U = q + w$ to relate q for a reversible, isothermal expansion to the change in volume of the gas. We know that $\Delta U = 0$ for the isothermal expansion of an ideal gas (Section 7.6); so we can conclude that $q + w = 0$ and therefore that $q = -w$. Physically, that equality means that the energy the system loses by doing expansion work is replaced by an influx of energy as heat, so the internal energy remains the same. The same relation applies if the change is carried out reversibly, and so we can write $q_{\text{rev}} = -w_{\text{rev}}$. Therefore, to calculate q_{rev}, we calculate the work done when an ideal gas expands reversibly and isothermally and then change the sign. For that calculation, we can use the following expression, which we derived in Section 7.3:

$$w_{\text{rev}} = -nRT \ln\frac{V_2}{V_1}$$

We can substitute this value in the expression for entropy and obtain

$$\Delta S = \frac{\Delta q_{\text{rev}}}{T} = \frac{(-w_{\text{rev}})}{T} = \frac{nRT\ln(V_2/V_1)}{T} = nR\ln\frac{V_2}{V_1}$$

We have shown that the change in entropy of an ideal gas when it expands isothermally from a volume V_1 to a volume V_2 is

$$\Delta S = nR \ln \frac{V_2}{V_1} \qquad (3a)^*$$

where n is the amount of gas molecules (in moles) and R is the gas constant (in joules per kelvin per mole). When the final volume is greater than the initial volume ($V_2 > V_1$), the change in entropy is positive, corresponding to an increase in entropy, as expected (Fig. 8.4).

Notice that here we see an important aspect of thermodynamics: although we have calculated the change in entropy for a reversible path, Eq. 3 is also the change in entropy of the gas when it expands *irreversibly* between the same two states, in this case from V_1 to V_2 at any constant temperature. As we saw in Section 8.2, this conclusion follows from the fact that entropy is a state function, and therefore independent of the path. You should not jump to the conclusion, though, that there is no difference between reversible and irreversible processes: at this point we are considering only the change in entropy of the system and have not yet discussed what is going on in the surroundings. We consider that in Section 8.9.

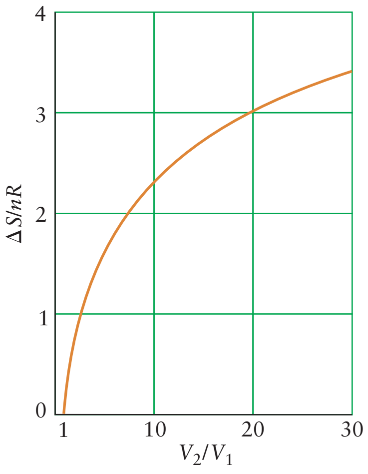


FIGURE 8.4 The change in entropy as a sample of a perfect gas expands at constant temperature. Here we have plotted $\Delta S/nR$ against the ratio of the final to the initial volume. The entropy increases logarithmically with volume.

EXAMPLE 8.3 Calculating the change in entropy when an ideal gas expands isothermally

What is the change in entropy of the gas when 1.00 mol N_2(g) expands isothermally from 22.0 L to 44.0 L?

Anticipate Because the greater volume provides more locations into which the molecules of the gas can spread, we should expect its entropy to increase.

PLAN Use Eq. 3a to calculate the entropy change for an isothermal expansion when the initial and final volumes are known.

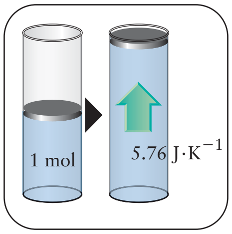
What should we assume? That nitrogen behaves as an ideal gas.

SOLVE

From $\Delta S = nR \ln (V_2/V_1)$,

$$\Delta S = (1.00\ \text{mol}) \times (8.3145\ \text{J·K}^{-1}\text{·mol}^{-1}) \times \ln \frac{44.0\ \text{L}}{22.0\ \text{L}}$$

$$= +5.76\ \text{J·K}^{-1}$$



Evaluate As expected, the entropy increases as the space available to the gas expands.

A note on good practice: Note that the entropy change *for* 1 mol of a substance is reported differently from the entropy change *per* mole: the units of the former are joules per kelvin (J·K^{-1}), those of the latter are joules per kelvin per mole ($\text{J·K}^{-1}\text{·mol}^{-1}$).

Self-Test 8.3A Calculate the change in molar entropy of an ideal gas when it is compressed isothermally to one-third its initial volume.

[***Answer:*** $-9.13\ \text{J·K}^{-1}\text{·mol}^{-1}$]

Self-Test 8.3B Calculate the change in molar entropy of carbon dioxide that is allowed to expand isothermally to 10. times its initial volume (treat carbon dioxide as an ideal gas).

The entropy change accompanying the isothermal compression or expansion of an ideal gas can be expressed in terms of its initial and final pressures. To do so, we use the ideal gas law—specifically, Boyle's law—to express the ratio of volumes in Eq. 3 in terms of the ratio of the initial and final pressures. Because pressure is inversely

proportional to volume (Boyle's law), we know that at constant temperature $V_2/V_1 = P_1/P_2$ where P_1 is the initial pressure and P_2 is the final pressure. Therefore,

$$\Delta S = nR \ln \frac{P_1}{P_2} \qquad \textbf{(3b)}$$

EXAMPLE 8.4 Calculating the change in entropy with pressure

Calculate the change in entropy when the pressure of 0.321 mol O_2(g) is increased from 0.300 atm to 12.00 atm at constant temperature.

Anticipate For a fixed amount of gas and a fixed temperature, the only way to increase the pressure is to compress it (that is, decrease the volume it occupies). We can therefore expect the entropy to decrease because the molecules are confined to a smaller volume.

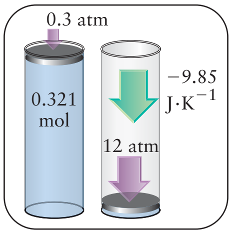
PLAN Use Eq. 3b to calculate the entropy change for an isothermal increase in pressure.

What should we assume? That oxygen is an ideal gas.

SOLVE

From $\Delta S = nR \ln(P_1/P_2)$,

$$\Delta S = (0.321 \text{ mol}) \times (8.3145 \text{ J·K}^{-1}\text{·mol}^{-1}) \times \ln \frac{0.300 \text{ atm}}{12.00 \text{ atm}}$$
$$= -9.85 \text{ J·K}^{-1}$$



Evaluate The entropy decreases, as expected for a sample that has been compressed into a smaller volume at constant temperature.

Self-Test 8.4A Calculate the change in entropy when the pressure of 1.50 mol Ne(g) is decreased isothermally from 20.00 bar to 5.00 bar. Assume ideal behavior.

[***Answer:*** $+17.3$ J·K^{-1}]

Self-Test 8.4B Calculate the change in entropy when the pressure of 70.9 g of chlorine gas is increased isothermally from 3.00 kPa to 24.00 kPa. Assume ideal behavior.

To calculate a change in entropy for a process we find a *reversible* path between the initial and final states. It is immaterial whether the actual process is irreversible or reversible. Because entropy is a state function, the change for that path will be the same as that for the irreversible path, provided the two paths have the same initial and final states.

EXAMPLE 8.5 Calculating the change in entropy when both temperature and volume change

In an experiment, 1.00 mol Ar(g) was compressed suddenly (and irreversibly) from 5.00 L to 1.00 L by driving in a piston (like a big bicycle pump), and in the process its temperature was increased from 20.0°C to 25.2°C. What is the change in entropy of the gas?

Anticipate The entropy will decrease when a gas is compressed, but increase when its temperature rises. Because the temperature rise is small, we expect an overall decrease, but must do the calculation to be sure.

PLAN Because the entropy is a state function, we can calculate the change in entropy by choosing a reversible path that results in the same final state. In this case, consider the following:

Step 1 Reversible isothermal compression at the initial temperature from the initial volume to the final volume (and use Eq. 3a).

Step 2 An increase in temperature of the gas at constant final volume to the final temperature (and use C_V in Eq. 2 with C the heat capacity at constant volume).

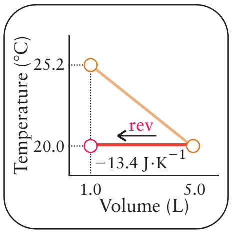
What should we assume? That argon is an ideal gas and that C_V is constant over the temperature range.

SOLVE

Step 1 From Eq. 3a, $\Delta S = nR \ln(V_2/V_1)$,

$$\Delta S = (1.00\text{ mol}) \times (8.3145\text{ J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}) \times \ln \frac{1.00\text{ L}}{5.00\text{ L}}$$

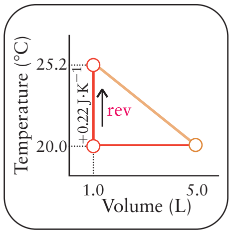
$$= -13.4\text{ J}\cdot\text{K}^{-1}$$



Step 2 From $\Delta S = C_V \ln(T_2/T_1)$ with $C_V = nC_{V,m}$,

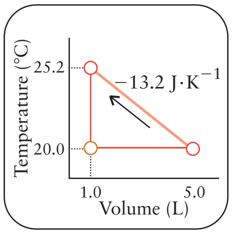
$$\Delta S = (1.00\text{ mol}) \times (12.47\text{ J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}) \times \ln \frac{298.4\text{ K}}{293.2\text{ K}}$$

$$= +0.22\text{ J}\cdot\text{K}^{-1}$$



Add the entropy changes for the two steps, $\Delta S = \Delta S$ (step 1) $+ \Delta S$ (step 2).

$$\Delta S = -13.4 + 0.22\text{ J}\cdot\text{K}^{-1} = -13.2\text{ J}\cdot\text{K}^{-1}$$



Evaluate As expected, the decrease in entropy due to the fivefold compression is much greater than that due to the small rise in temperature.

Self-Test 8.5A Calculate the change in entropy when the volume of 2.00 mol Ar(g) is increased from 5.00 L to 10.00 L while the temperature increases from 100. K to 300. K. Assume ideal behavior.

[***Answer:*** $+38.9\text{ J}\cdot\text{K}^{-1}$]

Self-Test 8.5B Calculate the change in entropy when the pressure of 23.5 g of oxygen gas is increased from 2.00 kPa to 8.00 kPa while the temperature increases from 240 K to 360 K. Assume ideal behavior.

The entropy of a system increases when its temperature increases and when its volume increases.

8.4 Entropy Changes Accompanying Changes in Physical State

We can expect the entropy to increase when a solid melts and its molecules become more disordered as they form a liquid. Similarly, we can expect an even greater increase in entropy when a liquid vaporizes, because its molecules then occupy a much greater volume and their motion is highly chaotic. As we saw in Section 4.8, a liquid vaporizes until its partial pressure has reached a certain value, called its vapor pressure. As the liquid is heated, its vapor pressure increases until it is equal to the external pressure. At that temperature, which is called the **boiling temperature,** the liquid boils.

In this section, we develop expressions for the change in entropy at the transition temperature for the prevailing pressure. For instance, if the pressure is 1 atm, then these expressions are applicable only at the **normal melting point,** T_f (the f stands for fusion, another term for melting), the temperature at which a solid melts when the

pressure is 1 atm, or the **normal boiling point,** T_b, the temperature at which a liquid boils when the pressure is 1 atm. In most cases, the boiling temperature at 1 bar is negligibly different from the normal boiling point.

To use Eq. 1 to calculate the entropy change for a substance undergoing a transition from one phase to another at its transition temperature, we need to note three facts:

1 At the transition temperature (such as the boiling point for vaporization), the temperature of the substance remains constant as heat is supplied.

All the energy supplied is used to drive the phase transition, such as the conversion of liquid into vapor, rather than to raise the temperature. The T in the denominator of Eq. 1 is therefore a constant and may be set equal to the transition temperature (in kelvins).

2 At the temperature of a phase transition, the transfer of heat is reversible.

Provided the external pressure is fixed (at 1 atm, for instance), raising the temperature of the surroundings an infinitesimal amount results in complete vaporization and lowering the temperature causes complete condensation.

3 Because the transition takes place at constant pressure (for instance, 1 atm), the heat supplied is equal to the change in enthalpy of the substance (Section 7.8).

It follows that we can replace q_{rev} in the expression for the entropy change with ΔH for the phase change.

The **entropy of vaporization,** ΔS_{vap}, is the change in entropy per mole of molecules when a substance changes from a liquid into a vapor. The heat required per mole to vaporize the liquid at constant pressure is equal to the enthalpy of vaporization (ΔH_{vap}, Section 7.11). It then follows from Eq. 1, by setting $q_{rev} = \Delta H_{vap}$, that the entropy of vaporization at the boiling temperature is

$$\text{At the boiling temperature: } \Delta S_{vap} = \frac{\Delta H_{vap}}{T_b} \qquad \textbf{(4)*}$$

When the liquid and the vapor are in their standard states (both pure, both at 1 bar) and the boiling temperature is for 1 bar, we refer to the **standard entropy of vaporization,** $\Delta S_{vap}°$. Because all standard entropies of vaporization are positive, they are normally reported without their positive sign.

EXAMPLE 8.6 Calculating the standard entropy of vaporization

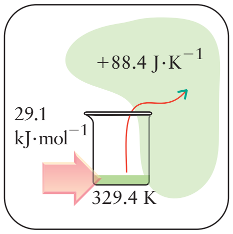
What is the standard entropy of vaporization of acetone at its normal boiling point of 56.2°C?

PLAN Find the standard enthalpy of vaporization of acetone at its boiling point in Table 7.3 and substitute the data into Eq. 4.

SOLVE The boiling point corresponds to 329.4 K, and we note from Table 7.3 that the standard enthalpy of vaporization of acetone at its boiling point is 29.1 kJ·mol⁻¹. Therefore,

From $\Delta S_{vap}° = \Delta H_{vap}°/T_b$,

$$\Delta S_{vap} = \frac{\overbrace{2.91 \times 10^4\ \text{J·mol}^{-1}}^{29.1\ \text{kJ·mol}^{-1}}}{\underbrace{329.4\ \text{K}}_{(273.15\ +\ 56.2)\ \text{K}}} = 88.3\ \text{J·K}^{-1}\text{·mol}^{-1}$$



Self-Test 8.6A Calculate the standard entropy of vaporization of argon at its normal boiling point (see Table 7.3).

[***Answer:*** 74 J·K⁻¹·mol⁻¹]

Self-Test 8.6B Calculate the standard entropy of vaporization of water at its normal boiling point (see Table 7.3).

TABLE 8.1 Standard Entropy of Vaporization at the Normal Boiling Point*

Liquid	Boiling point (K)	$\Delta S_{vap}°$ ($J \cdot K^{-1} \cdot mol^{-1}$)
acetone	329.4	88.3
ammonia	239.7	97.6
argon	87.3	74
benzene	353.2	87.2
ethanol	351.5	124
helium	4.22	20.
mercury	629.7	94.2
methane	111.7	73
methanol	337.8	105
water	373.2	109

*The normal boiling point is the boiling temperature at 1 atm.

Table 8.1 lists the standard entropies of vaporization of a number of liquids. These and other data show a striking pattern: many values are close to 85 $J \cdot K^{-1} \cdot mol^{-1}$. This observation is called **Trouton's rule.** The explanation of Trouton's rule is that approximately the same increase in positional disorder occurs when any liquid is converted into vapor, and so we can expect the change in entropy to be much the same in each case. Because all gases behave similarly, substantial departures from Trouton's rule normally indicate that the molecules have a more orderly arrangement in the liquid than is typical of most liquids, and so there is a greater increase in disorder when such liquids vaporize. The molecules in a liquid are relatively highly ordered if there are extensive intermolecular interactions. Liquids such as water that can take part in extensive hydrogen bonding typically have entropies of vaporization greater than 85 $J \cdot K^{-1} \cdot mol^{-1}$.

Thinking point: Why does mercury have such a high entropy of vaporization?

Self-Test 8.7A Use Trouton's rule to estimate the standard enthalpy of vaporization of liquid bromine, which boils at 59°C.

[***Answer:*** 28 $kJ \cdot mol^{-1}$ (experimentally, 29.45 $kJ \cdot mol^{-1}$)]

Self-Test 8.7B Use Trouton's rule to estimate the standard enthalpy of vaporization of diethyl ether, $C_4H_{10}O$, which boils at 34.5°C.

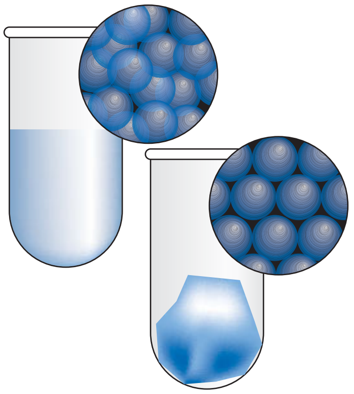


FIGURE 8.5 A representation of the arrangement of molecules in (a) a liquid and (b) a solid. When the liquid freezes, the molecules lie in an ordered array; consequently there is a decrease in the disorder of the system (a drop in entropy). The entropy rises again when the solid melts.

Lab Video 8.5

A smaller increase in entropy occurs when solids melt than when liquids vaporize, because a liquid is only slightly more disordered than a solid (Fig. 8.5). By applying the same argument used for vaporization to the standard entropy of fusion of a substance at its melting (or freezing) point, we obtain

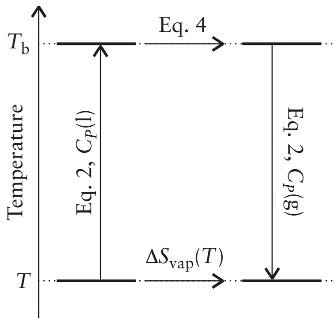
$$\text{At the freezing temperature: } \Delta S_{fus}° = \frac{\Delta H_{fus}°}{T_f} \qquad (5)^*$$

Here, $\Delta H_{fus}°$ is the standard enthalpy of fusion and T_f is the melting point. All entropies of fusion are positive (there is a single exception: solid helium-3), and so they are normally reported without their positive sign.

Self-Test 8.8A Calculate the standard entropy of fusion of mercury at its freezing point (see Table 7.3).

[***Answer:*** 9.782 $J \cdot K^{-1} \cdot mol^{-1}$]

Self-Test 8.8B Calculate the standard entropy of fusion of benzene at its melting point (see Table 7.3).



1

Because entropy changes may depend on temperature, to find the entropy of transition at a temperature other than the normal transition temperature, we have to break the calculation down into three steps (**1**). For example, if we want to know the entropy of vaporization of water at 25°C and 1 bar we imagine that we

- heat the liquid to its normal boiling point, 100.°C,

- allow it to vaporize,
- then cool the vapor back to 25°C.

To match these steps:

- Use Eq. 2 to calculate the entropy change accompanying the heating of water from 25°C to 100.°C (the heat capacity of water is approximately constant over that range).
- Use Eq. 4 to calculate the entropy of vaporization at 100.°C.
- Use Eq. 2 to calculate the entropy change accompanying the cooling of water vapor from 100.°C back to 25°C (a negative value).

Finally, we add the three contributions together to get the quantity that we require:

$$\Delta S_{\text{vap}}(25°\text{C}) = \Delta S(\text{heating liquid from 25°C to 100.°C}) + \Delta S_{\text{vap}}(100.°\text{C}) + \Delta S(\text{cooling vapor from 100.°C to 25°C})$$

We can break the overall calculation down in this way because entropy is a state function. For an example of this type of calculation, see Exercise 8.43.

The entropy of a substance increases when it melts and when it vaporizes.

8.5 A Molecular Interpretation of Entropy

So far, we have calculated only *changes* in the entropy of a substance. However, entropy is a measure of disorder, and it is possible to imagine a perfectly orderly state of matter with neither positional nor, at $T = 0$, thermal disorder. Such a state represents a natural zero of entropy, a state of perfect order; therefore, we should be able to set up an absolute scale of entropy just as we can set up an absolute scale of temperature. This idea is summarized by the **third law of thermodynamics:**

> The entropies of all perfect crystals approach zero as the absolute temperature approaches zero.

That is, $S \longrightarrow 0$ as $T \longrightarrow 0$. The "perfect crystal" part of this statement of the third law refers to a substance in which all the atoms are in a perfectly orderly array, and so there is no positional disorder. The $T \longrightarrow 0$ part of the statement implies the absence of thermal motion—thermal disorder vanishes as the temperature approaches zero. As the temperature of a substance is raised from zero, more orientations become available to the molecules and their thermal disorder increases. Thus we can expect the entropy of any substance to be greater than zero above $T = 0$.

In 1877, the Austrian physicist Ludwig Boltzmann proposed a molecular definition of entropy that enables us to calculate the *absolute* entropy at any temperature (Fig. 8.6). His formula provided a way of calculating the entropy when measurements could not be made and deepened our insight into the meaning of entropy at the molecular level. The **Boltzmann formula** for the entropy is

$$S = k \ln W \qquad \textbf{(6)*}$$

We met Boltzmann's constant, $k = 1.381 \times 10^{-23}\ \text{J·K}^{-1}$, in Section 7.7 in connection with the equipartition theorem and saw that it is related to the gas constant by $R = kN_A$. The quantity W is the *number of ways that the atoms or molecules in the sample can be arranged and yet still give rise to the same total energy*. Each arrangement of the molecules in a sample is a different state called a **microstate;** so W is equal to the number of different microstates that correspond to the same energy. A microstate lasts only for an instant; so, when we measure the bulk properties of a system, we are measuring an average taken over the many microstates that the system has occupied during the measurement. The entropy calculated from the Boltzmann formula is called the **statistical entropy.**

To understand Eq. 6, imagine that we have a large number of replicas of the system that we are investigating, with each replica having the same total energy. This collection is called an **ensemble.** Although the energy of each replica is the same, the molecules

FIGURE 8.6 Ludwig Boltzmann (1844–1906). His formula for entropy (using an earlier notation for natural logarithms) became his epitaph.

may be distributed differently over the available energy levels. We can imagine that all the replicas are placed in a box, and we select them blindly, one by one. If there is only one way of achieving the energy (for instance, all the molecules are in exactly the same energy level), then $W = 1$. In this case every replica that we select will have exactly the same distribution of molecules and will be in exactly the same microstate. Such a system has zero entropy ($\ln 1 = 0$) and zero disorder because each time we make a selection we find the system in that single microstate. We can be absolutely certain that the selection will be the same in each case. However, if there is more than one way of arranging the molecules in the sample to achieve the same energy, then not every replica that we draw will be the same. For instance, if a certain energy can be achieved with 1000 different microstates ($W = 1000$), then there is only 1 chance in 1000 of drawing a *specific* one of those microstates. Because the disorder of the system is higher for this state than for that with $W = 1$, the entropy for this state is greater than zero.

EXAMPLE 8.7 Calculating the entropy of a system

Calculate the entropy of a tiny solid made up of four diatomic molecules of a compound such as carbon monoxide, CO, at $T = 0$ when (a) the four molecules have formed a perfectly ordered crystal in which all molecules are aligned with their C atoms on the left (top-left image in Fig. 8.7) and (b) the four molecules lie in random orientations (but parallel, any of the images in Fig. 8.7).

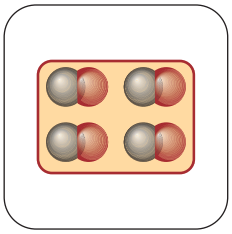
Anticipate We expect that at $T = 0$ the sample in (a) will have zero entropy, because there is no disorder in either location or energy as all the molecules are in their lowest possible energy state. The sample in (b) has greater disorder, so we expect its entropy to have a positive value.

PLAN Use the Boltzmann formula (Eq. 6) to calculate the entropy of the sample.

SOLVE (a) Because there is only one way of arranging the molecules in the perfect crystal, $W = 1$.

From $S = k \ln W$ and $W = 1$,

$$S = k \ln 1 = 0$$



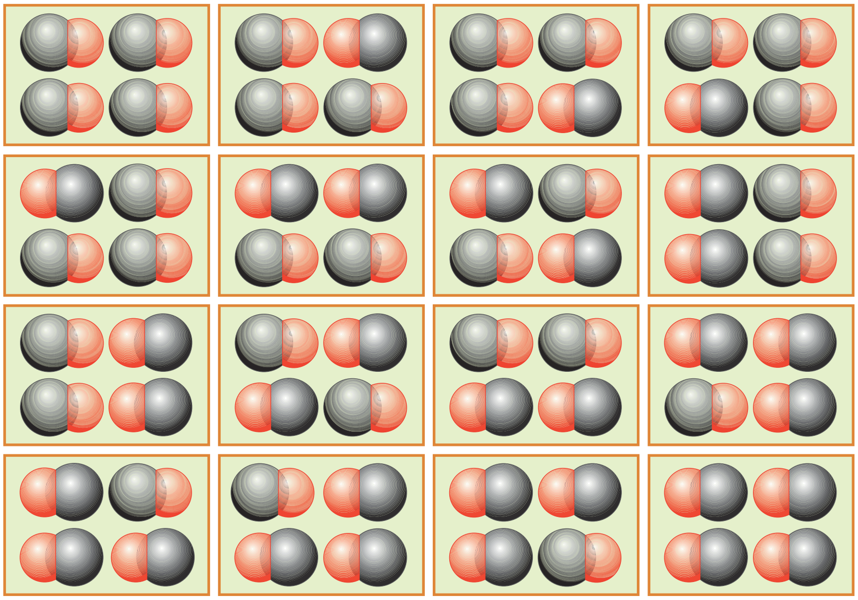


FIGURE 8.7 A tiny sample of solid carbon monoxide consisting of four molecules. Each box represents a different arrangement of the four molecules. When there is only one way of arranging the four molecules so that they all point in one direction (as in the top left image), the entropy of the solid is zero. When all sixteen ways of arranging four CO molecules are accessible, the entropy of the solid is greater than zero.

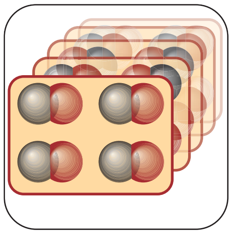
In this case, every member of the ensemble is identical, and we can be sure that any selection results in the same microstate. (b) Because each of the four molecules can take two orientations, the total number of ways of arranging them is

$$W = 2 \times 2 \times 2 \times 2 = 2^4$$

or 16 different possible arrangements corresponding to the same total energy. Now there is only 1 chance in 16 of selecting a given microstate from the ensemble, and so we can be less sure about the actual state of the system. The entropy of this tiny solid is therefore

From $S = k \ln W$ and $W = 2^4$,

$$S = k \ln 2^4 = (1.3807 \times 10^{-23}\ \text{J·K}^{-1}) \times \ln 16$$
$$= 3.8281 \times 10^{-23}\ \text{J·K}^{-1}$$



Evaluate As expected, the entropy of the disordered solid is higher than that of the perfectly ordered solid.

Self-Test 8.9A Calculate the entropy of a sample of a solid in which the molecules may be found in any one of three orientations with the same energy. Suppose there are 30 molecules in the sample.

[***Answer:*** $4.5 \times 10^{-22}\ \text{J·K}^{-1}$]

Self-Test 8.9B Calculate the entropy of a sample of a solid in which it is supposed that a substituted benzene molecule, C_6H_5F, may be found in any one of six orientations with the same energy. Suppose there is 1.0 mol of molecules in the sample.

For a more realistic sample size than that in Example 8.7, one that contains 1.00 mol CO, corresponding to 6.02×10^{23} CO molecules, each of which could be oriented in either of two ways, there are $2^{6.02\times10^{23}}$ (an astronomically large number) different microstates, and a chance of only 1 in $2^{6.02\times10^{23}}$ of drawing a given microstate in a blind selection. We can expect the entropy of the solid to be high and calculate by using $\ln x^a = a \ln x$ that

From $S = k \ln W$ and $W = 2^{6.02\times10^{23}}$

$$S = k \ln 2^{6.02\times10^{23}}$$
$$= (1.3807 \times 10^{-23}\ \text{J·K}^{-1}) \times (6.02 \times 10^{23}) \times \ln 2$$
$$= 5.76\ \text{J·K}^{-1}$$

When the entropy of 1.00 mol CO is actually measured at temperatures close to $T = 0$, the value found is $4.6\ \text{J·K}^{-1}$. This value—which is called the **residual entropy** of the sample, the entropy of a sample at $T = 0$ arising from positional disorder surviving at that temperature—is close enough to $5.76\ \text{J·K}^{-1}$ to suggest that in the crystal the molecules are indeed arranged nearly randomly. The reason for this randomness is that the electric dipole moment of a CO molecule is very small, and so there is little energy advantage in the molecules lying head-to-tail, head-to-head, or tail-to-tail; thus the molecules lie in either direction. For solid HCl, the same experimental measurements give $S \approx 0$ close to $T = 0$. This value indicates that the bigger dipole moments of the HCl molecules pull them into an orderly arrangement; so they lie strictly head-to-tail and there is no positional disorder at $T = 0$.

EXAMPLE 8.8 Using the Boltzmann formula to interpret a residual entropy

The entropy of 1.00 mol $FClO_3$(s) at $T = 0$ is $10.1\ \text{J·K}^{-1}$. Suggest an interpretation.

Anticipate The observation that the entropy is nonzero at $T = 0$ should suggest that the molecules are positionally disordered at that temperature.

PLAN From the shape of the molecule (which can be obtained by using VSEPR theory), we need to determine how many orientations, W, it is likely to be able to adopt in a crystal;

then we can use the Boltzmann formula to see whether that number of orientations leads to the observed value of S.

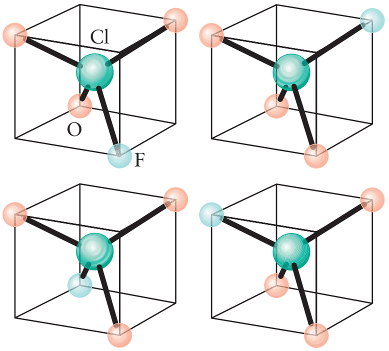


FIGURE 8.8 The four possible orientations of a tetrahedral $FClO_3$ molecule in a solid.

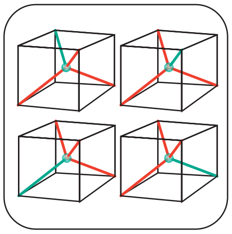
SOLVE An $FClO_3$(s) molecule is tetrahedral, and—provided the energy of each orientation is almost the same—can take any of four orientations in the solid, with the F atom in a different position in each case (Fig. 8.8). The total number of ways of arranging the molecules in a crystal containing N molecules is therefore

$$W = (4 \times 4 \times 4 \times \cdots \times 4)_{N \text{ factors}} = 4^N$$

The entropy is

From $S = k \ln W$, $W = 4^N$, $N = 6.02 \times 10^{23}$, and $\ln x^a = a \ln x$,

$$\begin{aligned} S &= k \ln 4^{6.02\times 10^{23}} \\ &= (1.3807 \times 10^{-23}\ \text{J}\cdot\text{K}^{-1}) \times (6.02 \times 10^{23}) \times \ln 4 \\ &= 11.5\ \text{J}\cdot\text{K}^{-1} \end{aligned}$$



Evaluate This value is reasonably close to the experimental value of 10.1 $\text{J}\cdot\text{K}^{-1}$, which suggests that, at $T = 0$, the molecules lie nearly randomly in any of four possible orientations.

Self-Test 8.10A Explain the observation that the entropy of 1 mol N_2O(s) at $T = 0$ is 6 $\text{J}\cdot\text{K}^{-1}$.

[***Answer:*** In the crystal, the orientations NNO and ONN are equally likely.]

Self-Test 8.10B Suggest a reason why the entropy of ice is nonzero at $T = 0$; think about how the structure of ice is affected by the hydrogen bonds.

The Boltzmann formula relates the entropy of a substance to the number of arrangements of molecules that result in the same energy: when many energy levels are accessible, this number and the corresponding entropy are large.

8.6 The Equivalence of Statistical and Thermodynamic Entropies

The expressions in Eq. 1 ($\Delta S = q_{rev}/T$) and Eq. 6 ($S = k \ln W$) are two apparently very different definitions of entropy. The first was established by considerations of the behavior of bulk matter and the second by statistical analysis of molecular behavior. To verify that the two definitions are in fact essentially the same we need to show that the entropy changes predicted on the basis of Eq. 6 are the same as those deduced from Eq. 1. To do so, we will show that the Boltzmann formula predicts the correct form of the volume dependence of the entropy of an ideal gas (Eq. 3a). More detailed calculations show that the two definitions are consistent with each other in every respect. In the process of developing these ideas, we shall also deepen our understanding of what we mean by "disorder."

An ideal gas consists of a large number of molecules that can be viewed as occupying the energy levels characteristic of a particle in a box. For simplicity, we consider a one-dimensional box (Fig. 8.9a), but the same considerations apply to a real three-dimensional container of any shape. At $T = 0$, only the lowest energy level is occupied; so $W = 1$ and the entropy is zero. There is no "disorder," because we know which state each molecule occupies.

At any temperature above $T = 0$, the molecules occupy large numbers of different energy levels, as shown in Fig. 8.9. Because the molecules can now be found in a larger number of microstates, W is greater than 1. Therefore, the entropy (which is proportional to ln W) is greater than zero. Now the disorder has increased; consequently we are less confident about precisely which state a given molecule occupies. For instance, in a tiny system with only two molecules, A and B, at $T = 0$ we can be confident that both molecules occupy the lowest energy level. However, if at a higher temperature a second state becomes available, we don't know whether it is molecule A that occupies the higher level, with B still in the ground state, or vice versa.

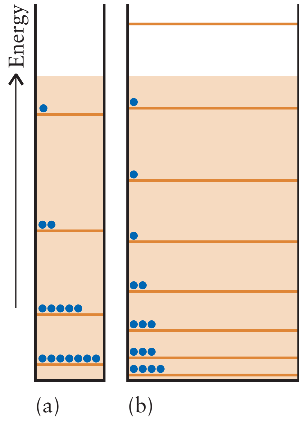


FIGURE 8.9 The energy levels of a particle in a box (a) become closer together as the width of the box is increased. (b) As a result, the number of levels accessible to the particles in the box increases, and the entropy of the system increases accordingly. The range of thermally accessible levels is shown by the tinted band. The change from part (a) to part (b) is a model of the isothermal expansion of an ideal gas. The total energy of the particles is the same in each case.

When the length of the box is increased at constant temperature (with $T > 0$), more energy levels become accessible to the molecules because the levels now lie closer together (Fig. 8.9b). Because the molecules are now distributed across more levels , we are less sure about which energy level any given molecule occupies. Therefore, the value of W increases as the box is lengthened and, by the Boltzmann formula, the entropy increases, too. The same argument applies to a three-dimensional box: as the volume of the box increases, the number of accessible states increases, too. We can use this relationship to show that the expression in Eq. 3a ($\Delta S = nR \ln V_2/V_1$), which we derived from Eq. 1, can also be deduced from Eq. 6.

HOW DO WE DO THAT?

To deduce Eq. 3 from the Boltzmann formula we start by supposing that the number of microstates available to a single molecule is proportional to the volume available to it. Then we can write $W = \text{constant} \times V$. For N molecules, the number of microstates is proportional to the Nth power of the volume:

$$W = (\text{constant} \times V) \times (\text{constant} \times V) \ldots_{N \text{ times}} = (\text{constant} \times V)^N$$

Therefore, the change in the statistical entropy when a sample expands isothermally from volume V_1 to a volume V_2 is

From $S = k \ln W$,

$$\Delta S = k \ln (\text{constant} \times V_2)^N - k \ln (\text{constant} \times V_1)^N$$

Use $\ln x^a = a \ln x$.

$$\Delta S = Nk \ln (\text{constant} \times V_2) - Nk \ln (\text{constant} \times V_1)$$

Use $\ln x - \ln y = \ln (x/y)$ and cancel the constants.

$$\Delta S = Nk \ln \frac{\text{constant} \times V_2}{\text{constant} \times V_1} = Nk \ln \frac{V_2}{V_1}$$

This expression is identical to Eq. 3 because $N = nN_A$ (where N_A is Avogadro's constant) and $N_A k = R$, the gas constant; therefore, $Nk = nN_A k = nR$ and $\Delta S = Nk \ln(V_2/V_1) = nR \ln(V_2/V_1)$. In at least the case of the isothermal expansion of an ideal gas, the two definitions give identical results. A further point is that the logarithm of the volume in Eq. 3 can now be seen to stem from the logarithm of W in the Boltzmann formula, and this derivation shows that the fact that S depends on the logarithm of V is related to the fact that the number of accessible states (as measured by W) increases with the size of the container.

TABLE 8.2 Standard Molar Entropy of Water at Various Temperatures

Phase	Temperature (°C)	S_m° ($J \cdot K^{-1} \cdot mol^{-1}$)
solid	−273 (0 K)	3.4
	0	43.2
liquid	0	65.2
	20	69.6
	50	75.3
	100	86.8
vapor	100	196.9
	200	204.1

We can also use the Boltzmann formula to interpret the increase in entropy of a substance as its temperature is raised (Eq. 2 and Table 8.2). We use the same particle-in-a-box model of a gas, but this reasoning also applies to liquids and solids, even though their energy levels are much more complicated. At low temperatures, the molecules of a gas can occupy only a few of the energy levels; so W is small and the entropy is low. As the temperature is raised, the molecules have access to larger numbers of energy levels (Fig. 8.10); so W rises and the entropy increases, too.

We have shown that the statistical and thermodynamic entropies lead to the same conclusions. We can expect their more general properties to be the same, too:

1 Both are state functions.

Because the number of microstates available to the system depends only on its current state, not on its past history, W depends only on the current state of the system, and therefore the statistical entropy does, too.

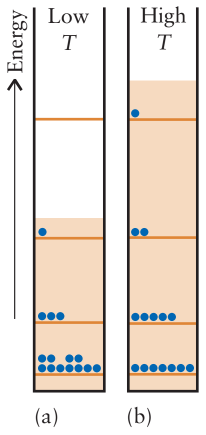

FIGURE 8.10 More energy levels become accessible in a box of fixed width as the temperature is raised. The change from part (a) to part (b) is a model of the effect of heating an ideal gas at constant volume. The thermally accessible levels are shown by the tinted band. The average energy of the molecules also increases as the temperature is raised: that is, both internal energy and entropy increase with temperature.

2 Both are extensive properties.

Doubling the number of molecules increases the number of microstates from W to W^2, and so the entropy changes from $k \ln W$ to $k \ln W^2$, or $2k \ln W$. Therefore, the statistical entropy, like the thermodynamic entropy, is an extensive property.

3 Both increase in a spontaneous change.

In any irreversible change, the overall disorder of the system and its surroundings increases, which means that the number of microstates increases. If W increases, then so does $\ln W$, and the statistical entropy increases, too.

4 Both increase with temperature.

When the temperature of the system increases, more microstates become accessible, and so the statistical entropy increases.

The equations used to calculate changes in the statistical entropy and the thermodynamic entropy lead to the same result.

8.7 Standard Molar Entropies

To *calculate* the entropy of a substance, we use Boltzmann's formula, but the calculations are sometimes very difficult and require a lot of manipulation of Eq. 6. To *measure* the entropy of a substance, we use the thermodynamic definition, Eq. 1, in combination with the third law of thermodynamics. Because the third law tells us that $S(0) = 0$ and Eq. 2 can be used to calculate the change in entropy as a substance is heated to the temperature of interest, we can write

$$S(T) = S(0) + \Delta S(\text{heating from 0 to } T) = \Delta S(\text{heating from 0 to } T)$$

The change in entropy on heating is calculated from the heat capacity and the temperature, as we did in Example 8.2. However, because we cannot assume that the heat capacity is constant all the way down to $T = 0$, we have to use a more general expression.

HOW DO WE DO THAT?

To take into account the possibility that the heat capacity changes with temperature, we go back to the expression

$$\Delta S(\text{heating from } T_1 \text{ to } T_2) = \int_{T_1}^{T_2} \frac{C\mathrm{d}T}{T}$$

We set $T_1 = 0$ and $T_2 = T$, the temperature of interest, in the limits of the integral. Heating commonly takes place at constant pressure, and so we replace C by C_P:

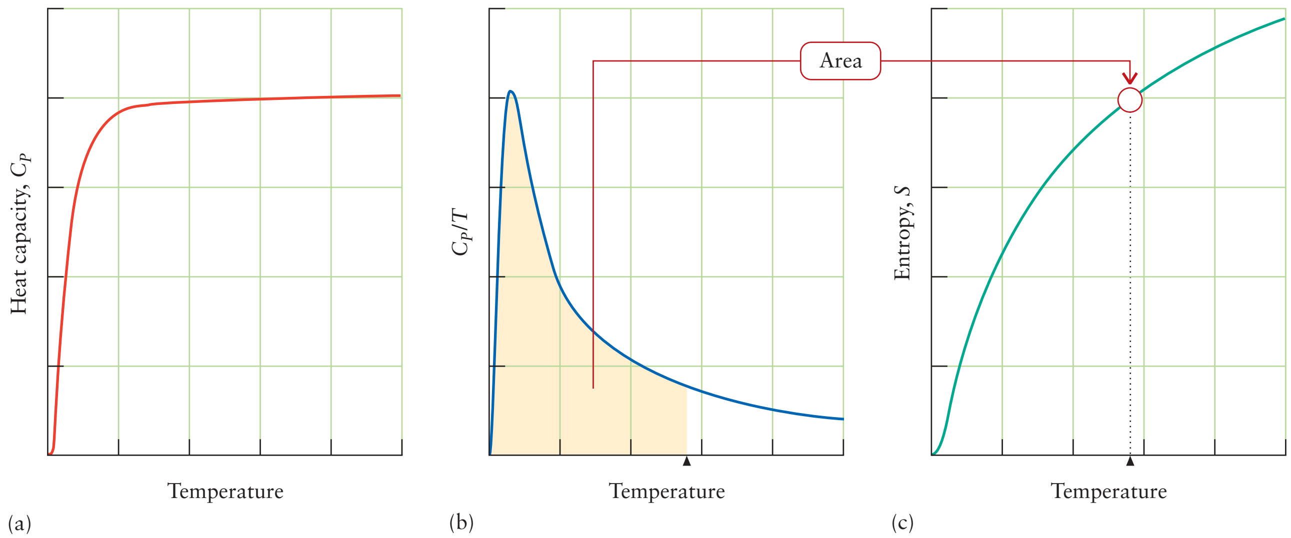
$$\Delta S(\text{heating from 0 to } T) = \int_0^T \frac{C_P\mathrm{d}T}{T}$$

Therefore, by invoking the third law and setting $S(0) = 0$, we have

$$\Delta S(T) = \int_0^T \frac{C_P\mathrm{d}T}{T}$$

An integral of a function—in this case, the integral of C_P/T—is the area under the graph of the function. Therefore, to measure the entropy of a substance, we need to measure the heat capacity (typically the constant-pressure heat capacity) at all temperatures from $T = 0$ to the temperature of interest. Then the entropy of the substance is obtained by plotting C_P/T against T and measuring the area under the curve (Fig. 8.11).

Note that we have drawn C_P approaching zero as $T \longrightarrow 0$. This feature is a general phenomenon, and explained by quantum mechanics. At low temperatures, the energy available is so small that there is not enough to stimulate transitions to higher energy states, so the sample cannot take up energy, and its "capacity for heat" is zero. This property of matter is one reason why the absolute zero of temperature has never been reached (Box 8.1).



Living Graph 8.11

FIGURE 8.11 The experimental determination of entropy. (a) The heat capacity (at constant pressure in this instance) of the substance is determined from close to absolute zero up to the temperature of interest. (b) The area under the plot of C_P/T against T is determined up to the temperature of interest. (c) This area is the entropy of the substance at that temperature.

BOX 8.1 FRONTIERS OF CHEMISTRY: THE QUEST FOR ABSOLUTE ZERO

The possibility of achieving absolute zero ($T = 0$) has intrigued scientists for many years. At absolute zero it would be possible to study the properties of materials in their lowest allowed energy state. For instance, at very low temperatures an interference pattern of laser beams can be used to create an "optical lattice," a set of spatially symmetric potential energy wells in which atoms can be trapped to form perfect crystals. These arrays could be used to create tiny building blocks for nanoscale computers.

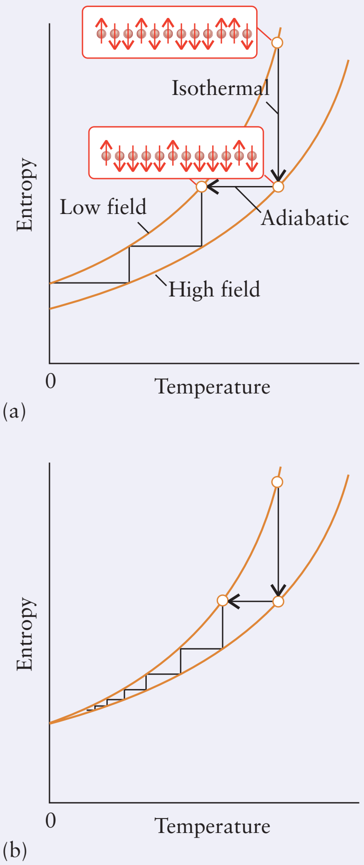
The third law of thermodynamics tells us that it is not possible to reach absolute zero in a cyclical thermodynamic process with a finite number of steps. However, it may still be possible to reach absolute zero by using a noncyclic process, and record low temperatures have recently been reached by a variety of means.

One method to approach $T = 0$ is to alternate isothermal magnetization with adiabatic demagnetization. This approach takes advantage of the fact that in a magnetic field electrons with down spins ($\downarrow$) have slightly lower energies than electrons with up spins ($\uparrow$). If the up spins can be converted to down spins, the sample will have lower energy overall and therefore a lower temperature. If all the up spins could be converted to down spins, the temperature would reach absolute zero.

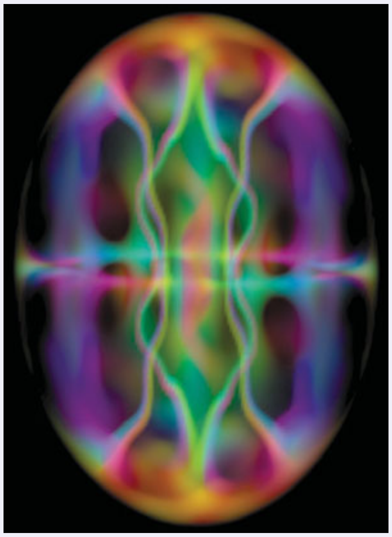
A cool paramagnetic sample that is not in a magnetic field has equal numbers of up and down electrons because the two spin states have the same energy (see Box 3.2). This is true whatever the temperature. So the first step is to cool the sample by conventional means (for instance, by putting it in contact with liquid helium). Then a magnetic field is turned on. The down spin states now have lower energy than the up spin states, and so they are slightly more numerous. We shall call this state A. The sample in this state has a characteristic entropy that reflects the slightly greater number of down spins than up spins and the temperature of the sample. If there were even more down spins, we would report that the temperature of the sample was lower. Our task, therefore, is to turn some up spins into down spins.

To do so, we use two steps, as summarized in the first figure. In the first step, the field is increased. As a result, the energies of the two states diverge and the populations adjust. This adjustment of populations takes place while the sample is in contact with its surroundings and occurs without change of temperature: it is the *isothermal magnetization step*. The entropy decreases in this step because, although the temperature remains the same, the spins have become more ordered. We shall call this state B.

In the second step, thermal contact with the surroundings is broken, so any subsequent change will be adiabatic; that is, not involve a transfer of energy as heat between the system and the surroundings. In any reversible adiabatic process the entropy does not change (because $\Delta S = q_{rev}/T$ and $q_{rev} = 0$). Under these adiabatic conditions, the magnetic field is reduced to the value it had in state A. However, although the magnetic field has been reduced, the entropy is the same as in state B when a high magnetic field was present. As we saw, this lower entropy corresponds to a lower temperature than the sample had initially: the sample has been cooled. The two steps are repeated until the temperature has been lowered as much as possible. However, because the two curves in the illustration converge at $T = 0$, this cyclic process cannot achieve absolute zero itself.



The cooling of a sample by adiabatic demagnetization follows the steps shown here. The arrows in the inset represent the spin alignment of the electrons in the sample. The arrows in the graph show the direction the sample takes. First the entropy decreases at constant temperature as a magnetic field is applied, then as the sample is demagnetized in an adiabatic environment its temperature decreases to maintain a constant entropy. (a) If the two curves did not coincide, absolute zero could be reached. However, (b) the curves coincide before absolute zero can be reached.



This 3-D visualization of a Bose–Einstein condensate illustrates how the circulating atoms are held together by a magnetic field. Variations in brightness show variations in density. The darker the area, the denser the matter. The brightest areas are vortices created by the interacting forces. The line around the equator is an artifact of the visualization.

In a refinement of the process, nuclear spins are used instead of electron spins. Because nuclear magnetic moments are much weaker than electron magnetic moments, they do not interact so strongly with the surroundings and so are insulated from it more effectively. Very low temperatures can be reached using nuclear spins, which is called *nuclear adiabatic demagnetization*.

Other approaches have been used to reach very low temperatures. At the University of Colorado, Eric Cornell and Carl Wieman worked with a team of students and researchers to create one of the lowest temperatures ever reached. They cooled a tiny sample of only 10 million rubidium atoms by arranging a beam of infrared radiation along the line of flight of the atoms in a beam traveling in the opposite direction. The impact of the infrared photons brought the atoms almost to a standstill. The atoms were then held in place by a magnetic field and cooled further by allowing the atoms with higher energies to escape. The team achieved a temperature of about 700 nK. At such a low temperature the atoms appear to lose their individual identities and by a quantum mechanical process form a "condensate," a new form of matter in which atoms merge to form a single large particle that behaves as a single atom. The second figure is a visualization of the condensate.

At MIT researchers have found a way to use lasers to reduce the temperature of large objects to within one degree of absolute zero. At such a low temperature quantum effects can be seen even in macroscopic objects.

? HOW MIGHT YOU CONTRIBUTE?

Methods for bringing large samples to very low temperatures need to be refined further. In addition, there are many unanswered questions about absolute zero that remain to be solved. For example, many substances become superconducting at very low temperatures. What would happen to conductivity at absolute zero?

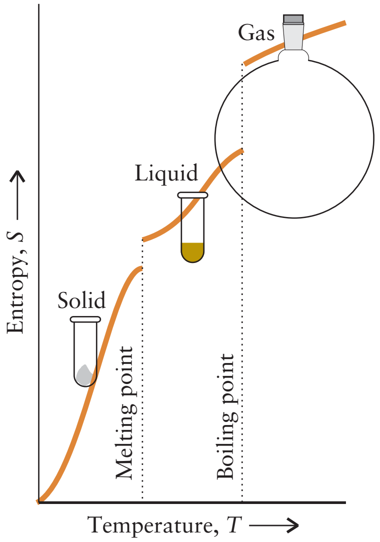

FIGURE 8.12 The entropy of a solid increases as its temperature is raised. The entropy increases sharply when the solid melts to form the more disordered liquid and then gradually increases again up to the boiling point. A second, larger jump in entropy occurs when the liquid vaporizes.

We have seen that

$$S(T) = \text{area under graph of } C_P/T \text{ against } T \text{ from 0 to the temperature of interest} \quad (7)$$

If a phase transition takes place between $T = 0$ and the temperature of interest, then we also have to include in $S(T)$ the corresponding entropy of transition by using Eq. 5 and possibly Eq. 4 (Fig. 8.12). For instance, if we want to know the entropy of liquid water at 25°C, we measure the heat capacity of ice from $T = 0$ (or as close to it as we can get) to $T = 273.15$ K, determine the entropy of fusion at that temperature from the enthalpy of fusion, and then measure the heat capacity of liquid water from $T = 273.15$ K to $T = 298.15$ K. Table 8.3 gives selected values of the **standard molar entropy,** $S_m°$, the molar entropy of the pure substance at 1 bar. All the values in Table 8.3 refer to 298.15 K, the conventional temperature for reporting thermodynamic data.

We can use the molecular interpretation of entropy to understand why some substances have high molar entropies and others have low molar entropies. For example, compare the molar entropy of diamond, 2.4 $J\cdot K^{-1}\cdot mol^{-1}$, with the much higher value for lead, 64.8 $J\cdot K^{-1}\cdot mol^{-1}$. The low entropy of diamond is what we should expect for a solid that has rigid bonds: at room temperature, its atoms are not able to jiggle around as much as the atoms of lead. Lead atoms are also much heavier than carbon atoms, and heavier atoms have more vibrational energy levels available than do lighter ones (because their allowed energies are closer together).

The difference in molar entropy between two gases (compare H_2 and N_2 in Table 8.3, for instance) can be understood in terms of the particle-in-a-box model and the fact that the greater the mass of the molecules, the closer together are the energy levels (Fig. 8.13). We also see that large, complex species have higher molar entropies than smaller, simpler ones (compare $CaCO_3$ with CaO or C_2H_5OH with H_2O). Liquids have higher molar entropies than solids because the greater freedom of movement of the molecules in a liquid results in a less ordered state of matter. The molar entropies of gases, in which molecules occupy much larger volumes and undergo almost completely disordered motion, are substantially higher than those of the corresponding liquids.

Self-Test 8.11A Which substance in each of the following pairs has the higher molar entropy: (a) 1 mol CO_2(g) at 25°C and 1 bar or 1 mol CO_2(g) at 25°C and 3 bar; (b) 1 mol He(g) at 25°C or 1 mol He(g) at 100°C in the same volume; (c) Br_2(l) or Br_2(g) at the same temperature? Explain your conclusions.

[***Answer:*** (a) CO_2(g) at 1 bar, because disorder increases with volume; (b) He(g) at 100°C, because disorder increases with temperature; (c) Br_2(g), because the vapor state has greater disorder than the liquid state.]

Self-Test 8.11B Use the information in Table 8.3 or Appendix 2A to determine which allotrope is the more ordered form and predict the sign of ΔS for each transition: (a) white tin (Fig. 8.14) changes into gray tin at 25°C; (b) diamond changes into graphite at 25°C.

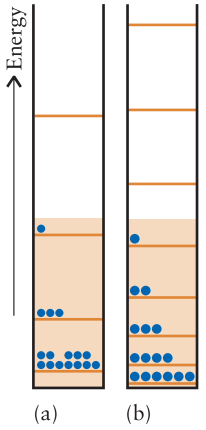

FIGURE 8.13 The energy levels of a particle in a box are more widely spaced for (a) light molecules than for (b) heavy molecules. As a result, the number of thermally accessible levels, as shown by the tinted band, is greater for heavy molecules than for light molecules at the same temperature, and the entropy of the substance with heavy molecules is correspondingly greater.

TABLE 8.3 Standard Molar Entropies at 25°C ($J\cdot K^{-1}\cdot mol^{-1}$)*

Gases	$S_m°$	Liquids	$S_m°$	Solids	$S_m°$
ammonia, NH_3	192.4	benzene, C_6H_6	173.3	calcium oxide, CaO	39.8
carbon dioxide, CO_2	213.7	ethanol, C_2H_5OH	160.7	calcium carbonate, $CaCO_3$†	92.9
hydrogen, H_2	130.7	water, H_2O	69.9	diamond, C	2.4
nitrogen, N_2	191.6			graphite, C	5.7
oxygen, O_2	205.1			lead, Pb	64.8

*Additional values are given in Appendix 2A.
†Calcite.

Standard molar entropies increase as the complexity of a substance increases. The standard molar entropies of gases are higher than those of comparable solids and liquids at the same temperature.

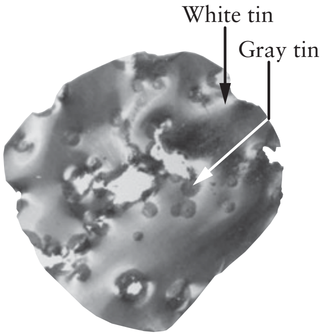

FIGURE 8.14 Gray tin and white tin are two solid forms of tin. The denser white metallic form is the more stable phase above 13°C, and the powdery gray form is more stable below that temperature.

8.8 Standard Reaction Entropies

Entropy is an important concept in chemistry because it is the basis for predicting the natural direction of a reaction. However, we have to remember that the entropy of the surroundings, not only that of the system, changes as the heat produced or absorbed by the reaction enters or leaves them. Both the entropy change of the system and that of the surroundings affect the direction of a reaction, because both contribute to the entropy of the universe.

It is easy to predict the sign of the entropy change of the surroundings if the sign of the reaction enthalpy is known. If the reaction is exothermic, heat is released into the surroundings and their entropy increases ($\Delta S_{surr} > 0$). If the reaction is endothermic, heat leaves the surroundings, so their entropy decreases ($\Delta S_{surr} < 0$). We shall develop this point quantitatively in the following section, but it will be very helpful to keep this qualitative conclusion in mind.

In some cases, we can also predict the sign of the entropy change of the system without doing any calculation. For instance, because the molar entropy of a gas is so much greater than that of solids and liquids, a change in the amount of gas molecules normally dominates any other entropy change in a reaction. A net increase in the amount of gas usually results in a positive change in entropy. Conversely, a net consumption of gas usually results in a negative change. Reactions that produce a large number of small molecules and the dissolving of a substance typically have positive entropies. However, entropy changes are much more finely balanced for reactions in which there is no net change in the amount of gas or in which gases do not take part, and for these reactions we have to use numerical data to predict the sign of the entropy change of the system.

Self-Test 8.12A Without doing any calculations, estimate the sign of the entropy change of the system for the reaction $N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g)$ and explain your answer.

[***Answer:*** negative, because there is a net decrease in the number of moles of gas molecules]

Self-Test 8.12B Without doing any calculations, estimate the sign of the entropy change of the system for the reaction $CaCO_3(s) \longrightarrow CaO(s) + CO_2(g)$ and explain your answer.

To calculate the change in entropy that accompanies a reaction, we need to know the molar entropies of all the substances taking part; then we calculate the difference between the entropies of the products and those of the reactants. More specifically, the **standard reaction entropy,** $\Delta S°$, is the difference between the standard molar entropies of the products and those of the reactants, taking into account their stoichiometric coefficients:

$$\Delta S° = \sum nS_m°(\text{products}) - \sum nS_m°(\text{reactants}) \qquad (8)^*$$

The first term on the right is the total standard entropy of the products, and the second term is that of the reactants; n denotes the amount of each substance in the chemical equation. Provided the temperature of interest is 25°C, we can use the values in Table 8.3 and Appendix 2A to calculate $\Delta S°$.

EXAMPLE 8.9 Calculating the standard reaction entropy

Calculate the standard reaction entropy of $N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g)$ at 25°C.

Anticipate We expect a decrease in entropy because there is a net reduction in the amount of gas molecules.

PLAN To find the numerical value, we use the chemical equation to write an expression for $\Delta S°$, as shown in Eq. 8, and then substitute values from Table 8.3 or Appendix 2A.

SOLVE

From the chemical equation, we can write

$$\Delta S^\circ = \overbrace{(2\ \text{mol})S_m^\circ(\text{NH}_3,\text{g})}^{\text{Product}} - \overbrace{\{(1\ \text{mol})S_m^\circ(\text{N}_2,\text{g}) + (3\ \text{mol})S_m^\circ(\text{H}_2,\text{g})\}}^{\text{Reactants}}$$
$$= 2(192.4\ \text{J}\cdot\text{K}^{-1}) - \{(191.6\ \text{J}\cdot\text{K}^{-1}) + 3(130.7\ \text{J}\cdot\text{K}^{-1})\}$$
$$= -198.9\ \text{J}\cdot\text{K}^{-1}$$

Evaluate Because the value of ΔS° is negative, the product is less disordered than the reactants—in part because it occupies a smaller volume—just as we expected.

A note on good practice: Avoid the error of setting the standard entropies of elements equal to zero, as you would for ΔH_f°: the entropies to use are the absolute values for the given temperature and are zero only at $T = 0$.

Self-Test 8.13A Use data from Appendix 2A to calculate the standard reaction entropy of $N_2O_4(g) \longrightarrow 2\ NO_2(g)$ at 25°C.

[***Answer:*** $+175.83\ \text{J}\cdot\text{K}^{-1}$]

Self-Test 8.13B Use data from Appendix 2A to calculate the standard reaction entropy of $C_2H_4(g) + H_2(g) \longrightarrow C_2H_6(g)$ at 25°C.

The standard reaction entropy is the difference between the standard molar entropy of the products and that of the reactants weighted by the amounts of each species taking part in the reaction. It is positive (an increase in entropy) if there is a net production of gas in a reaction; it is negative (a decrease) if there is a net consumption of gas.

GLOBAL CHANGES IN ENTROPY

Some processes seem to defy the second law. For example, water spontaneously freezes to ice at low temperatures, and cold packs for athletic injuries spontaneously become ice cold, even on warm days, when the ammonium nitrate inside the pack dissolves in the water that it contains. Life itself appears to go against the second law. Every cell of a living being is organized to an extraordinary extent. Thousands of different compounds, each one having a specific function to perform, move in the intricately organized dance we call life. How can the molecules in our bodies form such highly organized, complex structures from slime, mud, or gas? Our existence seems at first sight to be a contradiction of the second law.

The dilemma is resolved when we realize that the second law refers to an *isolated* system. To interpret the second law correctly, we must consider any system to be part of a larger isolated system that includes the surroundings of the system of interest. The process is spontaneous only if the *total* change in entropy, the sum of the changes in the system and the surroundings, is positive. Our task, therefore, is first to see how to calculate the change in entropy of the surroundings and then to combine that change with the change in entropy of the system. We have already mentioned what we should expect qualitatively: exothermic processes lead to an increase in the entropy of the surroundings and endothermic processes reduce it. Now we have to make this qualitative conclusion quantitative. Then, once we know the total entropy change, we shall be able to predict whether a reaction is spontaneous, whether its reverse is spontaneous, or whether the system is at equilibrium.

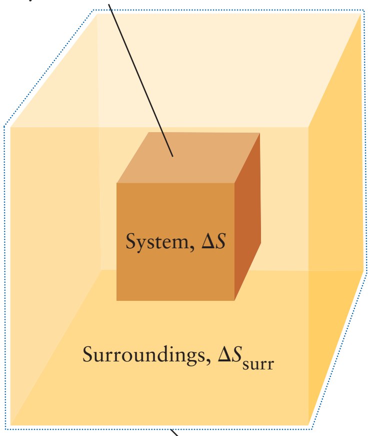

FIGURE 8.15 The global isolated system that models events taking place in the world consists of a smaller system together with its immediate surroundings. The only events that can take place spontaneously in the global isolated system are those corresponding to an increase in the total entropy of both the smaller system and its immediate surroundings.

8.9 The Surroundings

The system of interest and its surroundings constitute the "isolated system" to which the second law refers (Fig. 8.15). Only if the *total* entropy change,

$$\overbrace{\Delta S_{tot}}^{\text{Total entropy change}} = \overbrace{\Delta S}^{\text{Entropy change of system}} + \overbrace{\Delta S_{surr}}^{\text{Entropy change of surroundings}} \qquad (9)^*$$

is positive will the process be spontaneous. As is customary, properties of the system are written without subscripts; so here ΔS is the entropy change of the system and ΔS_{surr} that of the surroundings. It is critically important to understand that a process in which ΔS decreases may be spontaneous, provided that the entropy increases so much in the surroundings that ΔS_{tot} increases.

An example of the role of the surroundings in determining the spontaneous direction of a process is the freezing of water. We can see from Table 8.2 that, at 0°C, the molar entropy of liquid water is 22.0 $J \cdot K^{-1} \cdot mol^{-1}$ higher than that of ice at the same temperature. It follows that, when water freezes at 0°C, its entropy decreases by 22.0 $J \cdot K^{-1} \cdot mol^{-1}$. Although the entropies of substances increase as the temperature increases, they do so at about the same rate, so entropy changes for a phase transition or chemical reaction do not vary much with temperature. Therefore, just below 0°C, we can expect almost the same decrease. Yet we know from everyday experience that the freezing of water is spontaneous below 0°C. Clearly, the surroundings must be playing a deciding role: if their entropy increases by more than 22.0 $J \cdot K^{-1} \cdot mol^{-1}$ when water freezes, then the total entropy change will be positive.

We can use Eq. 1 to calculate the entropy change of the surroundings by noting the following steps:

- Because the surroundings are always taken to be large, their temperature remains constant however much energy is transferred to or from them as heat, so we can always use Eq. 1 in the form $\Delta S_{surr} = q_{surr, rev}/T$.
- The heat that leaves the system enters the surroundings, $q_{surr} = -q$ (so if $q = -10$ kJ, meaning that 10 kJ has left the system, $q_{surr} = +10$ kJ, meaning that 10 kJ has entered the surroundings).
- For a system maintained at constant pressure the heat that leaves the system can be equated to the change in enthalpy of the system and we can write $q = \Delta H$, and therefore $q_{surr} = -\Delta H$.
- Because the surroundings are large, any transfer of heat into them will, from their perspective, be so tiny that it can be regarded as occurring reversibly and hence $q_{surr,rev} = -\Delta H$.

We can therefore write

$$\Delta S_{surr} = -\frac{\Delta H}{T} \quad \text{at constant temperature and pressure} \qquad (10)^*$$

This important formula, which can be derived more formally from the laws of thermodynamics, applies when any change takes place in a system maintained at constant pressure and temperature. Notice that, for a given enthalpy change of the system (that is, a given output of heat), the entropy of the surroundings increases more if their temperature is low than if it is high (Fig. 8.16). The explanation is the "sneeze in the street" analogy mentioned in Section 8.2. Because ΔH is independent of path, Eq. 10 is applicable whether the process occurs reversibly or irreversibly.

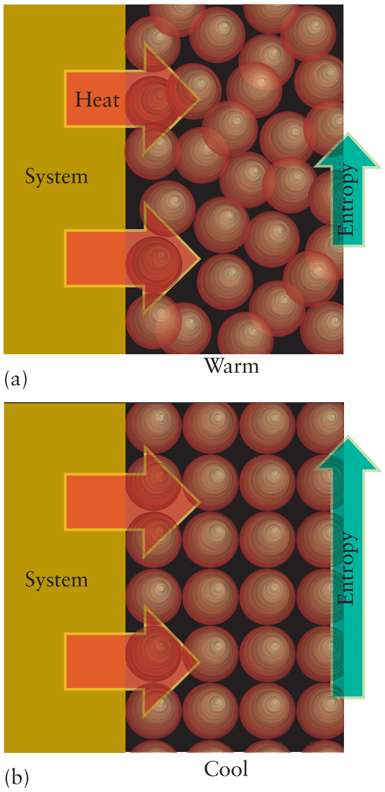

FIGURE 8.16 (a) When a given quantity of heat flows into hot surroundings, it produces very little additional chaos and the increase in entropy is small. (b) When the surroundings are cool, however, the same quantity of heat can make a considerable difference to the disorder, and the change in entropy of the surroundings is correspondingly large.

EXAMPLE 8.10 Calculating the change in entropy of the surroundings

Calculate the change in entropy of the surroundings when water freezes at −10.°C; use $\Delta H_{fus}(H_2O) = 6.0\ kJ \cdot mol^{-1}$ at −10.°C.

Anticipate We expect the entropy of the surroundings to increase when water freezes because the heat released stirs up the thermal motion of the atoms in the surroundings (Fig. 8.17).

PLAN To calculate the change in entropy of the surroundings when water freezes we write $\Delta H_{freeze} = -\Delta H_{fus}$ and convert the temperature to kelvins.

What should we assume? That the temperature of the surroundings is constant and that ΔH_{fus} is the same at −10.°C as it is at 0°C.

SOLVE

$$\Delta H_{freeze} = -\Delta H_{fus} = -6.0\ kJ \cdot mol^{-1} \quad \text{and} \quad T = (-10. + 273)\ K = 263\ K. \text{ Then}$$

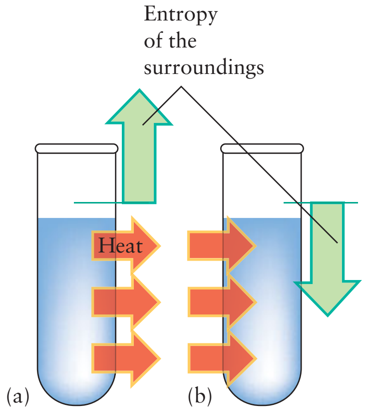

FIGURE 8.17 (a) In an exothermic process, heat escapes into the surroundings and increases their entropy. (b) In an endothermic process, the entropy of the surroundings decreases. The red arrows represent the transfer of heat between system and surroundings, and the green arrows indicate the entropy change of the surroundings.

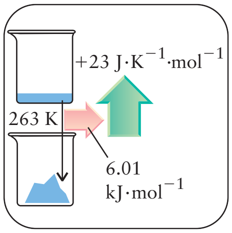
From $\Delta S_{surr} = -\Delta H/T$,

$$\Delta S_{surr} = -\frac{(-6.0 \times 10^3 \text{ J·mol}^{-1})}{263}$$
$$= +23 \text{ J·K}^{-1}\text{·mol}^{-1}$$



Evaluate Note that the increase in entropy of the surroundings is indeed greater than the decrease in entropy of the system, -22.0 J·K^{-1} (the value at −10.°C is similar to that at 0°C), so the overall change is positive and the freezing of water is spontaneous at −10.°C.

Self-Test 8.14A Calculate the entropy change of the surroundings when 1.00 mol $H_2O(l)$ vaporizes at 90°C and 1 bar. Take the enthalpy of vaporization of water as 40.7 kJ·mol^{-1}.

[***Answer:*** −112 J·K^{-1}]

Self-Test 8.14B Calculate the entropy change of the surroundings when 2.00 mol $NH_3(g)$ is formed from the elements at 298 K.

The entropy change of the surroundings due to a process taking place at constant pressure and temperature is equal to −ΔH/T, where ΔH is the change in enthalpy of the system.

8.10 The Overall Change in Entropy

As we have already emphasized, *to use the entropy to judge the direction of spontaneous change, we must consider the change in the entropy of the system plus the entropy change in the surroundings:*

If ΔS_{tot} is positive (an increase), the process is spontaneous.
If ΔS_{tot} is negative (a decrease), the reverse process is spontaneous.
If $\Delta S_{tot} = 0$, the process has no tendency to proceed in either direction.

In an exothermic reaction, such as the synthesis of ammonia or a combustion reaction, the heat released by the reaction increases the disorder of the surroundings. In some cases, the entropy of the system may decrease, as when a gaseous reactant is converted into a solid or liquid. However, provided that ΔH is large and negative, the release of energy as heat into the surroundings increases their entropy so much that it dominates the overall change in entropy and the reaction is spontaneous (Fig. 8.18).

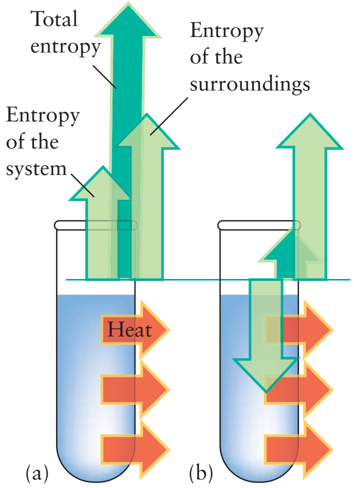


FIGURE 8.18 In an exothermic reaction, (a) the overall entropy change is certainly positive when the entropy of the system increases. (b) The overall entropy change may also be positive when the entropy of the system decreases. The reaction is spontaneous in both cases.

EXAMPLE 8.11 Calculating the total change in entropy accompanying a reaction

Assess whether the combustion of magnesium is spontaneous at 25°C under standard conditions, given

$$2\,Mg(s) + O_2(g) \longrightarrow 2\,MgO(s) \qquad \Delta S° = -217 \text{ J·K}^{-1} \qquad \Delta H° = -1202 \text{ kJ}$$

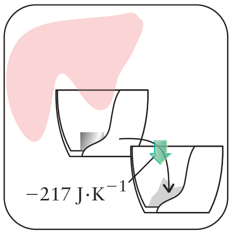
Anticipate We know that magnesium burns in air with a brilliant flame (recall the illustration on p. F2), so we should be confident that the combustion, like all combustions, is spontaneous (in the thermodynamic sense).

PLAN Find the entropy change in the surroundings by using Eq. 10, then calculate the total entropy change by using Eq. 9.

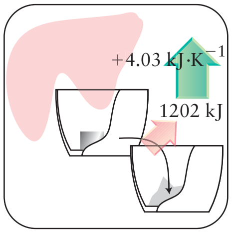
SOLVE

Determine the change in entropy of the system (given in this case).

$$\Delta S° = -217 \text{ J·K}^{-1}$$

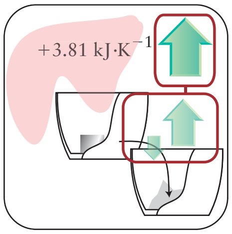


Determine the change in entropy of the surroundings from $\Delta S_{surr}° = -\Delta H°/T$.



$$\Delta S_{surr}° = -\frac{(-1.202 \times 10^6\ \text{J})}{298\ \text{K}}$$
$$= +4.03 \times 10^3\ \text{J·K}^{-1}$$

Determine the total change in entropy from $\Delta S_{tot}° = \Delta S° + \Delta S_{surr}$.



$$\Delta S_{tot}° = -217\ \text{J·K}^{-1} + (4.03 \times 10^3\ \text{J·K}^{-1})$$
$$= +3.81 \times 10^3\ \text{J·K}^{-1}$$

Evaluate Because $\Delta S_{tot}°$ is positive, the reaction is spontaneous under standard conditions even though the entropy of the system decreases.

Self-Test 8.15A Is the formation of hydrogen fluoride from its elements spontaneous under standard conditions at 25°C? For the reaction $H_2(g) + F_2(g) \longrightarrow 2\ HF(g)$, $\Delta H° = -542.2$ kJ and $\Delta S° = +14.1$ J·K^{-1}.

[***Answer:*** $\Delta S_{surr} = +1819$ J·K^{-1}; therefore, $\Delta S_{tot} = +1833$ J·K^{-1}; spontaneous]

Self-Test 8.15B Is the formation of benzene from its elements spontaneous at 25°C? For the reaction $6\ C(s, \text{graphite}) + 3\ H_2(g) \longrightarrow C_6H_6(l)$, $\Delta H° = +49.0$ kJ and $\Delta S° = -253.18$ J·K^{-1}.

Spontaneous endothermic reactions were a puzzle for nineteenth-century chemists, who believed that reactions ran only in the direction of decreasing energy of the system. It seemed to them that, in endothermic reactions, reactants were rising spontaneously to higher energies, like a weight suddenly leaping up from the floor onto a table. However, the criterion for spontaneity is an *increase in the total entropy of the system and its surroundings*, not a decrease in the energy of a system. In an endothermic reaction, the entropy of the surroundings certainly decreases as heat flows from them into the system. Nevertheless, there can still be an overall increase in entropy if the disorder of the system increases enough. Every endothermic reaction must be accompanied by increased disorder of the system if it is to be spontaneous (Fig. 8.19): spontaneous endothermic reactions are driven by the dominating increase in disorder of the system.

By considering the total entropy change, we can draw some far-reaching conclusions about processes going on in the universe. For instance, we saw in Section 7.3 that maximum work is achieved if expansion takes place reversibly, by matching the external pressure to the pressure of the system at every stage. That relation is always true: *a process produces maximum work if it takes place reversibly*. That is, w_{rev} is more negative (more energy leaves the system as work) than w_{irrev}. However, because the internal energy is a state function, ΔU is the same for any path between the same two states. Therefore, because $\Delta U = q + w$, it follows that q_{rev}, the heat absorbed along the reversible path, must be greater than q_{irrev}, the heat absorbed along any other path, because only then can the sums of q and w be the same for the two paths. If now we replace q_{rev} in Eq. 1 by the smaller quantity q_{irrev}, we get $\Delta S > q_{irrev}/T$. In general, we can write the **Clausius inequality:**

$$\Delta S \geq \frac{q}{T} \qquad \textbf{(11a)*}$$

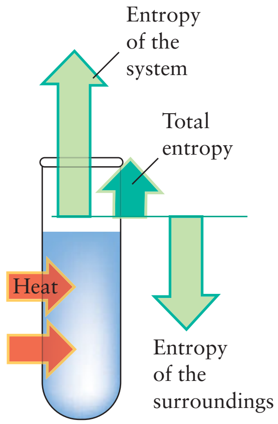


FIGURE 8.19 An endothermic reaction is spontaneous only if the entropy of the system increases enough to overcome the decrease in entropy of the surroundings.

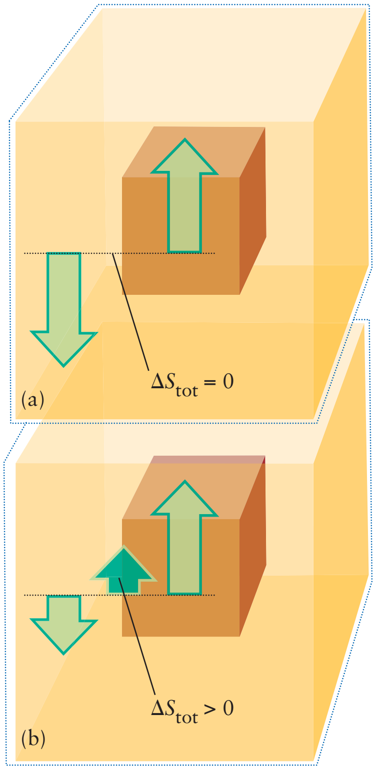

FIGURE 8.20 (a) When a process takes place reversibly—that is, when the system is at equilibrium with its surroundings—the change in entropy of the surroundings is the negative of the change in entropy of the system and the overall change is zero. (b) For an irreversible change between the same two states of the system, the final state of the surroundings is different from the final state in part (a), and the change in the system is not canceled by the entropy change of the surroundings. Overall, there is an increase in entropy.

with the equality valid for a reversible process. For a fully isolated system like that in Fig. 8.15, $q = 0$ for any process taking place inside the system. It follows from Eq. 11a that

$$\Delta S \geq 0 \text{ for any process in an isolated system} \qquad \textbf{(11b)}$$

That is, we have shown that *the entropy cannot decrease in an isolated system*. This is another statement of the second law of thermodynamics. It tells us, in effect, that, as a result of all the processes going on around us, the entropy of the universe is steadily increasing.

Now consider an isolated system consisting of both the system that interests us and its surroundings (again like that in Fig. 8.15). For any spontaneous change in this isolated system, we know from Eq. 11b that $\Delta S_{tot} > 0$. If we calculate for a particular hypothetical process that $\Delta S_{tot} < 0$, we can conclude that the reverse of that process is spontaneous.

A final point is that reversible and irreversible paths between two given states of the system leave the surroundings in different states. Because entropy is a state function, the value of ΔS, the change in entropy of the system, is the same for both paths. However, ΔS_{tot} is different for the two paths because the entropy of the surroundings changes by different amounts in each case. For example, the isothermal expansion of an ideal gas always results in the change in the entropy of the system given by Eq. 3. However, the change in entropy of the surroundings is different for reversible and irreversible paths because the surroundings are left in different states in each case (Fig. 8.20). Table 8.4 lists the characteristics of reversible and irreversible processes.

EXAMPLE 8.12 Calculating the total entropy change for the expansion of an ideal gas

Calculate ΔS, ΔS_{surr}, and ΔS_{tot} for (a) the isothermal, reversible expansion and (b) the isothermal, free expansion of 1.00 mol of ideal gas molecules from 8.00 L to 20.00 L at 292 K. Explain any differences between the two paths.

Anticipate (a) We should expect a positive increase in the entropy of the expanding gas but because the expansion is reversible, a total entropy change of zero. (b) For an irreversible expansion we should expect the total entropy change to be positive.

PLAN Because entropy is a state function, the change in entropy of the system is the same regardless of the path between the two states, so we can use Eq. 3 to calculate ΔS for both part (a) and part (b). For the entropy of the surroundings, we need to find the heat transferred to the surroundings. In each case, we can combine the fact that $\Delta U = 0$ for an isothermal expansion of an ideal gas with $\Delta U = w + q$ and conclude that $q = -w$. We then use Eq. 4 in Chapter 7 to calculate the work done in an isothermal, reversible expansion of an ideal gas and Eq. 9 in this chapter to find the total entropy. The changes that we calculate are summarized in Fig. 8.21.

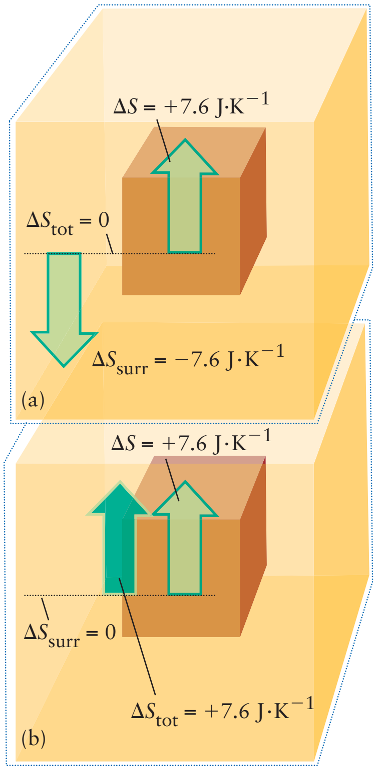

FIGURE 8.21 The changes in entropy and internal energy when an ideal gas undergoes (a) reversible and (b) irreversible changes between the same two states, as described in Example 8.12.

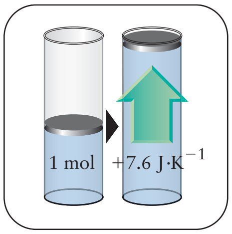
TABLE 8.4 Criteria for Spontaneity

ΔS	ΔS_{surr}	ΔS_{tot}	Character
>0	>0	>0	spontaneous
<0	<0	<0	not spontaneous; reverse change is spontaneous
>0	<0		spontaneous if ΔS is greater than $-\Delta S_{surr}$
<0	>0		spontaneous if ΔS_{surr} is greater than $-\Delta S$

SOLVE (a) For the reversible path,

From $\Delta S = nR \ln (V_2/V_1)$,

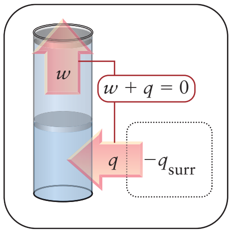
$$\Delta S = (1.00\ \text{mol}) \times (8.3145\ \text{J·K}^{-1}\text{·mol}^{-1}) \times \ln\frac{20.0\ \text{L}}{8.00\ \text{L}}$$
$$= +7.6\ \text{J·K}^{-1}$$



The change in the entropy of the gas is positive, as expected. Because $\Delta U = 0$, $q = -w$. Therefore, because the heat that flows into the surroundings is equal to the heat that flows *out* of the system,

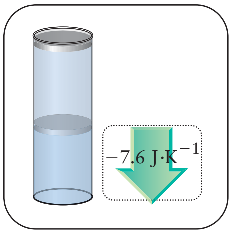
From $q_{surr} = -q$, $q = -w$, and $w = -nRT \ln (V_2/V_1)$,

$$q_{surr} = -nRT \ln \frac{V_2}{V_1}$$



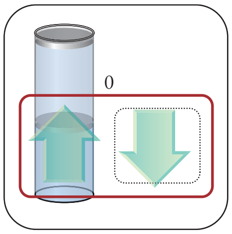
From $\Delta S_{surr} = q_{surr}/T$,

$$\Delta S_{surr} = -\frac{nRT}{T}\ln\frac{V_2}{V_1} = -nR\ln\frac{V_2}{V_1} = -\Delta S = -7.6\ \text{J·K}^{-1}$$



From $\Delta S_{tot} = \Delta S + \Delta S_{surr}$,

$$\Delta S_{tot} = 7.6\ \text{J·K}^{-1} - 7.6\ \text{J·K}^{-1} = 0$$



(b) For the irreversible process.

No work is done in free expansion (Section 7.3), and so $w = 0$. Because $\Delta U = 0$, it follows that $q = 0$ and therefore

$$q_{surr} = 0$$

From $\Delta S_{surr} = q_{surr}/T$,

$$\Delta S_{surr} = 0$$

ΔS is the same, at $+7.6\ \text{J·K}^{-1}$. The total change in entropy is therefore

$$\Delta S_{tot} = +7.6\ \text{J·K}^{-1}$$

Evaluate As expected, for the reversible process $\Delta S_{tot} = 0$ and for the irreversible process $\Delta S_{tot} > 0$.

Self-Test 8.16A Determine ΔS, ΔS_{surr}, and ΔS_{tot} for (a) the reversible, isothermal expansion and (b) the isothermal free expansion of 1.00 mol of ideal gas molecules from 10.00 atm and 0.200 L to 1.00 atm and 2.00 L at 298 K.

[***Answer:*** (a) $\Delta S = +19.1\ \text{J·K}^{-1}$; $\Delta S_{surr} = -19.1\ \text{J·K}^{-1}$; $\Delta S_{tot} = 0$; (b) $\Delta S = +19.1\ \text{J·K}^{-1}$; $\Delta S_{surr} = 0$; $\Delta S_{tot} = +19.1\ \text{J·K}^{-1}$]

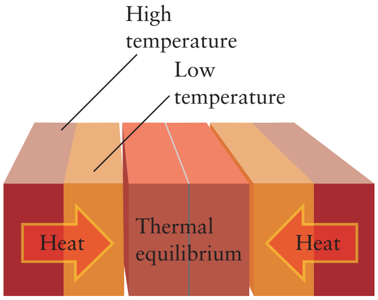


FIGURE 8.22 Energy flows as heat from a high-temperature region (dark red) to a low-temperature region (tan) through a thermally conducting wall. A system is in thermal equilibrium with its surroundings when the temperatures on both sides of the wall are the same (center). However, because the systems are in contact, energy continues to flow as heat, but at the same rate in each direction.

Self-Test 8.16B Determine ΔS, ΔS_{surr}, and ΔS_{tot} for the reversible, isothermal compression of 2.00 mol of ideal gas molecules from 1.00 atm and 4.00 L to 20.00 atm and 0.200 L at 298 K.

A process is spontaneous if it is accompanied by an increase in the total entropy of the system and the surroundings.

8.11 Equilibrium

Although this section provides only a brief introduction to equilibrium, the principles presented here are critically important, because the tendency of reactions to proceed toward equilibrium is the basis of much of chemistry. The material in this section lays the foundation for the next five chapters, including phase changes, the reactions of acids and bases, and redox reactions.

A system at **equilibrium** has no tendency to change in either direction (forward or reverse). Such a system remains in its current state until it is disturbed by changing the conditions, such as raising the temperature, decreasing the volume, or adding more reactants. The equilibrium state important in chemistry is a **dynamic equilibrium**, in which forward and reverse processes still continue but at matching rates. For example, when a block of metal is at the same temperature as its surroundings, it is in **thermal equilibrium** with its surroundings. Energy continues to flow in both directions, but at the same rate; there is no *net* flow (Fig. 8.22). When a gas confined to a cylinder by a piston has the same pressure as that of the surroundings, the system is in **mechanical equilibrium** with the surroundings and the gas has no tendency to expand or contract. The pressure inside is causing the piston to move outward, but the pressure outside is causing the piston to move inward to the same extent, and there is no net change.

When a solid, such as ice, is in contact with its liquid form, such as water, at certain conditions of temperature and pressure (at 0°C and 1 atm for water), the two states of matter are in dynamic equilibrium with each other, and there is no tendency for one form of matter to change into the other form. When solid and liquid water are at equilibrium, water molecules continually leave solid ice to form liquid water, and water molecules continually leave the liquid phase to form ice. However, there is no *net* change, because these processes occur at the same rate and so balance each other.

When a chemical reaction mixture reaches a certain composition, the reaction seems to come to a halt. A mixture of substances at **chemical equilibrium** has no tendency either to produce more products or to revert to reactants. At equilibrium, reactants are still forming products, but products are decaying at a matching rate into reactants and there is no *net* change of composition.

The common characteristic of any kind of dynamic equilibrium is the continuation of processes at the microscopic level but no *net* tendency for the system to change in either the forward or the reverse direction. That is, neither the forward nor the reverse process is spontaneous. Expressed thermodynamically,

$$\Delta S_{tot} = 0 \qquad (12)^*$$

The total entropy varies with the composition of a reaction mixture and by looking for the composition at which $\Delta S_{tot} = 0$, we can predict the equilibrium composition of the reaction. At this composition, the reaction has no tendency either to form more products or to decompose into reactants.

Self-Test 8.17A Confirm that liquid water and water vapor are in equilibrium when the temperature is 100.°C and the pressure is 1 atm. Data are available in Tables 7.3 and 8.2.

[*Answer:* $\Delta S_{tot} = 0$ at 100.°C]

Self-Test 8.17B Confirm that liquid benzene and benzene vapor are in equilibrium at the normal boiling point of benzene, 80.1°C, and 1 atm pressure. The enthalpy of vaporization of benzene at its boiling point is 30.8 $kJ{\cdot}mol^{-1}$ and its entropy of vaporization is 87.2 $J{\cdot}K^{-1}{\cdot}mol^{-1}$.

The general criterion for equilibrium in thermodynamics is $\Delta S_{tot} = 0$.

GIBBS FREE ENERGY

One of the problems with using the second law to judge whether a reaction is spontaneous is that to get the total entropy change we must calculate three quantities: the entropy change of the system, the entropy change of the surroundings, and the sum of the two changes. We could avoid some of this work if a single property combined the entropy calculations for the system and the surroundings. We could then carry out the calculation in one step by using a single table of data. This simplification is achieved by introducing a new state function, the "Gibbs free energy." Not only does the Gibbs free energy allow us to assess whether a reaction is spontaneous, it also tells us how much nonexpansion work we can get from the system—a central consideration in the study of foods and fuels—and how a change in temperature can change the spontaneity of a reaction. In Chapter 10, we shall also see how the Gibbs free energy controls the composition of a reaction mixture at equilibrium. The Gibbs free energy is probably the single most widely used and useful quantity in the application of thermodynamics to chemistry.

8.12 Focusing on the System

The total entropy change, ΔS_{tot}, is the sum of the changes in the system, ΔS, and its surroundings, ΔS_{surr}, with $\Delta S_{tot} = \Delta S + \Delta S_{surr}$. For a process at constant temperature and pressure, the change in the entropy of the surroundings is given by Eq. 10, $\Delta S_{surr} = -\Delta H/T$. Therefore,

$$\Delta S_{tot} = \Delta S + \underbrace{\Delta S_{surr}}_{-\Delta H/T} = \Delta S - \frac{\Delta H}{T} \quad \text{at constant temperature and pressure} \qquad (13)$$

This equation shows how to calculate the total entropy change from information about the system alone. The limitation is that the equation is valid only at constant temperature and pressure.

To take the next step, we introduce the **Gibbs free energy,** G, which is defined as

$$G = H - TS \qquad (14)^*$$

This quantity, which is commonly known as the *free energy* and more formally as the *Gibbs energy*, is defined solely in terms of state functions, and so G is a state function. Throughout chemistry, we use only changes in Gibbs free energy, not its absolute values; and, for a process occurring at constant temperature, the change in Gibbs free energy is

$$\Delta G = \Delta H - T\Delta S \quad \text{at constant temperature} \qquad (15)^*$$

By comparing this expression rearranged into

$$\frac{\Delta G}{T} = \frac{\Delta H}{T} - \Delta S$$

with Eq. 13, where there is the additional constraint of constant pressure, we see that $\Delta G/T = -\Delta S_{tot}$ and therefore that

$$\Delta G = -T\Delta S_{tot} \quad \text{at constant temperature and pressure} \qquad (16)$$

The minus sign in this equation means that, provided the temperature and pressure are constant, an increase in total entropy corresponds to a decrease in Gibbs free energy. Therefore, *at constant temperature and pressure, the direction of spontaneous change is the direction of decreasing Gibbs free energy* (Fig. 8.24). The great importance of the introduction of Gibbs free energy is that, *provided that the temperature and pressure are constant, we can predict the spontaneity of a process solely in terms of the thermodynamic properties of the system*. Note that we have restricted this discussion to processes at constant temperature and pressure, but by doing so we can express spontaneity under common laboratory conditions in terms of the system alone.

The Gibbs free energy is named for Josiah Willard Gibbs (Fig. 8.23), the nineteenth-century American physicist who was responsible for turning thermodynamics from an abstract theory into a subject of great usefulness.

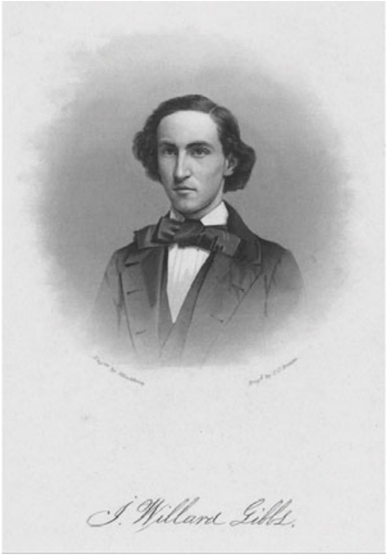

FIGURE 8.23 Josiah Willard Gibbs (1839–1903).

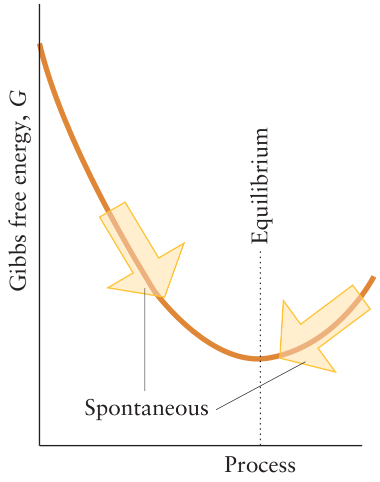

FIGURE 8.24 At constant temperature and pressure, the direction of spontaneous change is toward lower Gibbs free energy. The horizontal axis represents the progress of the reaction or process. The equilibrium state of a system corresponds to the lowest point on the curve.

TABLE 8.5 Factors That Favor Spontaneity

Enthalpy change	Entropy change	Spontaneous?
exothermic ($\Delta H < 0$)	increase ($\Delta S > 0$)	yes, $\Delta G < 0$
exothermic ($\Delta H < 0$)	decrease ($\Delta S < 0$)	yes, if $\lvert T\Delta S \rvert < \lvert \Delta H \rvert$, $\Delta G < 0$
endothermic ($\Delta H > 0$)	increase ($\Delta S > 0$)	yes, if $T\Delta S > \Delta H$, $\Delta G < 0$
endothermic ($\Delta H > 0$)	decrease ($\Delta S < 0$)	no, $\Delta G > 0$

Equation 15 summarizes the factors that determine the direction of spontaneous change at constant temperature and pressure: for a spontaneous change, we look for values of ΔH, ΔS, and T that result in a negative value of ΔG (Table 8.5). One condition that may result in a negative ΔG is a large negative ΔH, such as that for a combustion reaction. As we have seen, a large negative ΔH corresponds to a large increase in the entropy of the surroundings. However, a negative ΔG can occur even if ΔH is positive (an endothermic reaction), provided that $T\Delta S$ is large and positive. In this case, as we saw in Section 8.10, the driving force of the reaction is the increase in entropy of the system.

Self-Test 8.18A Can a nonspontaneous process with a negative ΔS become spontaneous if the temperature is increased (assuming that ΔH and ΔS are both independent of temperature)?

[***Answer:*** No]

Self-Test 8.18B Can a nonspontaneous process with a positive ΔS become spontaneous if the temperature is increased (assuming that ΔH and ΔS are both independent of temperature)?

We have seen that the criterion for equilibrium is $\Delta S_{tot} = 0$. It follows from Eq. 16 that, for a process at constant temperature and pressure, the condition for equilibrium is

$$\Delta G = 0 \quad \text{at constant temperature and pressure} \qquad (17)$$

If we find that $\Delta G = 0$ for a process, then we know at once that the system is at equilibrium. For example, when ice and water are in equilibrium with each other at a particular temperature and pressure, the Gibbs free energy of 1 mol $H_2O(l)$ must be the same as the Gibbs free energy of 1 mol $H_2O(s)$. In other words, the molar Gibbs free energy, the Gibbs free energy per mole, of water in each phase is the same.

EXAMPLE 8.13 Deciding whether a process is spontaneous

Calculate the change in molar Gibbs free energy, ΔG_m, for the process $H_2O(s) \longrightarrow H_2O(l)$ at 1 atm and (a) 10.°C; (b) 0.°C. Decide for each temperature whether melting is spontaneous or not. Treat ΔH_{fus} and ΔS_{fus} as independent of temperature.

Anticipate Because the solid and liquid phases are in equilibrium at the melting point, we expect to find that $\Delta G = 0$ at 0.°C. Above that temperature the melting of the solid state is favored so we expect that ΔG will be negative at 10.°C.

PLAN Find the enthalpy of fusion of water in Table 7.3 (the values there are for 1 atm and the transition temperature). The entropy of fusion of water is given in Section 8.9. Use Eq. 15 to calculate the change in free energy.

What should we assume? That ΔH_{fus} and ΔS_{fus} are constant over the temperature range of interest.

SOLVE The enthalpy of fusion is 6.01 $kJ\cdot mol^{-1}$ and the entropy of fusion is 22.0 $J\cdot K^{-1}\cdot mol^{-1}$. These values are almost independent of temperature over the temperature range considered.

(a) At 10.°C

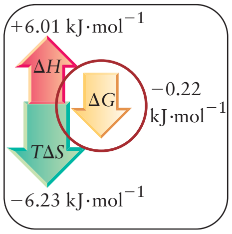
From $\Delta G_m = \Delta H_m - T\Delta S_m$,

$$\Delta G_m = \underbrace{6.01\ \text{kJ·mol}^{-1}}_{\Delta H_m} - \underbrace{(283\ \text{K})}_{(273.15\ +\ 10.)\ \text{K}} \times \underbrace{(22.0\ \text{J·K}^{-1}\text{·mol}^{-1})}_{\Delta S_m}$$

$$= 6.01\ \text{kJ·mol}^{-1} - 6.23 \times 10^3\ \text{J·mol}^{-1}$$

$$= 6.01\ \text{kJ·mol}^{-1} - 6.23\ \underbrace{\text{kJ}}_{10^3\ \text{J}}\text{·mol}^{-1}$$

$$= -0.22\ \text{kJ·mol}^{-1}$$



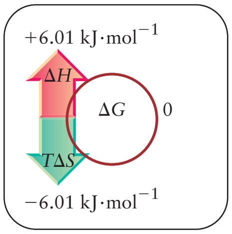
A note on good practice: Be sure to convert joules to kilojoules before subtracting $T\Delta S$ from ΔH.

(b) At 0.°C

From $\Delta G_m = \Delta H_m - T\Delta S_m$,

$$\Delta G_m = 6.01\ \text{kJ·mol}^{-1} - (273\ \text{K}) \times (22.0\ \text{J·K}^{-1}\text{·mol}^{-1})$$

$$= 6.01\ \text{kJ·mol}^{-1} - 6.01\ \text{kJ·mol}^{-1} = 0$$



Evaluate As expected, because the difference in molar Gibbs free energy is negative at 10.°C, melting is spontaneous at that temperature, but at 0.°C, ice and water are in equilibrium.

Self-Test 8.19A Calculate the change in molar Gibbs free energy for the process $H_2O(l) \longrightarrow H_2O(g)$ at 1 atm and (a) 95°C; (b) 105°C. The enthalpy of vaporization is 40.7 kJ·mol^{-1}, and the entropy of vaporization is 109·1 J·K^{-1}·mol^{-1}. In each case, indicate whether vaporization would be spontaneous or not.

[***Answer:*** (a) +0.6 kJ·mol^{-1}, not spontaneous; (b) −0.5 kJ·mol^{-1}, spontaneous]

Self-Test 8.19B Calculate the change in molar Gibbs free energy for the process $Hg(l) \longrightarrow Hg(g)$ at 1 atm and (a) 350.°C; (b) 370.°C. The enthalpy of vaporization is 59.3 kJ·mol^{-1}, and the entropy of vaporization is 94.2 J·K^{-1}·mol^{-1}. In each case, indicate whether or not vaporization would be spontaneous.

The Gibbs free energy of a substance decreases as its temperature is raised at constant pressure. This conclusion follows from the definition $G = H - TS$ and the fact that the entropy of a pure substance is invariably positive; as T increases, TS increases, too, and a larger quantity is subtracted from H. Another important conclusion is that, because the molar entropy of the gas phase of a substance is greater than that of its liquid phase, the Gibbs free energy decreases more sharply with temperature for the gas phase of a substance than for the liquid phase. Similarly, the Gibbs free energy of the liquid phase of a substance decreases more sharply than that of its solid phase (Fig. 8.25).

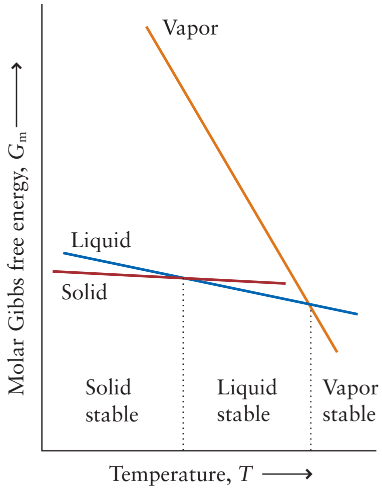


FIGURE 8.25 The variation of the (molar) Gibbs free energy with temperature for three phases of a substance at a given pressure. The most stable phase is the phase with lowest molar Gibbs free energy. We see that, as the temperature is raised, the solid, liquid, and vapor phases in succession become the most stable.

We can now see the thermodynamic origin of phase transitions. At low temperatures, the molar Gibbs free energy of the solid phase lies lowest; so there is a spontaneous tendency for a liquid to freeze and thereby reduce its Gibbs free energy. Above a certain temperature, the molar Gibbs free energy of the liquid has fallen below that of the solid, and the substance has a spontaneous tendency to melt. At an even higher temperature, the molar Gibbs free energy of the gas phase has fallen to below the liquid line, and the substance has a spontaneous tendency to vaporize. The temperature of each phase change corresponds to the point of intersection of the lines for the two phases, as can be seen in Fig. 8.25.

The relative positions of the three lines shown in Fig. 8.25 are different for each substance. One possibility—which depends on the strength of intermolecular interactions in the condensed phases—is for the liquid line to lie in the position shown in Fig. 8.26. In this case, the liquid line is never the lowest line, at any temperature. As soon as the temperature has been raised above the point corresponding to the intersection of the solid and gas lines, the direct transition of the solid to the vapor becomes spontaneous.

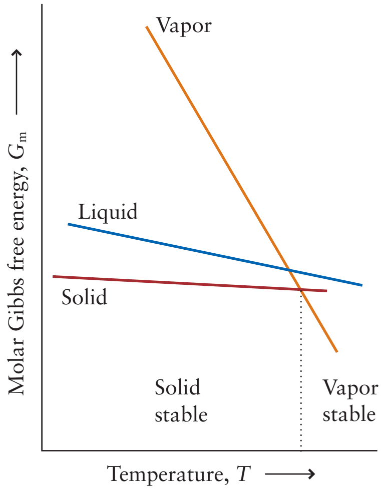

FIGURE 8.26 For some substances and at certain pressures, the molar Gibbs free energy of the liquid phase might never lie lower than those of the other two phases. For such substances, the liquid is never the stable phase and, at constant pressure, the solid sublimes when the temperature is raised to the point of intersection of the solid and vapor lines.

This plot is the type that we would expect for carbon dioxide, which sublimes at atmospheric pressure.

> ***The change in Gibbs free energy for a process is a measure of the change in the total entropy of a system and its surroundings at constant temperature and pressure. Spontaneous processes at constant temperature and pressure are accompanied by a decrease in Gibbs free energy.***

8.13 Gibbs Free Energy of Reaction

The decrease in Gibbs free energy as a signpost of spontaneous change and $\Delta G = 0$ as a criterion of equilibrium are applicable to any kind of process, provided that it is occurring at constant temperature and pressure. Because chemical reactions are our principal interest in chemistry, we now concentrate on them and look for a way to calculate ΔG for a reaction.

The thermodynamic function used as the criterion of spontaneity for a chemical reaction is the **Gibbs free energy of reaction,** ΔG (which is commonly referred to as the "reaction free energy"). This quantity is defined as the difference in molar Gibbs free energies, G_m, of the products and the reactants:

$$\Delta G = \sum nG_m(\text{products}) - \sum nG_m(\text{reactants}) \qquad (18)$$

The n are the stoichiometric amounts of each substance in the chemical equation. For example, for the formation of ammonia, $N_2(g) + 3\,H_2(g) \longrightarrow 2\,NH_3(g)$:

$$\Delta G = \{(2\text{ mol}) \times G_m(NH_3)\} - \{(1\text{ mol}) \times G_m(N_2) + (3\text{ mol}) \times G_m(H_2)\}$$

The molar Gibbs free energy of a substance in a mixture depends on what molecules it has as neighbors, so the molar Gibbs free energies of NH_3, N_2, and H_2 change as the reaction proceeds. For example, at an early stage of the reaction, an NH_3 molecule has mostly N_2 and H_2 molecules around it, but at a later stage of the reaction, most of its neighbors may be NH_3 molecules. Because the individual Gibbs free energies change as the reaction proceeds, the Gibbs free energy of reaction also changes. If $\Delta G < 0$ at a certain composition of the reaction mixture, then the reaction is spontaneous. If $\Delta G > 0$ at a certain composition, then the reverse reaction (the decomposition of ammonia in our example), is spontaneous.

Standard states are defined in Section 7.15.

The **standard Gibbs free energy of reaction,** $\Delta G°$, is defined like the Gibbs free energy of reaction but in terms of the *standard* molar Gibbs energies of the reactants and products:

$$\Delta G° = \sum nG_m°(\text{products}) - \sum nG_m°(\text{reactants}) \qquad (19)$$

That is, the standard Gibbs free energy of reaction is the difference in Gibbs free energy between the products in their standard states and the pure reactants in their standard states (at the specified temperature). Because the standard state of a substance is its pure form at 1 bar, the *standard* Gibbs free energy of reaction is the difference in Gibbs free energy between the *pure* products and the *pure* reactants: it is a fixed quantity for a given reaction and does not vary as the reaction proceeds. We shall unfold the enormous importance of this quantity shortly. The points to remember are:

- $\Delta G°$ is fixed for a given reaction and temperature,
- ΔG depends on the composition of the reaction mixture and so it varies—and might even change sign—as the reaction proceeds.

As remarked previously, in some texts you will see 1 atm used in the definition of standard states. The modern definition is 1 bar. The change in standard pressure has little effect on the tabulated values.

Equations 18 and 19 are not very useful in practice, because, as remarked earlier, we can know only *changes* in the Gibbs free energies of substances, not their absolute values. However, we can use the same technique that we used to find the standard reaction enthalpy in Section 7.18, where we assigned each compound a standard enthalpy of formation, $\Delta H_f°$. We can also tabulate Gibbs free energies of formation of substances

TABLE 8.6 Examples of the Most Stable Forms of Elements

Element	Most stable form at 25°C and 1 bar
H_2, O_2, Cl_2, Xe	gas
Br_2, Hg	liquid
C	graphite
Na, Fe, I_2	solid

TABLE 8.7 Standard Gibbs Free Energies of Formation at 25°C ($kJ\cdot mol^{-1}$)*

Gases	$\Delta G_f°$	Liquids	$\Delta G_f°$	Solids	$\Delta G_f°$
ammonia, NH_3	−16.45	benzene, C_6H_6	+124.3	Calcium carbonate, $CaCO_3$†	−1128.8
carbon dioxide, CO_2	−394.4	ethanol, C_2H_5OH	−174.8	silver chloride, AgCl	−109.8
nitrogen dioxide, NO_2	+51.3	water, H_2O	−237.1		
water, H_2O	−228.6				

*Additional values are given in Appendix 2A.
†Calcite.

and then use them to calculate $\Delta G°$. The **standard Gibbs free energy of formation,** $\Delta G_f°$ (the "standard free energy of formation"), of a substance is *the standard Gibbs free energy of reaction per mole for the formation of a compound from its elements in their most stable form*. The most stable form of an element is the state with the lowest Gibbs free energy (Table 8.6). For example, the standard Gibbs free energy of formation of hydrogen iodide gas at 25°C is $\Delta G_f°(HI, g) = +1.70\ kJ\cdot mol^{-1}$. It is the standard Gibbs free energy per mole of HI for the reaction $\frac{1}{2} H_2(g) + \frac{1}{2} I_2(s) \longrightarrow HI(g)$. It follows from the definition that the standard Gibbs free energies of formation of elements in their most stable forms are exactly zero; for example, $\Delta G_f°(I_2, s) = 0$ for the "null" reaction $I_2(s) \longrightarrow I_2(s)$, for there is no change between reactants and products.

Standard Gibbs free energies of formation can be determined in various ways. One straightforward way is to combine standard enthalpy and entropy data from tables such as Tables 7.5 and 8.3. A list of values for several common substances is given in Table 8.7, and a more extensive one appears in Appendix 2A.

EXAMPLE 8.14 Calculating a standard Gibbs free energy of formation from enthalpy and entropy data

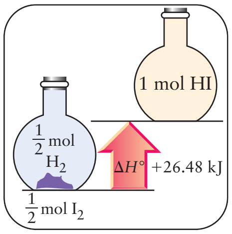
Calculate the standard Gibbs free energy of formation of HI(g) at 25°C from its standard molar entropy and standard enthalpy of formation.

PLAN We write the chemical equation for the formation of HI(g) and calculate the standard Gibbs free energy of reaction from $\Delta G° = \Delta H° - T\Delta S°$. It is best to write the equation with a stoichiometric coefficient of 1 for the compound of interest, because then $\Delta G° = \Delta G_f°$. The standard enthalpy of formation is found in Appendix 2A. The standard reaction entropy is found as shown in Example 8.9, by using the data from Table 8.3 or Appendix 2A.

SOLVE The chemical equation is $\frac{1}{2} H_2(g) + \frac{1}{2} I_2(s) \longrightarrow HI(g)$.

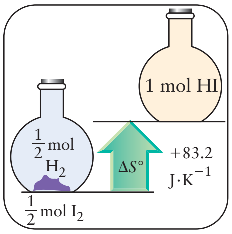
From data in Appendix 2A,

$$\Delta H° = (1\ mol) \times \Delta H_f°(HI, g) = +26.48\ kJ$$



From Eq. 8 of this chapter,

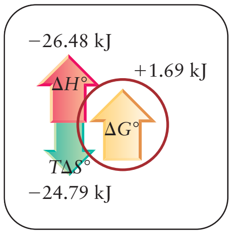
$$\Delta S° = S_m°(HI, g) - \left\{\tfrac{1}{2}S_m°(H_2, g) + \tfrac{1}{2}S_m°(I_2, s)\right\}$$
$$= \{(1\ mol) \times (206.6\ J\cdot K^{-1}\cdot mol^{-1})\}$$
$$- \left\{\left(\tfrac{1}{2}\ mol\right) \times (130.7) + \left(\tfrac{1}{2}\ mol\right) \times (116.1)\right\}\ J\cdot K^{-1}\cdot mol^{-1}$$
$$= +83.2\ J\cdot K^{-1} = +0.0832\ kJ\cdot K^{-1}$$



From $\Delta G° = \Delta H° - T\Delta S°$,

$$\Delta G° = (1\ \text{mol}) \times (+26.48\ \text{kJ·mol}^{-1}) - (298\ \text{K}) \times (0.0832\ \text{kJ·K}^{-1})$$

$$= +1.69\ \text{kJ}$$



Evaluate The standard Gibbs free energy of formation of HI(g) is therefore $+1.69\ \text{kJ·mol}^{-1}$, in good agreement with the value of $+1.70\ \text{kJ·mol}^{-1}$ quoted in the text. Note that, because this value is positive, the formation of pure HI from the elements at 1 bar is not spontaneous.

Self-Test 8.20A Calculate the standard Gibbs free energy of formation of NH_3(g) at 25°C from the enthalpy of formation and the molar entropies of the species taking part in its formation.

[***Answer:*** $-16.5\ \text{kJ·mol}^{-1}$]

Self-Test 8.20B Calculate the standard Gibbs free energy of formation of C_3H_6(g), cyclopropane, at 25°C.

The standard Gibbs free energy of formation at a given temperature is an indication of a compound's stability relative to its elements under standard conditions. The data in Appendix 2A are for 298.15 K, the conventional temperature for reporting thermodynamic data. If $\Delta G_f° < 0$ at a certain temperature, the pure compound has a lower Gibbs free energy than that of its pure elements and the elements are poised to change spontaneously into the compound at that temperature (Fig. 8.27). We say that the compound is "more stable" under standard conditions than the elements. If $\Delta G_f° > 0$, the Gibbs free energy of the compound is higher than that of its elements and the compound is poised to change spontaneously into the pure elements. In this case, we say that the pure elements are "more stable" than the pure compound. For example, the standard Gibbs free energy of formation of benzene is $+124\ \text{kJ·mol}^{-1}$ at 25°C, and benzene is unstable with respect to its elements under standard conditions at 25°C.

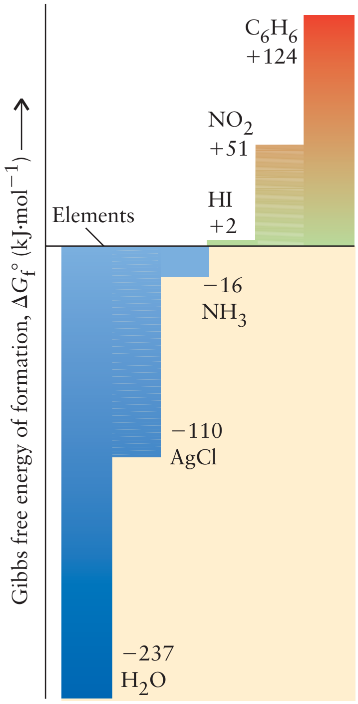


FIGURE 8.27 The standard Gibbs free energy of formation of a compound is defined as the standard reaction Gibbs free energy per mole of formula units of the compound when the compound is formed from its elements. It represents a "thermodynamic altitude" with respect to the elements at "sea level." The numerical values are in kilojoules per mole.

A **thermodynamically stable compound** is a compound with a negative standard Gibbs free energy of formation (water is an example). A **thermodynamically unstable compound** is a compound with a positive standard Gibbs free energy of formation (benzene is an example). Such a compound is poised to decompose spontaneously into its elements. However, that tendency may not be realized in practice, because the decomposition may be very slow. Benzene can, in fact, be kept indefinitely without decomposing at all. Substances that are thermodynamically unstable but survive for long periods are called **nonlabile** or even **inert.** For example, benzene is thermodynamically unstable but nonlabile. Substances that do decompose or react rapidly are called **labile.** Most radicals are labile. It is important to keep in mind the distinction between stability and lability:

- *Stable* and *unstable* are terms that refer to the thermodynamic tendency of a substance to decompose into its elements.
- *Labile*, *nonlabile*, and *inert* are terms that refer to the rate at which a thermodynamic tendency to react is realized.

The rates of reactions are discussed in Chapter 14.

Self-Test 8.21A Is glucose stable relative to its elements at 25°C and under standard conditions?

[***Answer:*** Yes; for glucose, $\Delta G_f° = -910.\ \text{kJ·mol}^{-1}$, a negative value.]

Self-Test 8.21B Is methylamine, CH_3NH_2, stable relative to its elements at 25°C and under standard conditions?

Just as we can combine standard enthalpies of formation to obtain standard reaction enthalpies, we can also combine standard Gibbs free energies of formation to obtain standard Gibbs free energies of reaction:

$$\Delta G° = \sum n\Delta G_f°(\text{products}) - \sum n\Delta G_f°(\text{reactants}) \qquad (20)^*$$

where, as usual, the n are the amounts of each substance in the chemical equation.

EXAMPLE 8.15 **Calculating the standard Gibbs free energy of reaction**

Calculate the standard Gibbs free energy of the reaction

$$4\ NH_3(g) + 5\ O_2(g) \longrightarrow 4\ NO(g) + 6\ H_2O(g)$$

and decide whether the reaction is spontaneous under standard conditions at 25°C.

Anticipate The reaction is a combustion (in this case, of ammonia), and combustions are typically spontaneous (in the thermodynamic sense); therefore, we should expect a negative Gibbs free energy.

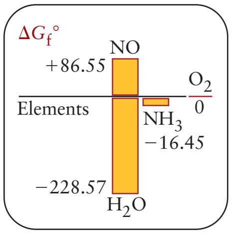
PLAN Obtain the standard Gibbs free energies of formation from Appendix 2A, then use Eq. 20 to calculate the reaction Gibbs free energy.

What should we assume? That all reactants and products are pure substances and that the pressure of each one is 1 bar.

SOLVE

From Appendix 2A and Eq. 20,

$$\begin{aligned}\Delta G° &= \{(4\text{ mol}) \times \Delta G_f°(NO, g) + (6\text{ mol}) \times \Delta G_f°(H_2O, g)\}\\ &\quad - \{(4\text{ mol}) \times \Delta G_f°(NH_3, g) + (5\text{ mol}) \times \Delta G_f°(O_2, g)\}\\ &= \{4(86.55) + 6(-228.57)\} - \{4(-16.45) + 0\}\text{ kJ}\\ &= -959.42\text{ kJ}\end{aligned}$$



Evaluate We can conclude that, as expected, the combustion of ammonia is spontaneous at 25°C under standard conditions.

Self-Test 8.22A Calculate the standard Gibbs free energy of the reaction $2\ CO(g) + O_2(g) \longrightarrow 2\ CO_2(g)$ from standard Gibbs free energies of formation at 25°C.

[***Answer:*** $\Delta G° = -514.38$ kJ]

Self-Test 8.22B Calculate the standard Gibbs free energy of the reaction $6\ CO_2(g) + 6\ H_2O(l) \longrightarrow C_6H_{12}O_6(s, \text{glucose}) + 6\ O_2(g)$ from standard Gibbs free energies of formation at 25°C.

The standard Gibbs free energy of formation of a substance is the standard Gibbs free energy of reaction per mole of compound when it is formed from its elements in their most stable forms. The sign of $\Delta G_f°$ tells us whether a compound is stable or unstable with respect to its elements. Standard Gibbs free energies of formation are used to calculate standard Gibbs free energies of reaction by using Eq. 20.

8.14 The Gibbs Free Energy and Nonexpansion Work

We are now ready to see why the Gibbs free energy is called the *free* energy: we shall see that the change in Gibbs free energy that accompanies a process allows us to predict the maximum *nonexpansion work* that the process can do at constant temperature and pressure. That is, the Gibbs free energy is a measure of the energy *free* to do nonexpansion work. As explained in Section 7.3, nonexpansion work, w_e, is any kind of work other than that due to expansion against an opposing pressure; so it includes electrical work and mechanical work (like stretching a spring or carrying a weight up a slope). The fact that nonexpansion work includes electrical work—the work of pushing electrons through an electrical

circuit—is the basis of the chemical generation of electrical power: we pursue that connection in Chapter 13. Nonexpansion work also includes the work of muscular activity, the work of linking amino acids together to form protein molecules, and the work of sending nerve signals through neurons; so a knowledge of changes in Gibbs free energy is central to an understanding of **bioenergetics,** the deployment and utilization of energy in living cells.

The challenge that we now face is to derive a *quantitative* relation between the Gibbs free energy and the maximum nonexpansion work that a system can do.

HOW DO WE DO THAT?

To find the relation between the Gibbs free energy and the maximum nonexpansion work, we start with Eq. 15 for an infinitesimal change (denoted d) in G at constant temperature:

$$dG = dH - TdS \qquad \text{at constant temperature}$$

We then use Eq. 9 of Chapter 7 ($H = U + PV$) to express the infinitesimal change in enthalpy at constant pressure in terms of the change in internal energy

$$dH = dU + PdV \qquad \text{at constant pressure}$$

Then we substitute this expression into the first:

$$dG = dU + PdV - TdS \qquad \text{at constant temperature and pressure}$$

Now we use Eq. 7 from Chapter 7 for an infinitesimal change in internal energy ($dU = dw + dq$) and obtain

$$dG = dw + dq + PdV - TdS \qquad \text{at constant temperature and pressure}$$

We are interested in the maximum work that a process can do, which means that the process has to occur reversibly (recall Section 7.3). For a reversible change,

$$dG = dw_{rev} + dq_{rev} + PdV - TdS \qquad \text{at constant temperature and pressure}$$

Now we use the infinitesimal version of Eq. 1 ($dS = dq_{rev}/T$) to replace dq_{rev} by TdS and cancel the two TdS terms:

$$\begin{aligned} dG &= dw_{rev} + TdS + PdV - TdS \\ &= dw_{rev} + PdV \qquad \text{at constant temperature and pressure} \end{aligned}$$

The subscript e in w_e stands for "extra."

At this point, we recognize that the system may do both expansion work and nonexpansion work:

$$dw_{rev} = dw_{rev,\,e} + dw_{rev,\,expansion}$$

Reversible expansion work (achieved by matching the external to the internal pressure) is given by the infinitesimal version of Eq. 3 of Chapter 7 ($w_{expansion} = -P_{ex}\Delta V$, which becomes $dw_{expansion} = -P_{ex}dV$) and setting the external pressure equal to the pressure of the gas in the system at each stage of the expansion:

$$dw_{rev,\,expansion} = -PdV$$

It follows that

$$dw_{rev} = dw_{rev,\,e} - PdV$$

When we substitute this expression into the last line of the expression for dG ($dG = dw_{rev} + PdV$), the PdV terms cancel and we are left with

$$dG = dw_{rev,\,e} \qquad \text{at constant temperature and pressure}$$

Because $dw_{rev,\,e}$ is the *maximum* nonexpansion work that the system can do (because it is achieved reversibly), we obtain

$$dG = dw_{e,\,max} \qquad \text{at constant temperature and pressure}$$

When we consider a measurable change in the Gibbs free energy, the equation we have derived becomes

$$\Delta G = w_{e,\,max} \qquad \text{at constant temperature and pressure} \qquad \mathbf{(21)}^*$$

This important relation tells us that, if we know the change in Gibbs free energy of a process taking place at constant temperature and pressure, then we immediately know how much nonexpansion work it can do.

Equation 21 is also important in practice because we are often interested in various types of work, not just heating (see Table 7.1). In particular, the equation lets us consider the energetics of biological processes quantitatively. For instance, for the oxidation of glucose,

$$C_6H_{12}O_6(s) + 6\ O_2(g) \longrightarrow 6\ CO_2(g) + 6\ H_2O(l)$$

the standard Gibbs free energy of reaction is −2879 kJ. Therefore, at 1 bar the maximum nonexpansion work obtainable from 1.000 mol $C_6H_{12}O_6(s)$, corresponding to 180.0 g of glucose, is 2879 kJ. Because about 17 kJ of work must be done to build 1 mol of peptide links (a link between amino acids) in a protein, the oxidation of 180 g of glucose can be used to build about (2879 kJ)/(17 kJ) = 170 moles of such links. In other words, the oxidation of one glucose molecule is needed to build about 170 peptide links. In practice, biosynthesis occurs indirectly, there are energy losses, and only about 10 such links can be built. A typical protein has several hundred peptide links, and so several glucose molecules must be sacrificed to build one protein molecule.

The change in Gibbs free energy for a process is equal to the maximum nonexpansion work that the system can do at constant temperature and pressure.

8.15 The Effect of Temperature

The enthalpies of reactants and products are both affected by a temperature rise and the *difference* between their values changes only a little with temperature (recall Section 7.21). The same is true of the entropies. As a result, the values of $\Delta H°$ and $\Delta S°$ do not change much with temperature. However, $\Delta G°$ does depend on temperature (remember the T in $\Delta G° = \Delta H° - T\Delta S°$) and might change sign as the temperature is changed. There are four cases to consider:

1 For an exothermic reaction ($\Delta H° < 0$) with a negative reaction entropy ($\Delta S° < 0$), $-T\Delta S°$ contributes a positive term to $\Delta G°$. For such a reaction, $\Delta G°$ is negative (and the formation of products spontaneous) at low temperatures because $\Delta H°$ dominates $-T\Delta S°$, but it may become positive (and the reverse reaction, the decomposition of pure products, spontaneous) at higher temperatures when $-T\Delta S°$ dominates $\Delta H°$ (Fig. 8.28a).

In this case, the increase in entropy of the surroundings drives the reaction forward, but it is opposed by the decrease in entropy of the system.

2 For an endothermic reaction ($\Delta H° > 0$) with a positive reaction entropy ($\Delta S° > 0$), the reverse is true (Fig. 8.28b). In this case, $\Delta G°$ is positive at low temperatures but may become negative when the temperature is raised to the point that $T\Delta S°$

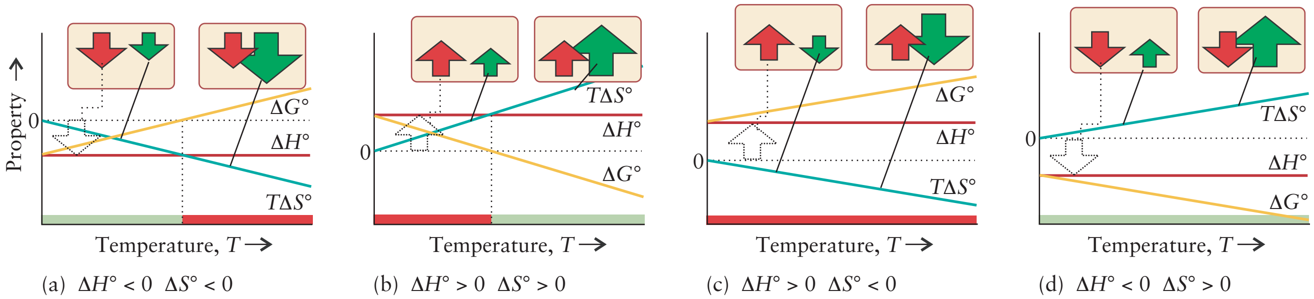


FIGURE 8.28 The effect of an increase in temperature on the spontaneity of a reaction under standard conditions. In each case, "spontaneous" is taken to mean $\Delta G° < 0$ and "nonspontaneous" is taken to mean $\Delta G° > 0$. (a) An exothermic reaction with negative reaction entropy becomes spontaneous *below* the temperature marked by the vertical dotted line. (b) An endothermic reaction with a positive reaction entropy becomes spontaneous *above* the temperature marked by the vertical dotted line. (c) An endothermic reaction with negative reaction entropy is not spontaneous at any temperature. (d) An exothermic reaction with positive reaction entropy is spontaneous at all temperatures.

becomes larger than $\Delta H°$. The formation of products from pure reactants becomes spontaneous when the temperature is high enough.

Here, the increase in entropy of the system is opposed by the decrease in entropy of the surroundings, the effect of which is reduced by raising the temperature.

3 For an endothermic reaction ($\Delta H° > 0$) with a negative reaction entropy ($\Delta S° < 0$), $\Delta G° > 0$ at all temperatures and the reaction is not spontaneous at any temperature (Fig. 8.28c).

In this case, the entropies of the system and the surroundings both decrease whatever the temperature.

4 For an exothermic reaction ($\Delta H° < 0$) with a positive reaction entropy ($\Delta S° > 0$), $\Delta G° < 0$ and the formation of products from pure reactants is spontaneous at all temperatures (Fig. 8.28d).

In this case, the entropies of the system and the surroundings both increase whatever the temperature.

EXAMPLE 8.16 Calculating the temperature at which an endothermic reaction becomes spontaneous

Estimate the temperature at which it is thermodynamically possible for carbon to reduce iron(III) oxide to iron under standard conditions by the endothermic reaction

$$2\,Fe_2O_3(s) + 3\,C(s) \longrightarrow 4\,Fe(s) + 3\,CO_2(g)$$

Anticipate Because a gas is produced, $\Delta S° > 0$; because $\Delta H° > 0$ also, we should expect the reaction to become spontaneous at a high temperature.

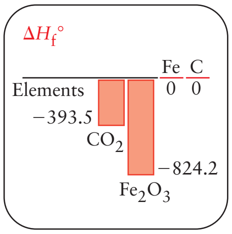
PLAN At low temperatures $\Delta G° = \Delta H° - T\Delta S° \approx \Delta H°$ and is positive (we are told the reaction is endothermic). If the temperature is increased there will come a point, when $T = \Delta H°/\Delta S°$, above which $\Delta G°$ is negative. That, therefore, is the temperature we seek. We use data from Appendix 2A.

What should we assume? That $\Delta H°$ and $\Delta S°$ are approximately constant over the temperature range considered.

SOLVE

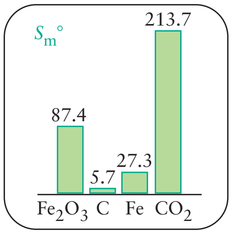
From Eq. 20 of Chapter 7,

$$\begin{aligned}\Delta H° &= (3\text{ mol}) \times \Delta H_f°(CO_2, g) - (2\text{ mol}) \times \Delta H_f°(Fe_2O_3, s)\\ &= 3(-393.5) - 2(-824.2)\text{ kJ}\\ &= +467.9\text{ kJ}\end{aligned}$$



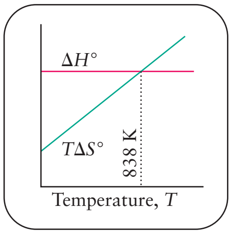
From Eq. 8 of this chapter,

$$\begin{aligned}\Delta S° &= \{(4\text{ mol}) \times S_m°(Fe, s) + (3\text{ mol}) \times S_m°(CO_2, g)\}\\ &\quad - \{(2\text{ mol}) \times S_m°(Fe_2O_3, s) + (3\text{ mol}) \times S_m°(C, s)\}\\ &= \{4(27.3) + 3(213.7)\} - \{2(87.4) + 3(5.7)\}\text{ J}\cdot\text{K}^{-1}\\ &= +558.4\text{ J}\cdot\text{K}^{-1}\end{aligned}$$



From $T = \Delta H°/\Delta S°$,

$$T = \frac{\overbrace{4.679 \times 10^5\text{ J}}^{467.9\text{ kJ}}}{558.4\text{ J}\cdot\text{K}^{-1}} = 838\text{ K}$$



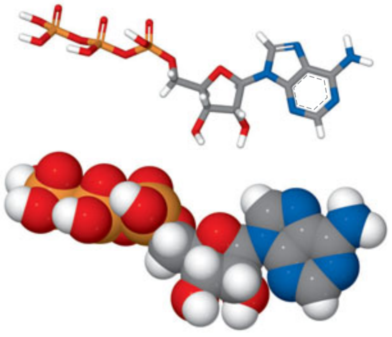
Evaluate As expected, because the reaction is endothermic, the minimum temperature at which reduction occurs at 1 bar is high, about 565°C.

Self-Test 8.23A What is the minimum temperature at which magnetite, Fe_3O_4, can be reduced to iron by using carbon (to produce CO_2)?

[***Answer:*** 943 K]

Self-Test 8.23B Estimate the temperature at which magnesium carbonate can be expected to decompose to magnesium oxide and carbon dioxide.

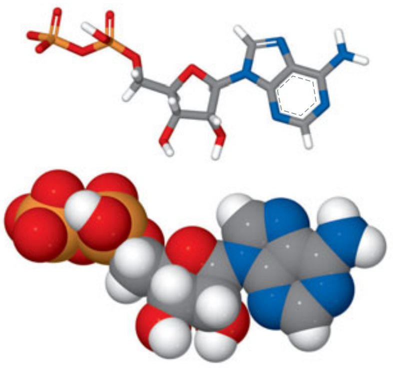
The Gibbs free energy increases with temperature for reactions with a negative $\Delta S°$ and decreases with temperature for reactions with a positive $\Delta S°$.



2 Adenosine triphosphate, ATP

8.16 Impact on Biology: Gibbs Free Energy Changes in Biological Systems

Many biological reactions, such as the construction of a protein from amino acids or the construction of a DNA molecule, are not spontaneous and therefore must be driven by an external source of energy. That energy comes from sunlight and the chemicals in food that have stored solar energy (Fig 8.29). When food is metabolized, the resulting exothermic reaction generates a lot of entropy, and if the reaction is coupled to a biochemical reaction that is nonspontaneous, the *overall* change in entropy may be positive, and the *overall* process spontaneous. In other words, *a reaction that produces a lot of entropy can drive a nonspontaneous reaction forward*. In terms of Gibbs free energy, one biochemical process may be driven uphill in Gibbs free energy by another reaction that rolls downhill. Staying alive is very much like the effect of a heavy weight tied to another weight by a string that passes over a pulley (Fig. 8.30). The lighter weight could never fly up into the air on its own. However, when it is connected to a heavier weight falling downward on the other side of a pulley, the light weight can soar upward.



3 Adenosine diphosphate, ADP

The hydrolysis of adenosine triphosphate, ATP (**2**), to adenosine diphosphate, ADP (**3**), is the reaction used most frequently by biological organisms to couple with and drive nonspontaneous reactions. This hydrolysis is the key metabolic reaction by which Gibbs free energy is stored and used in living systems. The value of $\Delta G°$ for the hydrolysis of 1 mol ATP is about -30 kJ. To restore ADP back to ATP, which is accompanied by a Gibbs free energy change of $+30$ kJ, an ADP molecule and a phosphate group must be linked by coupling them to another reaction for which the Gibbs free energy of reaction is more negative than -30 kJ. That is one reason why

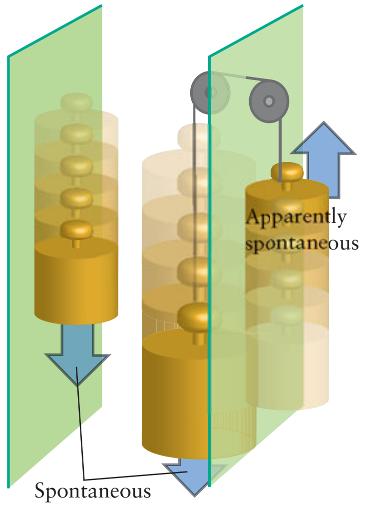


FIGURE 8.30 A natural process can be represented as a falling weight (left). A weight rising spontaneously would be regarded as highly unusual until we recognize that it is actually part of a natural process overall (right). The natural fall of the heavier weight causes the apparently "unnatural" rise of the smaller weight.

FIGURE 8.29 The process of life is fueled by energy from sunlight, either directly or from energy stored in food.

we have to eat. When we eat food containing glucose, we consume a fuel. Like all fuels, it has a spontaneous tendency to form combustion products. If we were simply to burn glucose in an open container, it would do no work other than pushing back the atmosphere, and it would give off a lot of heat. However, in our bodies, the "combustion" is a highly controlled and sophisticated version of burning. In such a controlled reaction, the nonexpansion work that the process can do approaches 2500 kJ per mole of glucose molecules, which is enough to "recharge" about 80 mol ADP molecules.

When living organisms die, they no longer ingest the second-hand sunlight stored in molecules of carbohydrate, protein, and fat. Then the natural direction of change becomes dominant, and the intricate molecules that support life start to decompose. Living organisms are engaged in a constant battle to generate enough entropy in their surroundings to go on building and maintaining their intricate interiors. As soon as they stop the battle, they stop generating that external entropy, and their bodies decay.

Reactions that are nonspontaneous can be made to take place by coupling them with spontaneous reactions. This coupling is used extensively in biological systems.

SKILLS YOU SHOULD HAVE MASTERED

❑ 1 Calculate the entropy change for reversible heat transfer (Example 8.1).

❑ 2 Calculate the entropy change when the temperature of a substance is changed (Example 8.2).

❑ 3 Determine the entropy change for the isothermal expansion or compression of an ideal gas (Examples 8.3, 8.4, and 8.5).

❑ 4 Calculate the standard entropy of a phase change (Example 8.6).

❑ 5 Use the Boltzmann formula to calculate and interpret the entropy of a substance (Examples 8.7 and 8.8).

❑ 6 Predict which of two systems has the greater entropy, given their compositions and conditions (Self-Test 8.11).

❑ 7 Calculate the standard reaction entropy from standard molar entropies (Example 8.9).

❑ 8 Estimate the change in entropy of the surroundings due to heat transfer at constant pressure and temperature (Example 8.10).

❑ 9 Calculate the total change in entropy for a process (Examples 8.11 and 8.12).

❑ 10 Use the change in Gibbs free energy to determine the spontaneity of a process at a given temperature (Example 8.13).

❑ 11 Calculate a standard Gibbs free energy of formation from enthalpy and entropy data (Example 8.14).

❑ 12 Calculate the standard Gibbs free energy of reaction from standard Gibbs free energies of formation (Example 8.15).

❑ 13 Estimate the maximum nonexpansion work that can be done by a process (Section 8.14).

❑ 14 Predict the minimum temperature at which an endothermic reaction can occur spontaneously (Example 8.16).

EXERCISES

Exercises labeled **C** *require calculus*

Entropy

8.1 A human body generates heat at the rate of about 100. W ($1\ W = 1\ J\cdot s^{-1}$). (a) At what rate does your body heat generate entropy in your surroundings, taken to be at 20.°C? (b) How much entropy do you generate each day? (c) Would the entropy generated be greater or less if you were in a room kept at 30.°C? Explain your answer.

8.2 An electric heater is rated at 2.3 kW ($1\ W = 1\ J\cdot s^{-1}$). (a) At what rate does it generate entropy in a room maintained at 24°C? (b) How much entropy does it generate in the course of a day? (c) Would the entropy generated be greater or less if the room were maintained at 21°C? Explain your answer.

8.3 (a) Calculate the change in entropy of a block of copper at 25°C that absorbs 65 J of energy from a heater. (b) If the block of copper is at 100.°C and it absorbs 65 J of energy from the heater, what is its entropy change? (c) Explain any difference in entropy change.

8.4 (a) Calculate the change in entropy of 1.0 L of water at 0.°C when it absorbs 470 J of energy from a heater. (b) If the 1.0 L of water is at 99°C, what is its entropy change? (c) Explain any difference in entropy change.

8.5 Assuming that the heat capacity of an ideal gas is independent of temperature, calculate the entropy change associated with raising the temperature of 1.00 mol of ideal gas atoms reversibly from 37.6°C to 157.9°C at (a) constant pressure and (b) constant volume.

8.6 Assuming that the heat capacity of an ideal gas is independent of temperature, calculate the entropy change associated with lowering the temperature of 2.92 mol of ideal gas atoms from 107.35°C to −52.39°C at (a) constant pressure and (b) constant volume.

8.7 Calculate the entropy change associated with the isothermal expansion of 5.25 mol of ideal gas atoms from 24.252 L to 34.058 L.

8.8 Calculate the entropy change associated with the isothermal compression of 4.80 mol of ideal gas atoms from 12.86 L to 4.80 L.

8.9 Calculate the change in entropy when the pressure of 1.50 mol Ne(g) is decreased isothermally from 15.0 atm to 0.500 atm. Assume ideal behavior and 1 mole of N_2(g).

8.10 Calculate the change in entropy when the pressure of 70.9 g of methane gas is increased isothermally from 7.00 kPa to 350.0 kPa. Assume ideal behavior.

8.11 During the test of an internal combustion engine, 3.00 L of nitrogen gas at 18.5°C was compressed suddenly (and irreversibly) to 0.500 L by driving in a piston. In the process the temperature of the gas increased to 28.1°C. Assume ideal behavior. What is the change in entropy of the gas?

8.12 Calculate the change in entropy when the pressure of 3.44 g of helium gas is decreased from 125.0 kPa to 65.0 kPa while the temperature decreases from 335 K to 273 K. Assume ideal behavior.

8.13 Show that, if two copper blocks with different temperatures are placed in contact, then the direction of spontaneous change is toward the equalization of temperatures. Do so by considering the transfer of 1 J of energy as heat from one to the other and assessing the sign of the entropy change. Assume that the temperatures of the blocks remain constant.

8.14 Suppose that 100. J of energy is taken from a hot source at 300.°C, passes through a turbine that converts some of the energy into work, and then releases the rest of the energy as heat into a cold sink at 20.°C. What is the maximum amount of work that can be produced by this engine if overall it is to operate spontaneously? What is the efficiency of the engine, with work done divided by heat supplied expressed as a percentage? How could the efficiency be increased?

8.15 A heat pump heats a house in winter by extracting heat from the cold outdoors and releasing it into the warm interior. For the transfer of a given amount of heat, (a) how do the entropies of the interior and exterior of the house change (increase or decrease)? (b) Which change is greater? Assume that the temperatures inside and outside the house do not change. Explain your answers.

8.16 Suppose that you were able to design an engine without a cold sink, so that the energy from a hot object could be transferred to the surroundings entirely as work, with no heat exchanged. (a) What would be the entropy change of the surroundings? (b) Could such an engine operate spontaneously? Explain your answer.

8.17 Use data in Table 7.3 or Appendix 2A to calculate the entropy change for (a) the freezing of 1.00 mol H_2O(l) at 0.00°C; (b) the vaporization of 50.0 g of ethanol, C_2H_5OH, at 351.5 K.

8.18 Use data in Table 7.3 or Table 8.2 to calculate the entropy change for (a) the vaporization of 2.40 mol H_2O(l) at 100.°C and 1 atm; (b) the freezing of 4.50 g of ethanol, C_2H_5OH, at 158.7 K.

8.19 (a) Using data provided in Appendix 2A, estimate the boiling point of ethanal, CH_3CHO(l). (b) From standard reference sources, find the actual boiling point of ethanal. (c) How do these values compare? (d) What gives rise to the differences?

8.20 Using data provided in Appendix 2A, estimate the boiling point of Br_2(l). (b) From standard reference sources, find the actual boiling point of bromine. (c) How do these values compare?

8.21 (a) Using Trouton's rule, estimate the boiling point of dimethyl ether, CH_3OCH_3, given that $\Delta H_{vap}° = 21.51\ kJ{\cdot}mol^{-1}$. (b) Using standard reference sources available in your library, find the actual boiling point of dimethyl ether and compare this value with the value obtained by using Trouton's rule. Explain any difference.

8.22 (a) Using Trouton's rule, estimate the boiling point of methylamine, CH_3NH_2, given that $\Delta H_{vap}° = 25.60\ kJ{\cdot}mol^{-1}$. (b) Using standard reference sources available in your library, find the actual boiling point of methylamine and compare this value with the value obtained by using Trouton's rule. Explain any difference.

8.23 The standard entropy of vaporization of benzene is approximately 85 $J{\cdot}K^{-1}{\cdot}mol^{-1}$ at its boiling point. (a) Estimate the standard enthalpy of vaporization of benzene at its normal boiling point of 80.°C. (b) What is the standard entropy change of the surroundings when 10. g of benzene, C_6H_6, vaporizes at its normal boiling point?

8.24 The standard entropy of vaporization of acetone is approximately 85 $J{\cdot}K^{-1}{\cdot}mol^{-1}$ at its boiling point. (a) Estimate the standard enthalpy of vaporization of acetone at its normal boiling point of 56.2°C. (b) What is the entropy change of the surroundings when 10. g of acetone, CH_3COCH_3, condenses at its normal boiling point?

8.25 Which would you expect to have a higher molar entropy at $T = 0$, single crystals of BF_3 or of COF_2? Why?

8.26 On the basis of the structures of each of the following molecules, predict which ones would be most likely to have a residual entropy in their crystal forms at $T = 0$: (a) CO_2; (b) NO; (c) N_2O; (d) Cl_2.

8.27 If SO_2F_2 adopts a disordered arrangement in its crystal form, what would its residual molar entropy be?

8.28 What would you expect the residual molar entropy of PH_2F to be if it were to adopt a disordered arrangement in its crystal form?

8.29 Which substance in each of the following pairs has the higher molar entropy at 298 K: (a) HBr(g) or HF(g); (b) NH_3(g) or Ne(g); (c) I_2(s) or I_2(l); (d) 1.0 mol Ar(g) at 1.00 atm or 1.0 mol Ar(g) at 2.00 atm?

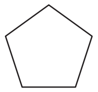
8.30 Which substance in each of the following pairs has the higher molar entropy? (Assume the temperature to be 298 K unless otherwise specified.) (a) CH_4(g) or C_2H_6(g); (b) KCl(aq) or KCl(s); (c) Ne(g) or Kr(g); (d) O_2(g) at 273 K and 1.00 atm or O_2(g) at 450. K and 1.00 atm.

8.31 List the following substances in order of increasing molar entropy at 298 K: H_2O(l), H_2O(g), H_2O(s), C(s, diamond). Explain your reasoning.

8.32 List the following substances in order of increasing molar entropy at 298 K: CO_2(g), Ar(g), H_2O(l), Ne(g). Explain your reasoning.

8.33 Which substance in each of the following pairs would you expect to have the higher standard molar entropy at 298 K?

Explain your reasoning. (a) Iodine vapor or bromine vapor; (b) the two liquids cyclopentane and 1-pentene (see structures); (c) ethene (ethylene) or an equivalent mass of polyethylene, a substance formed by the polymerization of ethylene.

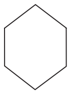


Cyclopentane, C_5H_{10}

1-Pentene, C_5H_{10}

8.34 Predict which of the hydrocarbons below has the greater standard molar entropy at 25°C. Explain your reasoning.

(a) Cyclobutane, C_4H_8



(b) Cyclohexane, C_6H_{12}

8.35 Without performing any calculations, predict whether there is an increase or a decrease in entropy for each of the following processes: (a) $Cl_2(g) + H_2O(l) \longrightarrow HCl(aq) + HClO(aq)$; (b) $Cu_3(PO_4)_2(s) \longrightarrow 3\,Cu^{2+}(aq) + 2\,PO_4^{3-}(aq)$; (c) $SO_2(g) + Br_2(g) + 2\,H_2O(l) \longrightarrow H_2SO_4(aq) + 2\,HBr(aq)$.

8.36 Without performing any calculations, state whether the entropy of the system increases or decreases in each of the following processes: (a) the dissolution of table salt: $NaCl(s) \longrightarrow NaCl(aq)$; (b) the photosynthesis of glucose: $6\,CO_2(g) + 6\,H_2O(l) \longrightarrow C_6H_{12}O_6(s) + 6\,O_2(g)$; (c) the evaporation of water from damp clothes. Explain your reasoning.

8.37 Container A is filled with 1.0 mol of the atoms of an ideal monatomic gas. Container B has 1.0 mol of atoms bound together as diatomic molecules that are not vibrationally active. Container C has 1.0 mol of atoms bound together as diatomic molecules that are vibrationally active. The containers all start at T_i and the temperature is increased to T_f. Rank the containers in order of increasing change in entropy. Explain your reasoning.

8.38 A closed vessel of volume 2.5 L contains a mixture of neon and fluorine. The total pressure is 3.32 atm at 0.0°C. When the mixture is heated to 15°C, the entropy of the mixture increases by $0.345\ J\cdot K^{-1}$. What amount (in moles) of each substance (Ne and F_2) is present in the mixture?

8.39 Use data in Table 8.3 or Appendix 2A to calculate the standard reaction entropy for each of the following reactions at 25°C. For each reaction, interpret the sign and magnitude of the reaction entropy. (a) The formation of 1.00 mol $H_2O(l)$ from the elements in their most stable state at 298 K. (b) The oxidation of 1.00 mol CO(g) to carbon dioxide. (c) The decomposition of 1.00 mol calcite, $CaCO_3(s)$, to carbon dioxide gas and solid calcium oxide. (d) The decomposition of potassium chlorate: $4\,KClO_3(s) \longrightarrow 3\,KClO_4(s) + KCl(s)$.

8.40 Use data in Table 8.3 or Appendix 2A to calculate the standard entropy change for each of the following reactions at 25°C. For each reaction, interpret the sign and magnitude of the reaction entropy. (a) The synthesis of carbon disulfide from natural gas (methane): $CH_4(g) + 4\,S(s, \text{rhombic}) \longrightarrow CS_2(l) + 2\,H_2S(g)$. (b) The production of acetylene from calcium carbide and water: $CaC_2(s) + 2\,H_2O(l) \longrightarrow C_2H_2(g) + Ca(OH)_2(s)$. (c) The oxidation of ammonia, which is the first step in the commercial production of nitric acid: $4\,NH_3(g) + 5\,O_2(g) \longrightarrow 4\,NO(g) + 6\,H_2O(l)$. (d) The industrial synthesis of urea, a common fertilizer: $CO_2(g) + 2\,NH_3(g) \longrightarrow CO(NH_2)_2(s) + H_2O(l)$.

C 8.41 The temperature dependence of the heat capacity of a substance is commonly written in the form $C_{P,m} = a + bT + c/T^2$, with a, b, and c constants. Obtain an expression for the entropy change when the substance is heated from T_1 to T_2. Evaluate this change for graphite, for which $a = 16.86\ J\cdot K^{-1}\cdot mol^{-1}$, $b = 4.77\ mJ\cdot K^{-2}\cdot mol^{-1}$, and $c = -8.54 \times 10^5\ J\cdot K\cdot mol^{-1}$, heated from 298 K to 400. K. What is the percentage error in assuming that the heat capacity is constant with its mean value in this range?

C 8.42 At low temperatures, heat capacities are proportional to T^3. Show that, near $T = 0$, the entropy of a substance is equal to one-third of its heat capacity at the same temperature.

8.43 Calculate the standard entropy of vaporization of water at 85°C, given that its standard entropy of vaporization at 100.°C is $109.0\ J\cdot K^{-1}\cdot mol^{-1}$ and the molar heat capacities at constant pressure of liquid water and water vapor are $75.3\ J\cdot K^{-1}\cdot mol^{-1}$ and $33.6\ J\cdot K^{-1}\cdot mol^{-1}$, respectively, in this range.

8.44 Three liquid samples with known masses are heated to their boiling points with the use of a 500.-W heater. Once their boiling points are reached, heating continues for 4.0 min and some of each sample is vaporized. After 4.0 min, the samples are cooled and the masses of the remaining liquids are determined. The process is performed at constant pressure. Using the following data, (a) calculate ΔS_{vap} and ΔH_{vap} for each sample. Assume that all the heat from the heater goes into the sample. (b) What do the values of ΔS_{vap} indicate about the relative degree of order in the liquids?

Liquid	Boiling temperature (°C)	Initial mass (g)	Final mass (g)
C_2H_5OH	78.3	400.15	271.15
C_4H_{10}	0.0	398.05	74.95
CH_3OH	64.5	395.15	294.25

Global Changes in Entropy

8.45 Suppose that 50.0 g of $H_2O(l)$ at 20.0°C is mixed with 65.0 g of $H_2O(l)$ at 50.0°C at constant atmospheric pressure in a thermally insulated vessel. Calculate ΔS and ΔS_{tot} for the process.

8.46 Suppose that 150.0 g of ethanol at 22.0°C is mixed with 200.0 g of ethanol at 56.0°C at constant atmospheric pressure in a thermally insulated vessel. Calculate ΔS and ΔS_{tot} for the process.

8.47 Use the information in Table 7.3 to calculate the changes in entropy of the surroundings and of the system for (a) the vaporization of 1.00 mol $CH_4(l)$ at its normal boiling point; (b) the melting of 1.00 mol $C_2H_5OH(s)$ at its normal melting point; (c) the freezing of 1.00 mol $C_2H_5OH(l)$ at its normal freezing point.

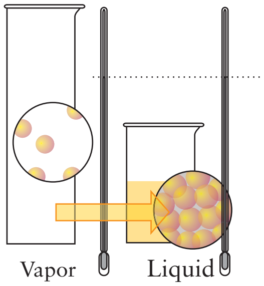
8.48 Use the information in Table 7.3 to calculate the changes in entropy of the surroundings and of the system for (a) the melting of 1.00 mol $NH_3(s)$ at its normal melting point; (b) the freezing of 1.00 mol $CH_3OH(l)$ at its normal freezing point; (c) the vaporization of 1.00 mol $H_2O(l)$ at its normal boiling point.

8.49 Initially a sample of ideal gas at 323 K occupies 1.67 L at 4.95 atm. The gas is allowed to expand to 7.33 L by two pathways: (a) isothermal, reversible expansion; (b) isothermal,

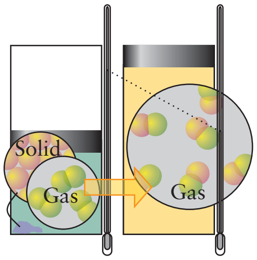
irreversible free expansion. Calculate ΔS_{tot}, ΔS, and ΔS_{surr} for each pathway.

8.50 Initially a sample of ideal gas at 412 K occupies 12.62 L at 0.6789 atm. The gas is allowed to expand to 19.44 L by two pathways: (a) isothermal, reversible expansion and (b) isothermal, irreversible free expansion. Calculate ΔS_{tot}, ΔS, and ΔS_{surr} for each pathway.

8.51 The following pictures show a molecular visualization of a system undergoing a spontaneous change. Account for the spontaneity of the process in terms of the entropy changes in the system and the surroundings. The thermometers show the temperature of the system.



8.52 The following pictures show a molecular visualization of a system undergoing a spontaneous change. Determine from the picture whether entropy increases or decreases during the process. Account for the spontaneity of the process in terms of the entropy changes in the system and the surroundings. The thermometers show the temperature of the system.



Gibbs Free Energy

8.53 Why are so many exothermic reactions spontaneous?

8.54 Explain how an endothermic reaction can be spontaneous.

8.55 Calculate the standard enthalpy, entropy, and Gibbs free energy at 298 K for each of the following reactions by using data in Appendix 2A. For each case, confirm that the value obtained from the Gibbs free energies of formation is the same as that obtained by using the relation $\Delta G° = \Delta H° - T\Delta S°$.
(a) the oxidation of magnetite to hematite:
$2\ Fe_3O_4(s) + \frac{1}{2}\ O_2(g) \longrightarrow 3\ Fe_2O_3(s)$
(b) the dissolution of CaF_2 in water: $CaF_2(s) \longrightarrow CaF_2(aq)$
(c) the dimerization of NO_2: $2\ NO_2(g) \longrightarrow N_2O_4(g)$

8.56 Calculate the standard enthalpy, entropy, and Gibbs free energy for each of the following reactions at 298 K by using data in Appendix 2A. For each case, confirm that the value obtained from the Gibbs free energies of formation is the same as that obtained by using the relation $\Delta G° = \Delta H° - T\Delta S°$.
(a) the hydration of copper sulfate:
$CuSO_4(s) + 5\ H_2O(l) \longrightarrow CuSO_4{\cdot}5H_2O(s)$
(b) the reaction of $H_2SO_4(l)$, an effective dehydrating agent, with water to form aqueous sulfuric acid: $H_2SO_4(l) \longrightarrow H_2SO_4(aq)$
(c) the reaction of calcium oxide with water to form calcium hydroxide: $CaO(s) + H_2O(l) \longrightarrow Ca(OH)_2(s)$
(d) Which of the reagents in parts (a)–(c) would you expect to be the most effective at removing water from a substance?

8.57 Write a balanced chemical equation for the formation reaction of (a) $NH_3(g)$; (b) $H_2O(g)$; (c) $CO(g)$; (d) $NO_2(g)$. For each reaction, determine $\Delta H°$, $\Delta S°$, and $\Delta G°$ from data in Appendix 2A.

8.58 Write a balanced chemical equation for the formation reaction of (a) $HCl(g)$; (b) $C_6H_6(l)$; (c) $CuSO_4{\cdot}5H_2O(s)$; (d) $CaCO_3$(s, calcite). For each reaction, determine $\Delta H°$, $\Delta S°$, and $\Delta G°$ from data in Appendix 2A.

8.59 Use the standard Gibbs free energies of formation in Appendix 2A to calculate $\Delta G°$ for each of the following reactions at 25°C. Comment on the spontaneity of each reaction under standard conditions at 25°C.
(a) $2\ SO_2(g) + O_2(g) \longrightarrow 2\ SO_3(g)$
(b) $CaCO_3$(s, calcite) $\longrightarrow CaO(s) + CO_2(g)$
(c) $2\ C_8H_{18}(l) + 25\ O_2(g) \longrightarrow 16\ CO_2(g) + 18\ H_2O(l)$

8.60 Use the standard Gibbs free energies of formation in Appendix 2A to calculate $\Delta G°$ for each of the following reactions at 25°C. Comment on the spontaneity of each reaction under standard conditions at 25°C.
(a) $NH_4Cl(s) \longrightarrow NH_3(g) + HCl(g)$
(b) $H_2(g) + D_2O(l) \longrightarrow D_2(g) + H_2O(l)$
(c) $N_2(g) + NO_2(g) \longrightarrow NO(g) + N_2O(g)$
(d) $2\ CH_3OH(g) + 3\ O_2(g) \longrightarrow 2\ CO_2(g) + 4\ H_2O(l)$

8.61 Determine which of the following compounds are stable with respect to decomposition into their elements under standard conditions at 25°C (see Appendix 2A): (a) $PCl_5(g)$; (b) $HCN(g)$; (c) $NO(g)$; (d) $SO_2(g)$.

8.62 Determine which of the following compounds are stable with respect to decomposition into their elements under standard conditions at 25°C (see Appendix 2A): (a) $C_3H_6(g)$, cyclopropane; (b) $CaO(s)$; (c) $N_2O(g)$; (d) $HN_3(g)$.

8.63 Which of the following compounds become less stable with respect to the elements as the temperature is raised: (a) $PCl_5(g)$; (b) $HCN(g)$; (c) $NO(g)$; (d) $SO_2(g)$?

8.64 Which of the following compounds become less stable with respect to their elements as the temperature is raised: (a) $C_3H_6(g)$, cyclopropane; (b) $CaO(s)$; (c`) $N_2O(g)$; (d) $HN_3(g)$?

8.65 Calculate the standard reaction entropy, enthalpy, and Gibbs free energy for each of the following reactions from data found in Appendix 2A:
(a) the decomposition of hydrogen peroxide:
$2\ H_2O_2(l) \longrightarrow 2\ H_2O(l) + O_2(g)$
(b) the preparation of hydrofluoric acid from fluorine and water:
$2\ F_2(g) + 2\ H_2O(l) \longrightarrow 4\ HF(aq) + O_2(g)$

8.66 Calculate the standard reaction entropy, enthalpy, and Gibbs free energy for each of the following reactions from data in Appendix 2A:
(a) the production of "synthesis gas," a low-grade industrial fuel:
$CH_4(g) + H_2O(g) \longrightarrow CO(g) + 3\ H_2(g)$
(b) the thermal decomposition of ammonium nitrate:
$NH_4NO_3(s) \longrightarrow N_2O(g) + 2\ H_2O(g)$

8.67 Assume that $\Delta H°$ and $\Delta S°$ are independent of temperature and use data in Appendix 2A to calculate $\Delta G°$ for each of the

following reactions at 80.°C. Over what temperature range will each reaction be spontaneous under standard conditions?
(a) $B_2O_3(s) + 6\ HF(g) \longrightarrow 2\ BF_3(g) + 3\ H_2O(l)$
(b) $CaC_2(s) + 2\ HCl\ (aq) \longrightarrow CaCl_2\ (aq) + C_2H_2(g)$
(c) $C(s, graphite) \longrightarrow C(s, diamond)$

8.68 Assume that $\Delta H°$ and $\Delta S°$ are independent of temperature and use data in Appendix 2A to calculate $\Delta G°$ for each of the following reactions at 250.°C. Over what temperature range will each reaction be spontaneous under standard conditions?
(a) $HCN(g) + 2\ H_2(g) \longrightarrow CH_3NH_2(g)$
(b) $2\ Cu^+(aq) \longrightarrow Cu(s) + Cu^{2+}(aq)$
(c) $CaCl_2(s) + 2\ HF(g) \longrightarrow CaF_2(s) + 2\ HCl(g)$

8.69 A scientist proposed the following two reactions to produce ethanol, a liquid fuel:

$$C_2H_4(g) + H_2O(g) \longrightarrow CH_3CH_2OH(l) \qquad (A)$$
$$C_2H_6(g) + H_2O(g) \longrightarrow CH_3CH_2OH(l) + H_2(g) \qquad (B)$$

Reaction B is preferred if spontaneous, because $C_2H_6(g)$ is a cheaper starting material than $C_2H_4(g)$. Assume standard-state conditions and determine if either reaction is thermodynamically spontaneous.

8.70 A rocket fuel would be useless if its oxidation were not spontaneous. Although rockets operate under conditions that are far from standard, an initial estimation of the potential of a rocket fuel might assess whether its oxidation at the high temperatures reached in a rocket is spontaneous. A chemist exploring potential fuels for use in space considered using vaporized aluminum chloride in a reaction for which the skeletal equation is

$$AlCl_3(g) + O_2(g) \longrightarrow Al_2O_3(s) + ClO(g)$$

Balance this equation. Then use the following data (which are for 2000 K) to decide whether the fuel is worth further investigation: $\Delta G_f°(AlCl_3, g) = -467\ kJ\cdot mol^{-1}$, $\Delta G_f°(Al_2O_3, s) = -1034\ kJ\cdot mol^{-1}$, $\Delta G_f°(ClO, g) = +75\ kJ\cdot mol^{-1}$.

Impact on Biology

8.71 Coupled reactions are used in organisms to drive important biochemical processes. Individual chemical reactions may be added together to form a net reaction, and the overall reaction Gibbs free energy is the sum of the individual Gibbs free energies of reaction. For example, ATP is the primary molecule that stores and releases energy to drive vital nonspontaneous chemical reactions in our bodies. However, the generation of ATP from ADP is nonspontaneous and must itself be coupled to a spontaneous reaction. This process is called *oxidative phosphorylation* and the reactions are:

(1) $ADP^{3-}(aq) + HPO_4{}^{2-}(aq) + H^+(aq) \longrightarrow ATP^{4-}(aq) + H_2O(l) \qquad \Delta G = +30.5\ kJ$
(2) $NADH(aq) \longrightarrow NAD^+(aq) + H^+(aq) + 2\ e^- \qquad \Delta G = -158.3\ kJ$
(3) $\frac{1}{2}\ O_2(g) + 2\ H^+(aq) + 2\ e^- \longrightarrow H_2O(l) \qquad \Delta G = -61.9\ kJ$

(The reaction Gibbs free energies are for pH = 7 but otherwise standard conditions.) What amount (in moles) of ATP could be formed if all the Gibbs free energy released in the oxidation of 3.00 mol NADH were used to generate ATP?

8.72 For the hydrolysis of acetyl phosphate under the conditions prevailing in the body, $\Delta G = -41\ kJ\cdot mol^{-1}$. If the phosphorylation of acetic acid (the reverse of the hydrolysis of acetyl phosphate) was driven by coupling to the hydrolysis of ATP at pH = 7, what is the minimum amount of ATP molecules (in moles) that would have to be hydrolyzed to form 1.0 mol acetyl phosphate molecules by the phosphorylation of acetic acid? (See Exercise 8.71 for more details.)

Integrated Exercises

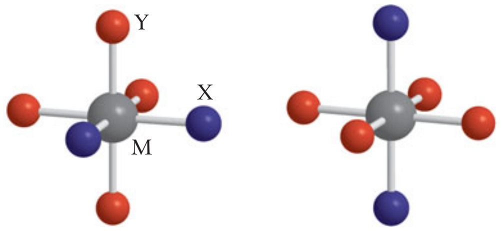
8.73 (a) Which substance would you expect to have the highest molar entropy in the liquid phase, benzene, methanol (CH_3OH), or 1-propanol ($CH_3CH_2CH_2OH$)? (b) Would your answer be different if these substances were in the gas phase?

8.74 (a) Before checking the numbers, which substance would you expect to have the higher standard molar entropy, $CH_3COOH(l)$ or $CH_3COOH(aq)$? Having made this prediction, examine the values in Appendix 2A and explain your findings.

8.75 Under what conditions, if any, does the sign of each of the following quantities provide a criterion for assessing the spontaneity of a reaction? (a) $\Delta G°$; (b) $\Delta H°$; (c) $\Delta S°$; (d) ΔS_{tot}.

8.76 The normal boiling point of methanol is lower than predicted by Trouton's rule. Provide a molecular interpretation for this observation.

8.77 Assuming statistical disorder, would you expect a crystal of octahedral *cis*-MX_2Y_4 to have the same, higher, or lower residual entropy than the corresponding trans isomer? Explain your conclusion.



cis-MX_2Y_4 *trans*-MX_2Y_4

8.78 There are three different substituted benzene compounds with the formula $C_6H_4F_2$. (a) Draw the structures of the three compounds. (b) Assume that the benzene rings pack similarly into their crystal lattices. If the positions of the H and F atoms are statistically disordered in the solid state, which isomer will have the *least* residual molar entropy?

8.79 Suppose that you create two tiny systems consisting of three atoms each, and each atom can accept energy in quanta of the same magnitude. (a) How many distinguishable arrangements are there of two quanta of energy distributed among the three atoms in one of these systems? (b) You now bring the two tiny systems together. How many distinguishable arrangements are there if the two quanta of energy are distributed among the six atoms? (c) In what direction will the energy quanta flow starting from the initial arrangement?

8.80 Suppose that you create two tiny systems consisting of four atoms each, and each atom can accept energy in quanta of the same magnitude. (a) How many distinguishable arrangements are there of two quanta of energy distributed among the four atoms in one of these systems? (b) You now bring the two tiny systems together. How many distinguishable arrangements are there if the two quanta of energy are distributed among the eight atoms? (c) Which state is more disordered, that in part (a) or that in part (b)?

8.81 Consider the enthalpies of fusion and the melting points of the following elements: Pb, 5.10 $kJ\cdot mol^{-1}$, 327°C; Hg, 2.29 $kJ\cdot mol^{-1}$, −39°C; Na, 2.64 $kJ\cdot mol^{-1}$, 98°C. Given these data, determine whether a relation similar to Trouton's rule can be obtained for the entropy of fusion of the metallic elements.

8.82 Determine whether titanium dioxide can be reduced by carbon at 1000. K in each of the following reactions:
(a) $TiO_2(s) + 2\ C(s) \longrightarrow Ti(s) + 2\ CO(g)$
(b) $TiO_2(s) + C(s) \longrightarrow Ti(s) + CO_2(g)$
given that, at 1000. K, $\Delta G_f°(CO, g) = -200.\ kJ\cdot mol^{-1}$, $\Delta G_f°(CO_2, g) = -396\ kJ\cdot mol^{-1}$; and $\Delta G_f°(TiO_2, s) = -762\ kJ\cdot mol^{-1}$.

8.83 Which is the thermodynamically more stable iron oxide in air, $Fe_3O_4(s)$ or $Fe_2O_3(s)$? Justify your selection.

8.84 (a) Calculate the work that must be done at 298.15 K and 1.00 bar against the atmosphere for the production of $CO_2(g)$ and $H_2O(g)$ in the combustion of 8.50 mol $C_6H_6(l)$. Using data in Appendix 2A, calculate the standard enthalpy of the reaction. (c) Calculate the change in internal energy, $\Delta U°$, of the system.

8.85 Hydrogen burns in an atmosphere of bromine gas to give hydrogen bromide gas. (a) What is the standard Gibbs free energy of the reaction $H_2(g) + Br_2(g) \longrightarrow 2\ HBr(g)$ at 298 K? (b) If 120. mL of H_2 gas at STP combines with a stoichiometric amount of bromine and the resulting hydrogen bromide dissolves to form 150. mL of an aqueous solution, what is the molar concentration of the resulting hydrobromic acid?

8.86 Hydrogen reacts with nitrogen gas to form ammonia. (a) What is the standard Gibbs free energy of the reaction $3\ H_2(g) + N_2(g) \longrightarrow 2\ NH_3(g)$ at 298 K? (b) If 50.1 L of H_2 gas at 1 bar and 298 K is added to 15.6 L of N_2, also at 1 bar and 298 K, and the resulting ammonia dissolves to form 2.00 L of an aqueous solution, (a) what amount of ammonia can be formed? (b) What is the molar concentration of the resulting aqueous ammonia solution?

8.87 Potassium nitrate dissolves readily in water, and its enthalpy of solution is +34.9 $kJ\cdot mol^{-1}$. (a) Does the enthalpy of solution favor the dissolving process? (b) Is the entropy change of the system likely to be positive or negative when the salt dissolves? (c) Is the entropy change of the system primarily a result of changes in positional disorder or thermal disorder? (d) Is the entropy change of the surroundings primarily a result of changes in positional disorder or thermal disorder? (e) What is the driving force for the dissolution of KNO_3?

8.88 Explain why each of the following statements is false. (a) Reactions with negative Gibbs free energies of reaction occur spontaneously and rapidly. (b) Every sample of a pure element, regardless of its physical state, is assigned zero Gibbs free energy of formation. (c) An exothermic reaction producing more moles of gas molecules than are consumed has a positive standard reaction Gibbs free energy.

8.89 A common antiseptic used in first aid for cuts and scrapes is a 3% aqueous solution of hydrogen peroxide. The oxygen that bubbles out of the hydrogen peroxide as it is decomposed by enzymes in blood into oxygen and water helps to clean the wound. Two possible industrial routes for the synthesis of hydrogen peroxide are: (i) $H_2(g) + O_2(g) \xrightarrow{\text{Catalyst}} H_2O_2(l)$, which uses either a metal such as palladium or the organic compound quinone as catalyst, and (ii) $2\ H_2O(l) + O_2(g) \longrightarrow 2\ H_2O_2(l)$. (a) At 298 K and 1 atm, which method releases more energy per mole of O_2? (b) Which method has the more negative standard Gibbs free energy? (c) Once hydrogen peroxide has been used at home, can it be regenerated easily from oxygen and water?

8.90 Acetic acid, $CH_3COOH(l)$, could be produced from (a) the reaction of methanol with carbon monoxide; (b) the oxidation of ethanol; (c) the reaction of carbon dioxide with methane. Write balanced chemical equations for each process. Carry out a thermodynamic analysis of the three possibilities and decide which you would expect to be the easiest to accomplish.

8.91 Some entries for $S_m°$ in Appendix 2A are negative. What is common about these entries and why would the entropy be negative?

8.92 According to current theories of biological evolution, complex amino and nucleic acids were produced from randomly occurring reactions of compounds thought to be present in the Earth's early atmosphere. These simple molecules then assembled into more and more complex molecules, such as DNA and RNA. Is this process consistent with the second law of thermodynamics? Explain your answer.

8.93 Using values in Appendix 2A, calculate the standard Gibbs free energy for the vaporization of water at 25.0°C, 100.0°C, and 150.0°C. (b) What should the value at 100.0°C be? (c) Why is there a discrepancy?

8.94 Propose the argument that, for any liquid at atmospheric pressure (that is, a liquid that boils above room temperature when the external pressure is 1 atm), the numerical value of ΔH_{vap} in joules per mole is greater than the numerical value of ΔS_{vap} in joules per kelvin per mole. (Explain and justify each step and any assumptions.)

8.95 The molar entropy of electron spins in a magnetic field B is

$$S = R\left\{\frac{\Delta E/kT}{e^{\Delta E/kT} - 1} - \ln\left(1 - e^{-\Delta E/kT}\right)\right\}$$

where $\Delta E = 2\mu_B B$ is the separation in energy of the two spin states in a magnetic field, μ_B is the Bohr magneton, $\mu_B = 9.274 \times 10^{-24}$ $J\ T^{-1}$. Plot this function against temperature for the following values of B: 0.1 T, 1 T, 10 T, and 100 T. (See Box 8.1. Notice that the unit of magnetic induction, tesla, T, where 1 T = 1 kg s^{-2} A^{-1}, cancels.)

8.96 The populations p of the up and down spin states of electrons in a magnetic field B are given by

$$p_{down} = \frac{1}{1 + e^{-\Delta E/kT}} \quad \text{and} \quad p_{up} = \frac{e^{-\Delta E/kT}}{1 + e^{-\Delta E/kT}}$$

where $\Delta E = 2\mu_B B$ is the energy difference between the two spin states (see Exercise 8.95). Plot these two populations as a function of temperature for B = 1 T. (See Box 8.1.)

8.97 Without doing any calculations, predict what temperature corresponds to equal populations of up and down spin states. (See Exercise 8.96.)

8.98 Suppose it could be arranged for there to be twice as many electrons with up spins than down spins in a sample in a magnetic field. Without doing any calculations, predict the sign of the temperature of such a sample. (See Exercise 8.96.)

8.99 It is helpful in understanding graphs of thermodynamic functions to interpret them in terms of molecular behavior. Consider the plot of the temperature dependence of the standard molar Gibbs free energy of the three phases of a substance in Fig. 8.25. (a) Explain in terms of molecular behavior why the Gibbs free energy of each phase decreases with temperature. (b) Explain in terms of molecular behavior why the Gibbs free energy of the vapor phase decreases more rapidly with temperature than that of the solid or liquid phase.

8.100 Because state functions depend only on the state of the system, when a system undergoes a series of processes that bring it back to the original state, a thermodynamic cycle has been carried out and all the state functions have returned to their original value. However, functions that depend on the path may have changed. (a) Verify that there is no difference in the state function S, for a process in which 1.00 mol of ideal gas molecules in a 3.00-L cylinder at 302 K undergoes the following three steps: (i) cooling at constant volume until $T = 75.6$ K; (ii) heating at constant pressure until $T = 302$ K; (iii) compressing at constant temperature until $V = 3.00$ L. Calculate ΔU and ΔS for this entire cycle. (b) What are the values of q and w for the entire cycle? (c) What are ΔS_{surr} and ΔS_{total} for the cycle? If any values are nonzero, explain how this can be so, despite entropy being a state function. (d) Is the process spontaneous, nonspontaneous, or at equilibrium?

8.101 A technique used to overcome the unfavorable thermodynamics of one reaction is to "couple" that reaction with another process that is thermodynamically favored. For instance, the dehydrogenation of cyclohexane to form benzene and hydrogen gas is not spontaneous. Show that, if another molecule such as ethene is present to act as a hydrogen acceptor (that is, the ethene reacts with the hydrogen produced to form ethane), then the process can be made spontaneous.

8.102 Adenosine triphosphate (ATP) is an extremely important molecule in biological systems. Consult standard reference sources in your library to describe how this molecule is used in energy transfer to facilitate nonspontaneous processes necessary for life.

8.103 Three isomeric alkenes have the formula C_4H_8 (see the following table). (a) Draw Lewis structures of these compounds. (b) Calculate $\Delta G°$, $\Delta H°$, and $\Delta S°$ for the three reactions that interconvert each pair of compounds. (c) Which isomer is the most stable? (d) Rank the isomers in order of decreasing $S_m°$.

Compound	$\Delta H_f°$ ($kJ \cdot mol^{-1}$)	$\Delta G_f°$ ($kJ \cdot mol^{-1}$)
2-methylpropene	−16.90	+58.07
cis-2-butene	−6.99	+65.86
trans-2-butene	−11.17	+62.97

8.104 When a space shuttle re-enters the atmosphere, its temperature rises and it can heat the surrounding air to 1260°C. At that temperature some endothermic reactions take place that at lower temperatures are not spontaneous under standard conditions (pure substances, each at 1 bar). Estimate the temperatures at which the following stratospheric reactions become spontaneous under standard conditions. Which ones could occur during re-entry of the space shuttle? (a) The formation of nitrogen monoxide from nitrogen and oxygen; (b) the formation of ozone from molecular oxygen. *A word of warning:* Because at this stage we have to assume that $\Delta H°$ and $\Delta S°$ are constant over the temperature range and that the conditions are standard (but see Section 8.15), this calculation gives only a very approximate estimate of the temperature at which such reactions are significant in practice.

Chemistry Connections

8.105 Vehicle air bags protect passengers by allowing a chemical reaction to occur that generates gas rapidly. Such a reaction must be both spontaneous and explosively fast. A common reaction is the decomposition of sodium azide, NaN_3, to nitrogen gas and sodium metal.

(a) Write a balanced chemical equation for this reaction using the smallest whole-number coefficients.

(b) Predict the sign of the entropy change for this reaction without doing a calculation. Explain your reasoning.

(c) Determine the oxidation number of nitrogen in the azide ion and in nitrogen gas. Is nitrogen oxidized or reduced in the reaction?

(d) Use the data in Appendix 2A and the fact that, for sodium azide, $S_m° = 96.9\ J \cdot K^{-1} \cdot mol^{-1}$, to calculate $\Delta S°$ at 298 K for the decomposition of sodium azide.

(e) Use your result from part (d) and the fact that, for sodium azide, $\Delta H_f° = +21.7\ kJ \cdot mol^{-1}$, to calculate $\Delta H°$ and $\Delta G°$ at 298 K for the decomposition of sodium azide.

(f) Is the reaction spontaneous at 298 K and a constant pressure of 1 bar?

(g) Can the reaction become nonspontaneous (at a constant pressure of 1 bar) if the temperature is changed? If so, must the temperature be raised or lowered?

THE IMPACT ON BIOLOGY AND MATERIALS
9.21 Colloids
9.22 Bio-based and Biomimetic Materials

What Are the Key Ideas? Dynamic equilibrium between two phases is reached when the rate of conversion between them is the same in each direction. The rates are equal when the molar Gibbs free energy of the substance is the same in each phase and therefore there is no tendency to change in either direction. The same concepts apply to the dissolving of a solute. The presence of a solute alters the entropy of a solvent and consequently affects its thermodynamic properties.

Why Do We Need to Know This Material? In earlier chapters, we investigated the nature of the solid, liquid, and gaseous states of matter; in this chapter, we extend the discussion to transformations between these states. This chapter introduces the concept of equilibrium between different phases of a substance, a concept that will prove to be of the greatest importance for chemical and biochemical transformations. We also take a deeper look at solutions in this chapter. We shall see how the presence of solutes is used by the body to control the flow of nutrients into and out of living cells and how the properties of solutions are used to separate the components of petroleum.

What Do We Need to Know Already? This chapter develops the concepts of physical equilibria introduced in the context of thermodynamics (Chapters 7 and 8) and assumes a knowledge of intermolecular forces (Sections 5.1–5.5). The compositions of some of the solutions discussed are expressed in terms of mole fraction (Section 4.8).

Nearly all the gases, liquids, and solids we encounter in our daily life are mixtures or solutions. In Section 4.8 we considered gaseous mixtures. In this chapter we investigate liquid solutions and see how the solutes dissolved in them affect their physical properties. The largest solutions on Earth are the oceans, which account for 1.4×10^{21} kg of the Earth's surface water. That mass amounts to nearly 2×10^{18} t (1 t = 10^3 kg) of water for each inhabitant, more than enough to supply all the drinking water needed for a thirsty world. However, drinking seawater itself can be fatal, because of the high concentrations of dissolved salts, in particular Na^+ and Cl^- ions (Table 9.1). The transformation of seawater into potable (drinkable) water is a major challenge around the world. This chapter describes one way that this purification can be achieved.

Another solution of great importance to our lives is the plasma that carries the erythrocytes (red blood cells) through our bodies. These cells can cease to function if the concentrations of solutes in the plasma drift from their optimal values. This chapter explains why such changes occur and guides us through building a model that accounts for the behavior of solutions. We begin by examining phase changes in pure substances, then we see how the presence of a solute affects the properties of the substance.

PHASES AND PHASE TRANSITIONS

As we saw in Section 5.1, a single substance can exist in different *phases*, or physical forms. The phases of a substance include its solid, liquid, and gaseous forms. They also include its different solid forms, such as the diamond and graphite phases of carbon. In one case—helium—two liquid phases are known to exist. The conversion of a substance from one phase into another, such as the melting of ice, the vaporization of water, and the conversion of graphite into diamond, is called a **phase transition.**

The unifying concept of this chapter is *equilibrium*. For a given pressure, a substance undergoes a phase transition at a specific temperature, such as the change from solid to liquid at the melting temperature. At this characteristic temperature, the solid and liquid phases of a substance are in equilibrium, at which point there is no change in Gibbs free energy, $\Delta G = 0$, when one phase changes into the other. Thus, even though the entropy of the system would increase if some of it melted or vaporized,

TABLE 9.1 Principal Ions Found in Seawater

Element	Principal form	Concentration ($g \cdot L^{-1}$)
Cl	Cl^-	19.0
Na	Na^+	10.5
Mg	Mg^{2+}	1.35
S	SO_4^{2-}	0.89
Ca	Ca^{2+}	0.40
K	K^+	0.38
Br	Br^-	0.065
C	HCO_3^-, H_2CO_3, CO_2	0.028

there is a compensating reduction in entropy of the surroundings as heat is drawn in from them, and there is no change in the *total* entropy of the system and its surroundings. Likewise, although the entropy of the system would decrease if vapor condensed or liquid froze, there is a compensating increase in the entropy of the surroundings as heat is released into them. In short, there is no thermodynamic driving force in either direction when two phases are in equilibrium.

9.1 Vapor Pressure

A simple experiment can be used to show that, in a closed vessel, the liquid and vapor phases of a substance reach equilibrium with each other. First, we set up a mercury barometer. As we saw in Section 4.2, the mercury inside the tube falls to a height proportional to the external atmospheric pressure, leaving it about 76 cm high at sea level on Earth. The space above the mercury is almost a vacuum (the trace of mercury vapor present is so small that we can ignore it). Now suppose we inject a tiny drop of water into the space above the mercury. All the water added immediately evaporates and fills the space with vapor. The molecules in this vapor push the surface of the mercury down a few millimeters. The pressure exerted by the vapor—as measured by the change in the height of mercury—depends on the amount of water added. However, suppose we add so much water that a little liquid water remains on the surface of the mercury. The pressure of the vapor now remains constant, no matter how much liquid water is present (Fig. 9.1). We conclude that, *at a fixed temperature, as long as some liquid is present, the vapor exerts a characteristic pressure regardless of the amount of liquid water present*. For example, at 20°C, the mercury falls 18 mm, and so the pressure exerted by the water vapor is 18 Torr. The pressure of the water vapor is the same whether there is 0.1 mL or 1 mL of liquid water still present. This characteristic pressure is the "vapor pressure" of the liquid at the temperature of the experiment (Table 9.2).

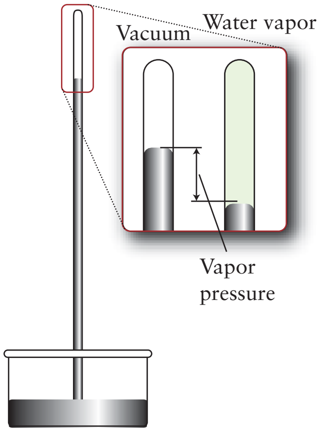

FIGURE 9.1 The apparatus is a mercury barometer. In the closeup, the left-hand column shows the vacuum above the mercury and the right-hand column shows the effect of the addition of a small amount of water. At equilibrium, some of the water has evaporated and the vapor pressure exerted by the water on the mercury has lowered the height of the mercury column. The vapor pressure is the same however much water is present in the column.

Liquids with high vapor pressures at ordinary temperatures are said to be **volatile.** Methanol (vapor pressure 98 Torr at 20°C) is highly volatile; mercury (1.4 mTorr) is not. Solids also exert a vapor pressure, but their vapor pressures are usually much lower than those of liquids because the molecules are gripped more tightly in a solid than they are in a liquid. Nevertheless, some solids vaporize in the process called "sublimation" (Section 7.11), which we can observe in the presence of some pungent solids—such as menthol and mothballs (naphthalene)—even at room temperature.

To build a molecular model of the equilibrium between a liquid and its vapor we first suppose that the liquid is introduced into an evacuated *closed* container. Vapor forms as molecules leave the surface of the liquid. Most evaporation takes place from the surface of the liquid because the molecules there are least strongly bound to their neighbors and can escape more easily than those in the bulk. However, as the number of molecules in the vapor increases, more of them become available to strike the surface of the liquid, stick to it, and become part of the liquid again. Eventually, the number of molecules returning to the liquid each second matches the number escaping (Fig. 9.2). The vapor is now condensing as fast as the liquid is vaporizing, and so the equilibrium is *dynamic* in the sense introduced in Section 8.11:

Rate of evaporation = rate of condensation

The dynamic equilibrium between liquid water and its vapor is denoted

$$H_2O(l) \rightleftharpoons H_2O(g)$$

Whenever we see the symbol $\rightleftharpoons$, it means that the species on both sides of the symbol are in dynamic equilibrium with each other. Although "products" (water molecules in the gas phase) are continually being formed from "reactants" (water molecules in the liquid phase), the products are changing back into reactants at a matching rate. With this picture in mind, we can now define the **vapor pressure** of a liquid (or a solid) as the pressure exerted by its vapor when the vapor and the liquid (or the solid) are in dynamic equilibrium with each other.

The vapor pressure of a substance is the pressure exerted by its vapor when the vapor is in dynamic equilibrium with the condensed phase.

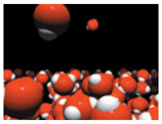
TABLE 9.2 Vapor Pressures at 25°C

Substance	Vapor pressure (Torr)
benzene	94.6
ethanol	58.9
mercury	0.0017
methanol	122.7
water*	23.8

*For values at other temperatures, see Table 9.3.

9.2 Volatility and Intermolecular Forces

We can expect high vapor pressure when the molecules of a liquid are held together by weak intermolecular forces in the liquid and low vapor pressure when the intermolecular forces are strong. We therefore expect compounds capable of forming hydrogen bonds (which are stronger than other types of intermolecular interactions) to be less volatile than other molecular compounds of similar molar mass but unable to form hydrogen bonds. We can see the effect of hydrogen bonding clearly when we compare dimethyl ether (**1**) and ethanol (**2**), which have the same molecular formula, C_2H_6O. Because the two compounds have the same numbers of electrons, we can expect them to have similar London interactions and therefore similar vapor pressures. However, an ethanol molecule has an —OH group and can form a hydrogen bond to another ethanol molecule. Ether molecules cannot form hydrogen bonds to one another because all their hydrogen atoms are attached to carbon atoms and the C—H bond is not very polar. As a result of this difference, ethanol is a liquid at room temperature, whereas dimethyl ether is a gas.



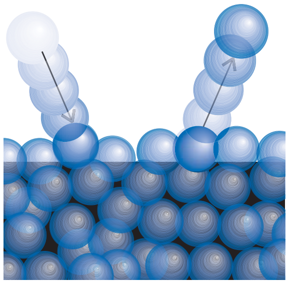


FIGURE 9.2 When a liquid and its vapor are in dynamic equilibrium inside a closed container, the rate of condensation is equal to the rate of evaporation.

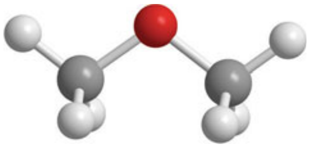
Animation 9.2

Thinking point: Why does mercury have such a low vapor pressure at room temperature?

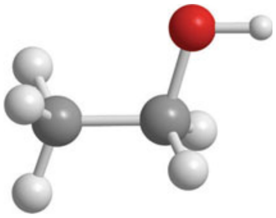
Self-Test 9.1A Which do you expect to have the higher vapor pressure at room temperature, tetrabromomethane, CBr_4, or tetrachloromethane, CCl_4? Give your reasons.

[***Answer:*** CCl_4; weaker London forces]

Self-Test 9.1B Which do you expect to have the higher vapor pressure at 25°C, CH_3CHO or $CH_3CH_2CH_3$?



1 Dimethyl ether



2 Ethanol

The vapor pressure of a liquid at a given temperature is expected to be low and its enthalpy of vaporization high if the forces acting between its molecules are strong.

9.3 The Variation of Vapor Pressure with Temperature

The vapor pressure of a liquid depends on how readily the molecules in the liquid can escape from the forces that hold them together. More energy to overcome these attractions is available at higher temperatures than at low, and so we can expect the vapor pressure of a liquid to rise with increasing temperature. Table 9.3 shows the temperature dependence of the vapor pressure of water and Fig. 9.3 shows how the vapor pressures of several liquids rise as the temperature increases. The data in the plot show the dependence of vapor pressure on the strengths of intermolecular forces. The compounds in the graph that can form hydrogen bonds (water and ethanol) have lower vapor pressures than diethyl ether.

We can use the thermodynamic relations introduced in Chapter 8 to find an expression for the temperature dependence of vapor pressure and trace it to the role of intermolecular forces.

TABLE 9.3 Vapor Pressure of Water

Temperature (°C)	Vapor pressure (Torr)
0	4.58
10	9.21
20	17.54
21	18.65
22	19.83
23	21.07
24	22.38
25	23.76
30	31.83
37*	47.08
40	55.34
60	149.44
80	355.26
100	760.00

*Body temperature.

HOW DO WE DO THAT?

To find how vapor pressure changes with temperature we make use of the fact that, when a liquid and its vapor are in equilibrium, there is no difference in the molar Gibbs free energies of the two phases:

$$\Delta G_{vap} = G_m(g) - G_m(l) = 0$$

The Gibbs free energy of a liquid is almost independent of pressure, and so we can replace $G_m(l)$ by its standard value (its value at 1 bar), $G_m°(l)$. To derive the pressure dependence for a gas we recall that $G = H - TS$, and therefore

$$G(g, P) - G_m°(g) = H_m(g, P) - H_m°(g) - T\{S_m(g, P) - S_m°(g)\}$$

The enthalpy of an ideal gas is independent of pressure at constant temperature, so the first two terms on the right cancel. In Chapter 8 we derived the relation (recall Eq. 3b in Chapter 8)

$$S_m(g, P_2) - S_m(g, P_1) = R \ln(P_1/P_2)$$

Therefore, by setting $P_1 = P$ and $P_2 = P°$,

$$-T\{S_m(g, P) - S_m°(g)\} = RT \ln(P/P°)$$

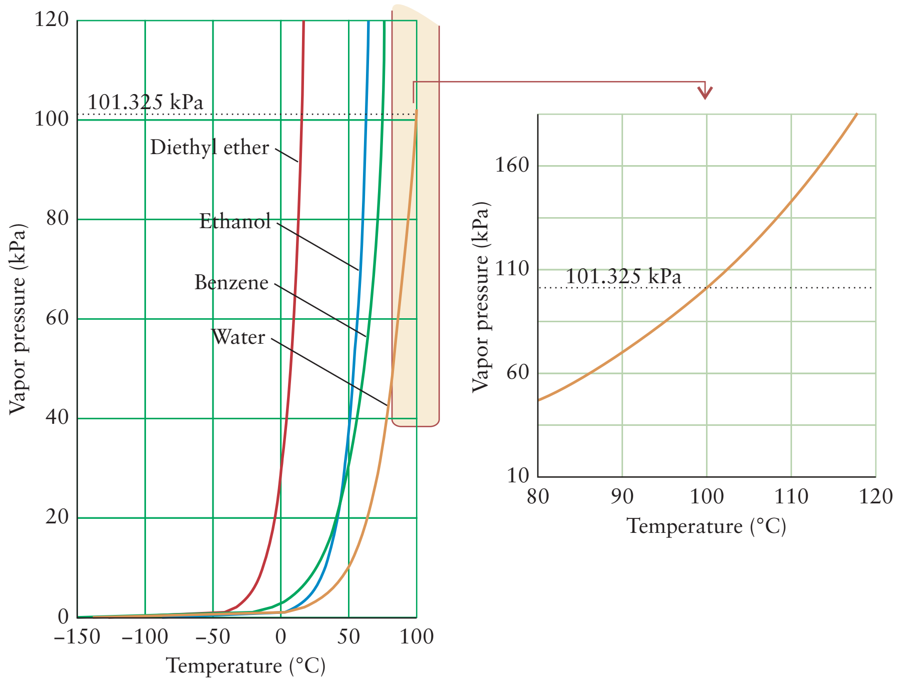


FIGURE 9.3 The vapor pressures of liquids increase sharply with temperature, as shown here for diethyl ether (red), ethanol (blue), benzene (green), and water (orange). The normal boiling point is the temperature at which the vapor pressure is 1 atm (101.325 kPa). Notice that the curve for ethanol, which has a higher enthalpy of vaporization than benzene, rises more steeply than that of benzene, as predicted by the Clausius–Clapeyron equation. The diagram on the right shows the vapor pressure of water close to its normal boiling point in more detail.

It follows that, for an ideal gas,

$$G_m(g, P) = G_m°(g) + RT \ln(P/P°)$$

where P is the pressure, $P°$ is the standard pressure (1 bar), and $G_m°$ is the standard molar Gibbs free energy of the gas (its value at 1 bar). This pressure dependence is illustrated in Fig. 9.4. It follows that when the pressure P is the vapor pressure of the liquid,

$$\Delta G_{vap} = \{G_m°(g) + RT \ln(P/P°)\} - G_m°(l) = \{G_m°(g) - G_m°(l)\} + RT \ln(P/P°)$$
$$= \Delta G_{vap}° + RT \ln(P/P°)$$

$\Delta G_{vap}°$ is the **standard Gibbs free energy of vaporization,** the change in molar Gibbs free energy when a liquid at 1 bar changes into a vapor at 1 bar. At equilibrium, $\Delta G_{vap} = 0$, and so

$$0 = \Delta G_{vap}° + RT \ln(P/P°)$$

It follows that

$$\ln(P/P°) = -\frac{\Delta G_{vap}°}{RT}$$

At this point we can use $\Delta G_{vap}° = \Delta H_{vap}° - T\Delta S_{vap}°$, where $\Delta H_{vap}°$ and $\Delta S_{vap}°$ are the standard enthalpy and entropy of vaporization, respectively, and obtain

$$\ln(P/P°) = -\frac{\Delta H_{vap}° - T\Delta S_{vap}°}{RT} = -\frac{\Delta H_{vap}°}{RT} + \frac{\Delta S_{vap}°}{R}$$

Neither the enthalpy nor the entropy of vaporization varies much with temperature; so, for a given substance, $\Delta S_{vap}°$ and $\Delta H_{vap}°$ can both be treated as approximately constant. It follows that the vapor pressures P_1 and P_2 at any two temperatures T_1 and T_2 are related by writing this equation for two temperatures and subtracting one from the other. In the process, the entropy terms cancel:

$$\ln(P_2/P°) - \ln(P_1/P°) = \left(-\frac{\Delta H_{vap}°}{RT_2} + \frac{\Delta S_{vap}°}{R}\right) - \left(-\frac{\Delta H_{vap}°}{RT_1} + \frac{\Delta S_{vap}°}{R}\right)$$
$$= \frac{\Delta H_{vap}°}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

We can also make use of the fact that $\ln x - \ln y = \ln(x/y)$ to write the left hand side of this expression as $\ln(P_2/P_1)$.

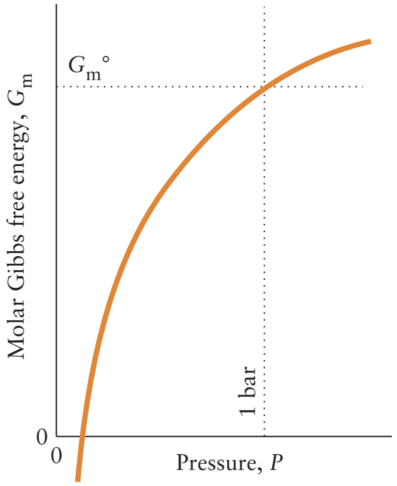

FIGURE 9.4 The variation of the molar Gibbs free energy of an ideal gas with pressure. The Gibbs free energy has its standard value when the pressure of the gas is 1 bar. The value of the Gibbs free energy approaches minus infinity as the pressure falls to zero.

We have deduced the **Clausius–Clapeyron equation** for the vapor pressure of a liquid at two different temperatures:

$$\ln\frac{P_2}{P_1} = \frac{\Delta H_{vap}°}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \qquad \textbf{(1)*}$$

What does this equation tell us? When $T_2 > T_1$, the term in parentheses is positive, and because the enthalpy of vaporization is positive, $\ln(P_2/P_1)$ is positive too and we can conclude that P_2 is greater than P_1. In other words, the equation tells us that the vapor pressure increases with increasing temperature. Because $\Delta H_{vap}°$ occurs in the numerator, the increase is greatest for substances with high enthalpies of vaporization (strong intermolecular interactions).

EXAMPLE 9.1 Estimating the vapor pressure of a liquid from its value at a different temperature

Tetrachloromethane, CCl_4, which is now known to be carcinogenic, was once used as a dry-cleaning solvent. The enthalpy of vaporization of CCl_4 is 33.05 $kJ\cdot mol^{-1}$ and its vapor pressure at 57.8°C is 405 Torr. What is the vapor pressure of tetrachloromethane at 25.0°C?

Anticipate Vapor pressure increases with temperature because the molecules have more energy to escape from their neighbors, so we should expect the vapor pressure of CCl_4 to be lower at 25.0°C than at 57.8°C. We therefore expect a vapor pressure of less than 405 Torr.

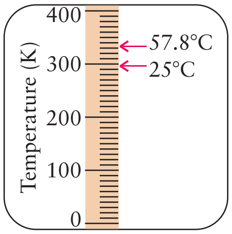
PLAN Substitute the temperatures and the enthalpy of vaporization into the Clausius–Clapeyron equation to find the ratio of vapor pressures. Then substitute the known vapor pressure to find the desired one. To use the equation, convert the enthalpy of vaporization into joules per mole and express all temperatures in kelvins.

What should we assume? That $\Delta H_{vap}°$ is constant over the temperature range of interest and that the vapor behaves as an ideal gas (so that the Clausius–Clapeyron equation is applicable).

SOLVE Note that $\Delta H_{vap}° = 33.05\ kJ\cdot mol^{-1}$ corresponds to $3.305 \times 10^4\ J\cdot mol^{-1}$.

Convert temperatures to kelvins.

$$T_1 = 57.8 + 273.15\ K = 331.0\ K$$
$$T_2 = 25.0 + 273.15\ K = 298.2\ K$$



From $\ln(P_2/P_1) = (\Delta H_{vap}°/R)\ (1/T_1 - 1/T_2)$,

$$\ln\frac{P_2}{P_1} = \frac{3.305 \times 10^4\ J\cdot mol^{-1}}{8.3145\ J\cdot K^{-1}\cdot mol^{-1}}\left(\frac{1}{331.0\ K} - \frac{1}{298.2\ K}\right)$$

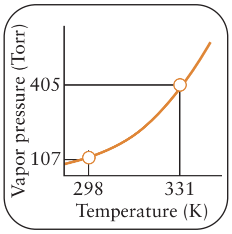
$$= \frac{3.305 \times 10^4}{8.3145}\left(\frac{1}{331.0} - \frac{1}{298.2}\right)$$

(This expression evaluates to −1.33.)

Solve for P_2 by taking the exponential (e^x) of both sides and using P_1 = 405 Torr.

$$P_2 = P_1 e^{\frac{\Delta H_{vap}°}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)}$$

$$P_2 = (405\ Torr) \times e^{\frac{3.305\times10^4}{8.3145}\left(\frac{1}{331.0} - \frac{1}{298.2}\right)} = 107\ Torr$$



Evaluate As expected, the vapor pressure at 25°C, 107 Torr, is lower than its value at 57.8°C (405 Torr).

A note on good practice: Exponential functions are very sensitive to rounding errors, so it is important to carry out the numerical calculation in one step. A common error is to forget to express the enthalpy of vaporization in joules (not kilojoules) per mole, but keeping track of units will help you to avoid that mistake.

Self-Test 9.2A The vapor pressure of water at 25°C is 23.76 Torr and its standard enthalpy of vaporization at that temperature is 44.0 $kJ\cdot mol^{-1}$. Estimate the vapor pressure of water at 35°C.

[*Answer:* 42 Torr]

Self-Test 9.2B The vapor pressure of benzene at 25°C is 94.6 Torr and its standard enthalpy of vaporization is 30.8 $kJ\cdot mol^{-1}$. Estimate the vapor pressure of benzene at 35°C.

The vapor pressure of a liquid increases as the temperature increases. The Clausius–Clapeyron equation gives the quantitative dependence of the vapor pressure of a liquid on temperature.

9.4 Boiling

Now consider what happens when we heat a liquid in a container that is open to the atmosphere—water heated in a kettle is an example. When the temperature is raised to the point at which the vapor pressure is equal to the atmospheric pressure (for instance, when water is heated to 100°C and the external pressure is 1 atm), vaporization occurs *throughout* the liquid, not just from its surface, and the liquid boils. At the boiling temperature any vapor formed can drive back the atmosphere and make room for itself. Thus, bubbles of vapor form in the liquid and rise rapidly to the surface. As described in Section 8.4, the normal boiling point, T_b, of a liquid is the temperature at which a liquid boils when the external pressure is 1 atm. In other words, *the normal boiling point is the temperature at which the vapor pressure of the liquid is 1 atm*. To find the normal boiling points of the compounds in Fig. 9.3, we draw a horizontal line at $P = 1$ atm (101.325 kPa) and note the temperatures at which it intersects the curves.

Thinking point: Can a liquid boil in a sealed container?

Boiling occurs at a temperature higher than the normal boiling point when the pressure is greater than 1 atm, as it is in a pressure cooker. In this case, a higher temperature is needed to raise the vapor pressure of the liquid to the higher pressure. Boiling occurs at a lower temperature when the pressure is less than 1 atm, because now the vapor pressure matches the external pressure at a lower temperature. At the summit of Mt. Everest—where the pressure is about 240 Torr—water boils at only 70°C.

The lower the vapor pressure at room temperature, the higher the boiling point. Therefore, a high normal boiling point is a sign of strong intermolecular forces.

EXAMPLE 9.2 Estimating the boiling point of a liquid

The vapor pressure of ethanol at 34.9°C is 13.3 kPa. Use the data in Table 7.3 to estimate the normal boiling point of ethanol.

Anticipate There is less hydrogen bonding between ethanol molecules than between H_2O molecules, so we should expect the boiling point of ethanol to be lower than that of water even though its molar mass is greater.

PLAN Use the Clausius–Clapeyron equation to find the temperature at which the vapor pressure has risen to 1 atm (101.325 kPa).

What should we assume? That $\Delta H_{vap}°$ is constant over the temperature range of interest and that the vapor behaves as an ideal gas (so that the Clausius–Clapeyron equation is applicable).

SOLVE From Table 7.3, $\Delta H_{vap}° = 43.5\ kJ\cdot mol^{-1}$ $(= 4.35 \times 10^4\ J\cdot mol^{-1})$.

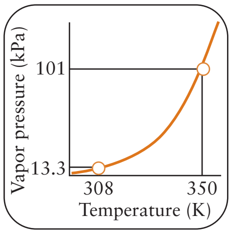
Convert the given temperature to kelvins.

$$T_2 = 34.9 + 273.15\ K = 308.0\ K$$

Record the values of the pressure at the two temperatures.

$P_1 = 101.325 \text{ kPa}, P_2 = 13.3 \text{ kPa}$

Rearrange the Clausius–Clapeyron equation to $1/T_1 = 1/T_2 + (R/\Delta H_{vap}°) \ln(P_2/P_1)$ and substitute the data.



$$\frac{1}{T_1} = \frac{1}{308.0 \text{ K}} + \frac{8.3145 \text{ J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}}{4.35 \times 10^4 \text{ J}\cdot\text{mol}^{-1}} \ln \frac{13.3 \text{ kPa}}{101.325 \text{ kPa}}$$

$$= \frac{1}{308.0 \text{ K}} + \frac{8.3145}{4.35 \times 10^4 \text{ K}} \ln \frac{13.3}{101.325} = \frac{1}{350. \text{ K}}$$

Take the reciprocal of the result to obtain T_1.

$T_1 = 350. \text{ K}$

Evaluate The calculated boiling point corresponds to 77°C (lower than the 100°C of water, as we anticipated); the experimental value is 78°C. The small error probably comes from assuming that the enthalpy of vaporization is a constant over the temperature range of the question and assuming that the vapor behaves as an ideal gas.

Self-Test 9.3A The vapor pressure of acetone, C_3H_6O, at 7.7°C is 13.3 kPa, and its enthalpy of vaporization is 29.1 kJ·mol^{-1}. Estimate the normal boiling point of acetone.

[***Answer:*** 62.3°C (actual: 56.2°C)]

Self-Test 9.3B The vapor pressure of methanol, CH_3OH, at 49.9°C is 400. Torr, and its enthalpy of vaporization is 35.3 kJ·mol^{-1}. Estimate the normal boiling point of methanol.

Boiling occurs when the vapor pressure of a liquid is equal to the external (atmospheric) pressure. Strong intermolecular forces usually lead to high normal boiling points.

9.5 Freezing and Melting

A liquid solidifies (freezes) when its molecules have such low energies that they are unable to wriggle past their neighbors. In the solid, the molecules vibrate about their average positions but rarely move from place to place. The **freezing temperature,** the temperature at which the solid and liquid phases are in dynamic equilibrium, varies slightly as the pressure is changed, and the **normal freezing point,** T_f, of a liquid is the temperature at which it freezes at 1 atm. In practice, a liquid sometimes does not freeze until the temperature is a few degrees below its freezing point. A liquid that survives below its freezing point is said to be **supercooled.** As described in Section 8.4, the normal melting point of a solid is the temperature at which it melts at 1 atm. The **melting temperature** of a solid is the same as the freezing temperature of the liquid.

For most substances, the density of the solid phase of a substance is greater than that of the liquid phase, because the molecules pack together more closely in the solid phase. Applied pressure helps to hold the molecules together, and so a high temperature must be reached before the molecules of a solid at high pressure can break apart. As a result, most solids melt at higher temperatures when subjected to pressure. However, except at very high pressures, the effect of pressure is usually quite small. Iron at 1 atm, for example, melts at 1800 K, but it melts at only a few degrees higher when the pressure is a thousand times as great. At the center of the Earth, however, the pressure is high enough for iron to be solid despite the high temperatures there, so the Earth's inner core is believed to be solid.

Water is highly unusual in that at 0°C the density of the liquid is greater than that of ice. We already know this fact from a common observation: ice floats on water. Therefore, at the melting point, the molar volume of liquid water is less than that of ice. This anomalous behavior is due to the hydrogen bonds in ice, which result in a very open structure (Fig. 9.5; also see Section 5.10). When ice melts, many of the hydrogen bonds collapse, thereby allowing the water molecules to pack together more closely. As

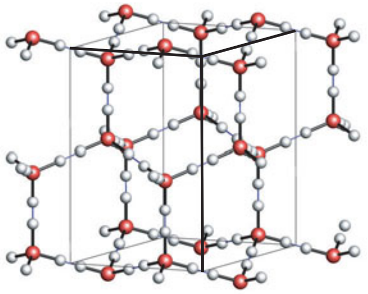


FIGURE 9.5 The structure of ice; notice how the hydrogen bonds, which are strongest when the hydrogen atom is directly between two oxygen atoms, hold the water molecules apart from one another in a hexagonal array. The two gray spheres between the oxygen atoms indicate the two possible locations of the hydrogen atom in that region of the structure. Only one of the positions is occupied.

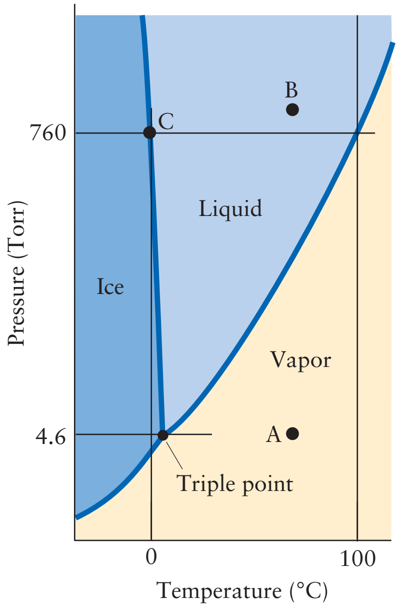

FIGURE 9.6 The phase diagram for water (not to scale). The heavy blue lines define the boundaries of the regions of pressure and temperature at which each phase is the most stable. Note that the freezing point decreases slightly with increasing pressure. The triple point is the point at which three phase boundaries meet. The letters A and B are referred to in Example 9.3.

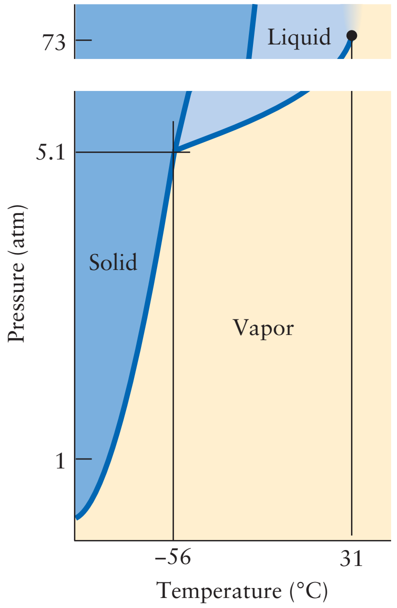

FIGURE 9.7 The phase diagram for carbon dioxide (not to scale). The liquid can exist only at pressures above 5.1 atm. Note the slope of the boundary between the solid and liquid phases; it shows that the freezing point rises as pressure is applied. This characteristic implies that the liquid is less dense than the solid.

a result, high pressure encourages the formation of the denser liquid and the melting point of ice decreases as the pressure is increased.

The melting points of most liquids increase with pressure. Water's hydrogen bonds make it anomalous: its melting point decreases with pressure.

9.6 Phase Diagrams

A **phase diagram** is a map that shows which phase is the most stable at different pressures and temperatures. The phase diagram for water is shown in Fig. 9.6, and that for carbon dioxide is shown in Fig. 9.7. These graphs are examples of phase diagrams for a single substance (water or carbon dioxide) and hence are known as **one-component phase diagrams.** Any point in the region marked "solid" (or, specifically, "ice" for water) corresponds to conditions for which the solid phase of the substance is the most stable; similarly, the regions marked "liquid" and "vapor" (or "gas") indicate the conditions under which liquid and vapor, respectively, are the most stable phase. We can see from the phase diagram for carbon dioxide, for instance, that a sample of carbon dioxide at 10°C and 2 atm will be a gas but, if the pressure is increased at constant temperature to 10 atm, then carbon dioxide will condense to a liquid. Sulfur has two solid phases (Fig. 9.8), rhombic and monoclinic, corresponding to the two ways in which its crown-like S_8 molecules can stack together. Many substances have several solid phases: even water forms at least ten kinds of ice, depending on how the H_2O molecules fit together, but only one of them is stable at ordinary pressures (Fig. 9.9). Ice-VIII, for instance, is stable only above 20 000 atm and 100°C.

The lines separating the regions in a phase diagram are called **phase boundaries.** At any point on a boundary between two regions, the two neighboring phases coexist in dynamic equilibrium. If one of the phases is a vapor, the pressure corresponding to this equilibrium is just the vapor pressure of the substance. Therefore, the liquid–vapor phase boundary shows how the vapor pressure of the liquid varies with temperature. For example, the point at 80.°C and 0.47 atm in the phase diagram for water lies on the phase boundary between liquid and vapor (Fig. 9.10), and so we know that the vapor pressure of water at 80.°C is 0.47 atm. Similarly, the solid–vapor phase boundary shows how the vapor pressure of the solid varies with temperature (see Fig. 9.6).

The solid–liquid boundary, the almost vertical line in Figs. 9.6 and 9.10, shows the pressures and temperatures at which solid and liquid water coexist in equilibrium. In other words, it shows how the melting temperature of ice (or the freezing temperature of water) varies with pressure. The steepness of the lines indicates that even large changes in pressure result in only small variations in melting temperature. The slope of the solid–liquid boundary reveals the relative densities of solid and liquid. A negative slope, such as that in the phase diagram for water (Fig. 9.6), implies that the liquid is the denser phase. Notice that as we increase the pressure of ice, it will eventually be converted to liquid. If the slope is positive, as for carbon dioxide (Fig. 9.7), then the solid is the denser phase and if we increase the pressure on liquid carbon dioxide, it will solidify.

Self-Test 9.4A A given metal melts at 1650 K at 1 atm and at 1700 K at 100 atm. Predict which phase of this metal is more dense, the solid or liquid. Explain your conclusion.

[***Answer:*** The solid, because the solid–liquid boundary slopes to the right, showing that the solid is the stable phase at higher pressures.]

Self-Test 9.4B From the phase diagram for sulfur (Fig. 9.8), predict which phase is more dense, liquid sulfur or monoclinic sulfur. Explain your conclusion.

A **triple point** is a point where three phase boundaries meet on a phase diagram. For water, the triple point for the solid, liquid, and vapor phases lies at 4.6 Torr and 0.01°C (see Fig. 9.6). At this triple point, all three phases (ice, liquid, and vapor) coexist in

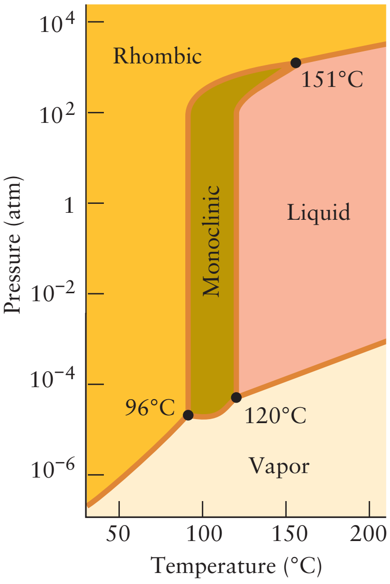

FIGURE 9.8 The phase diagram for sulfur. Notice that there are two solid phases and three triple points. The pressure scale, which is logarithmic, covers a very wide range of values.

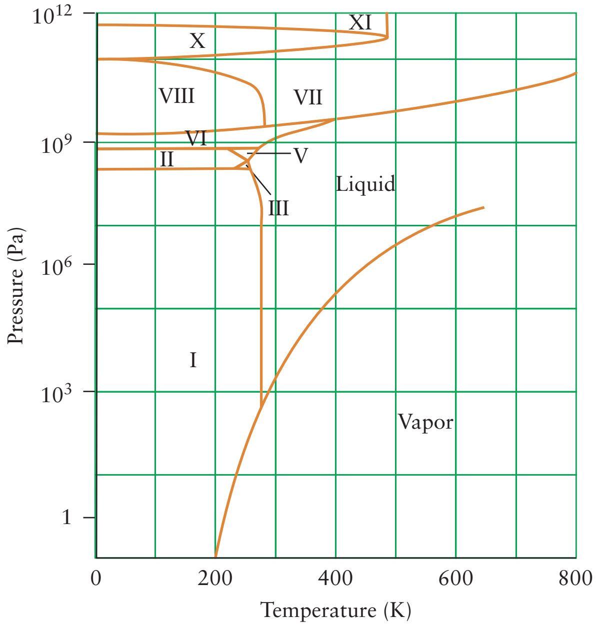

FIGURE 9.9 The phase diagram for water drawn with a logarithmic scale for pressure, in order to show the different solid phases of water in the high-pressure region.

mutual dynamic equilibrium: solid is in equilibrium with liquid, liquid with vapor, and vapor with solid. The location of a triple point of a substance is a fixed property of that substance and cannot be changed by changing the conditions. The triple point of water is used to define the size of the kelvin: by definition, there are exactly 273.16 kelvins between absolute zero and the triple point of water. Because the normal freezing point of water is found to lie 0.01 K below the triple point, 0°C (strictly, 0.00°C) corresponds to 273.15 K.

In Fig. 9.8, we see that sulfur can exist in any of four phases: two solid phases (rhombic and monoclinic sulfur), one liquid phase, and one vapor phase. There are three triple points in the diagram, where various combinations of these phases, such as monoclinic solid, liquid, and vapor or monoclinic solid, rhombic solid, and liquid, coexist. However, four phases in mutual equilibrium (such as the vapor, liquid, and rhombic and monoclinic solid forms of sulfur, all in mutual equilibrium) in a one–component system has never been observed, and thermodynamics can be used to prove that such a "quadruple point" cannot exist.

A phase diagram can be used to explain the changes that take place when the pressure or temperature of a substance is changed. Imagine that we have a sample of water in a cylinder fitted with a piston, that the temperature is constant at 50°C, and that the weights on the piston exert a pressure of 1.0 atm (Fig. 9.11). The piston presses on the surface of the liquid, as in Fig. 9.11a. Now we gradually reduce the pressure by removing some of the weights (Fig. 9.11b). At first, nothing seems to happen. The high pressure is keeping all the water molecules in the liquid state, and the volume of a liquid changes very little with pressure. However, when so many weights have been removed that the pressure has fallen to 0.12 atm (93 Torr, the vapor pressure of water at that temperature), vapor begins to appear (Fig. 9.11c). We are now at the vapor–liquid boundary on the phase diagram. The pressure remains constant so long as the liquid and vapor phases are both present at equilibrium. We are free to pull the piston up by an arbitrary extent (Fig. 9.11d), but enough water will evaporate to maintain the pressure at 0.12 atm. When we pull the piston out far enough, the liquid phase disappears (Fig. 9.11e); we are now free to modify the pressure of the vapor at will without changing the temperature (Fig. 9.11f).

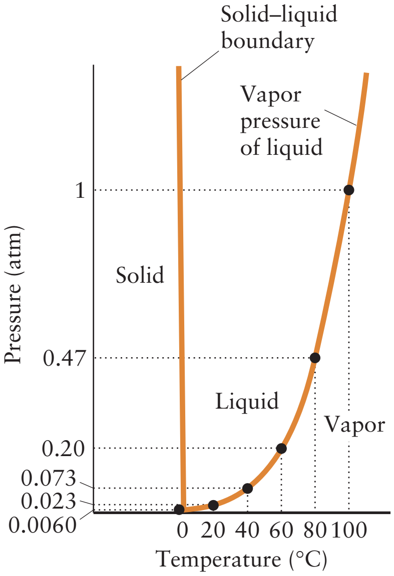

FIGURE 9.10 The liquid–vapor boundary curve is a plot of the vapor pressure of the liquid (in this case, water) as a function of temperature. The liquid and its vapor are in equilibrium at each point on the curve. At each point on the solid–liquid boundary curve (for which the slope is slightly exaggerated), the solid and liquid are in equilibrium.

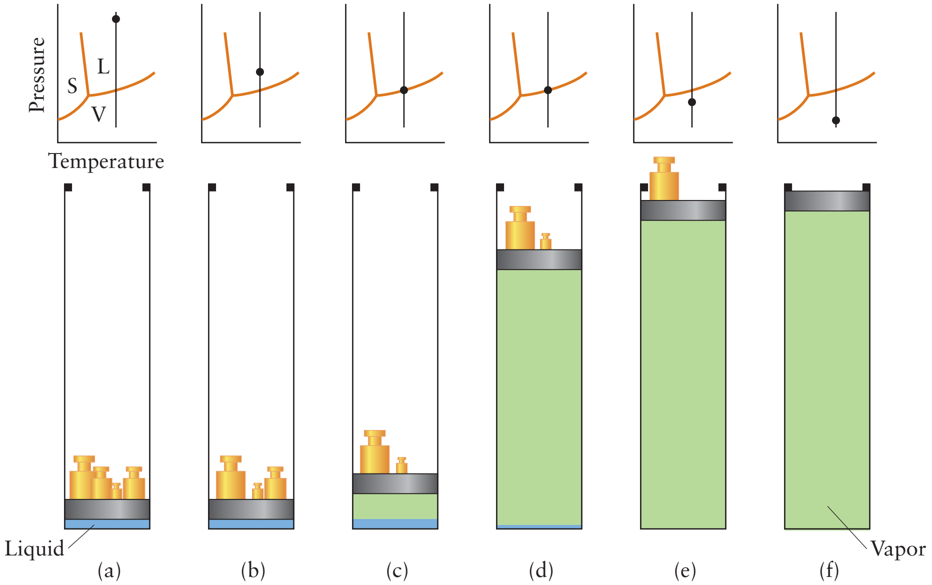

FIGURE 9.11 The changes undergone by a liquid as its pressure is decreased at constant temperature. The large dot on the vertical line in the phase diagram traces the path taken by the system, which is described in the text. The blue region in the container is the liquid and the light green region above it is the vapor.

EXAMPLE 9.3 Interpreting a phase diagram

Use the phase diagram in Fig. 9.6 to describe the physical states and phase changes of water as the pressure on it is increased from 5 Torr to 800 Torr at 70°C.

Anticipate Because the pressure is increasing, we should expect the vapor to condense.

PLAN First, locate the initial and final conditions on the phase diagram. The region in which each of these points lie shows the stable phase of the sample under those conditions. If a point lies on one of the curves, then both phases are present in mutual equilibrium.

SOLVE Although the phase diagram in Fig. 9.6 is not to scale, we can find the approximate locations of the points. Point A is at 5 Torr and 70°C; so it lies in the vapor region. Increasing the pressure takes the vapor to the liquid–vapor phase boundary, at which point liquid begins to form. At this pressure, liquid and vapor are in equilibrium and the pressure remains constant until all the vapor has condensed. The pressure is increased further to 800 Torr, which takes it to point B, in the liquid region.

Evaluate As expected, the vapor condenses.

Self-Test 9.5A The phase diagram for carbon dioxide is shown in Fig. 9.7. Describe the physical states and phase changes of carbon dioxide as it is heated at 2 atm from −155°C to 25°C.

[***Answer:*** Solid CO_2 is heated until it begins to sublime at the solid–vapor boundary. The temperature remains constant until all the CO_2 has vaporized. The vapor is then heated to 25°C.]

Self-Test 9.5B Describe what happens when liquid carbon dioxide in a container at 60 atm and 25°C is released into a room at 1 atm and the same temperature.

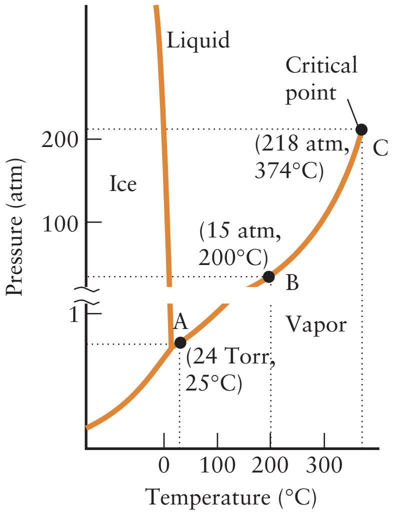

FIGURE 9.12 A version of the phase diagram for water with more detail close to the critical point. Pressures are in atmospheres, except for point A.

A phase diagram summarizes the regions of pressure and temperature at which each phase of a substance is most stable. The phase boundaries show the conditions under which two phases can coexist in dynamic equilibrium with each other. Three phases coexist in mutual equilibrium at a triple point.

9.7 Critical Properties

A feature of the phase diagram in Fig. 9.12 is that the liquid–vapor boundary comes to an end at point C. To see what happens at that point, suppose that a vessel like the one shown in Fig. 9.13 contains liquid water and water vapor at 25°C and 24 Torr (the

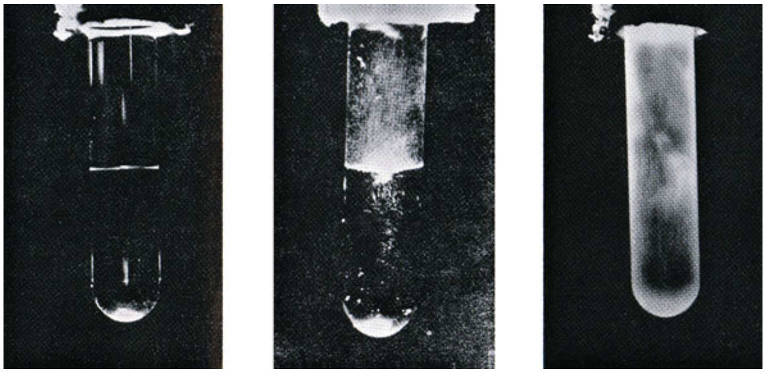

FIGURE 9.13 When the temperature of a liquid in a sealed, constant-volume container (left) is raised, the density of the liquid decreases and the density of the vapor increases (center). At the critical temperature, T_c, the density of the vapor becomes the same as the density of the liquid; at and above that temperature, a single uniform phase fills the container (right).

vapor pressure of water at 25°C). The two phases are in equilibrium, and the system lies at point A on the liquid–vapor curve in Fig. 9.12. Now let's raise the temperature, which moves the system from left to right along the phase boundary. At 100.°C, the vapor pressure is 760. Torr; and, at 200.°C, it has reached 11.7 kTorr (15.4 atm, point B). The liquid and vapor are still in dynamic equilibrium, but now the vapor is very dense because the pressure is so great.

When the temperature has been increased to 374°C (point C), the vapor pressure has reached 218 atm—the container must be very strong! The density of the vapor is now so great that it is equal to that of the remaining liquid. At this stage, the surface separating the liquid from its vapor vanishes and a single uniform phase fills the container. Because a substance that fills any container that it occupies is by definition a gas, we have to conclude that this single uniform phase is a gas, despite its high density (we shall see in a moment that a better term is "supercritical fluid"). Provided the temperature is at 374°C or above, it is found that even if the pressure is increased by compressing the sample, no surface appears. That is, 374°C is the **critical temperature,** T_c, of water, the temperature at and above which there can be no transition from vapor to liquid. Similar considerations apply to other substances (Table 9.4); for instance, the critical temperature of carbon dioxide is 31°C; at this temperature and above CO_2 gas will not condense to a liquid whatever the pressure. The pressure corresponding to the end of the liquid–vapor phase boundary is called the **critical pressure,** P_c, of the substance. The critical pressure of water is 218 atm; that of carbon dioxide is 73 atm. The critical temperature and critical pressure jointly define the **critical point** of the substance.

A note on good practice: We can now be more specific about when to call a gaseous phase a vapor. A "vapor" is the gaseous phase of a substance that is below its critical temperature.

A gas can be liquefied by applying pressure only if it is below its critical temperature (Fig. 9.14). For example, carbon dioxide can be liquefied by applying pressure only if its temperature is lower than 31°C. According to Table 9.4, the critical temperature of oxygen is –118°C, and so we know that it cannot exist as a liquid at room temperature whatever the pressure.

The dense fluid that exists above the critical temperature and pressure of a substance is called a **supercritical fluid.** It may be so dense that, although it is formally a gas, it is as dense as a liquid phase and can act as a solvent for liquids and solids. There is currently considerable interest in supercritical fluids as solvents for chemical reactions, as they are an important aspect of green chemistry. The use of supercritical carbon dioxide avoids contamination with potentially harmful solvents and allows rapid extraction on account of the high mobility of the molecules through the fluid. For example, because supercritical carbon dioxide can dissolve organic compounds it is used to remove caffeine from coffee beans, to separate drugs from biological fluids for later analysis, and to extract perfumes from flowers and phytochemicals from herbs. Supercritical hydrocarbons are used to extract useful compounds from coal and fly ash

TABLE 9.4 Critical Temperatures and Pressures of Selected Substances

Substance	Critical temperature (°C)	Critical pressure (atm)
He	–268 (5.2 K)	2.3
Ne	–229	27
Ar	–123	48
Kr	–64	54
Xe	17	58
H_2	–240	13
O_2	–118	50
H_2O	374	218
N_2	–147	34
NH_3	132	111
CO_2	31	73
CH_4	–83	46
C_6H_6	289	49

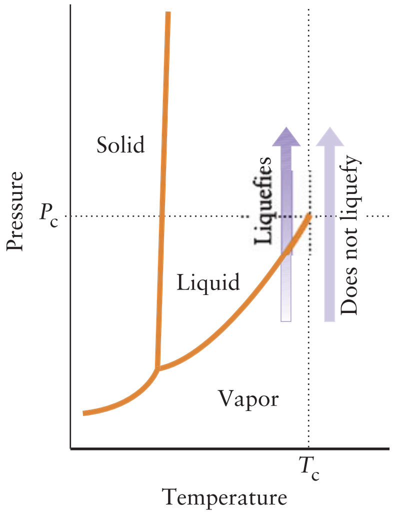

FIGURE 9.14 When pressure is applied to a vapor below its critical temperature, the vapor may be liquefied. However, if the temperature is above the critical temperature (the vertical dotted line), an increase in pressure does not take the vapor into the liquid region. At high pressures above its critical temperature, the substance becomes a supercritical fluid.

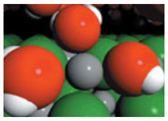

and a variety of supercritical fluids are being investigated for recovering petroleum from oil-rich tar sands.

Thinking point: What might be some disadvantages of using supercritical fluids for solvent extraction?

Self-Test 9.6A Identify trends in the data in Table 9.4 that indicate the relationship of the strength of London forces to the critical temperature.

[*Answer:* Noble gases have higher critical temperatures as their atomic number increases; so critical temperature increases with the strength of London forces.]

Self-Test 9.6B Identify trends in the data in Table 9.4 that indicate the effect of hydrogen bonding on the critical temperature.

The vapor of a substance can be condensed to a liquid by the application of pressure only if it is below its critical temperature.

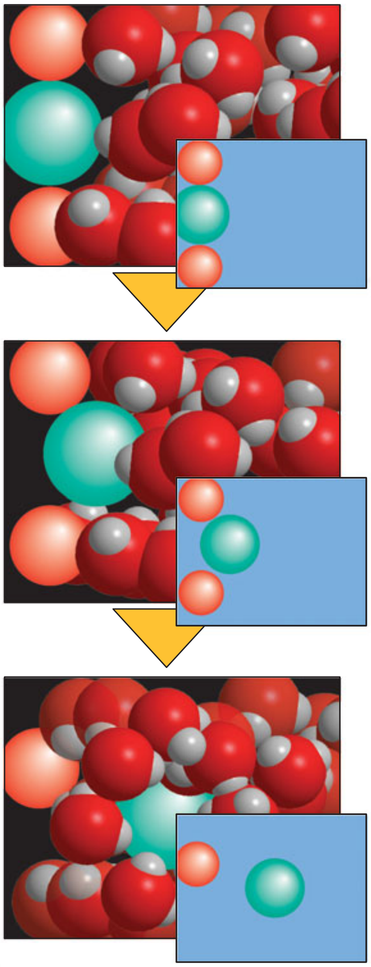

FIGURE 9.15 The events that take place at the interface of a solid ionic solute and a solvent (water). Only the surface layer of ions is shown. When the ions at the surface of the solid become hydrated, they move off into the solution. The insets at the right show the ions alone.

Animation 9.15

SOLUBILITY

The presence of a solute affects the physical properties of the solvent. For instance, when salt is spread on icy sidewalks, a mixture is created with a lower freezing point than that of pure water and the ice melts to form a salt solution. In this part of the chapter we explore the molecular nature of these effects and see how to treat them quantitatively.

9.8 The Limits of Solubility

Let's imagine that we could see at the molecular level what happens when we add a crystal of glucose to some water. The water molecules next to the surface of the crystal form hydrogen bonds to the glucose molecules. As a result, the surface glucose molecules are pulled toward the solution by water molecules but are held back by other glucose molecules. When the interactions with water molecules are comparable to the interactions with the other glucose molecules, the glucose molecules can drift off into the solvent, surrounded by water molecules. A similar process takes place when an ionic solid dissolves. The polar water molecules hydrate the ions (surround them in a

FIGURE 9.16 When a little glucose is stirred into 100 mL of water, all the glucose dissolves (left). However, when enough glucose is added, some undissolved glucose remains and the solution is saturated with glucose (right).

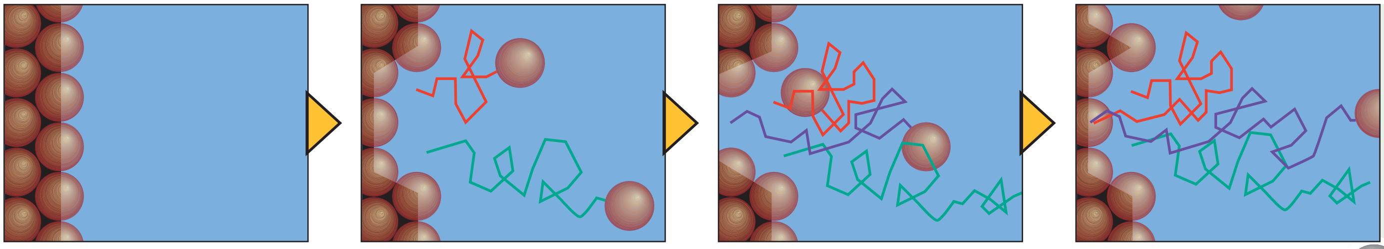

FIGURE 9.17 The solute in a saturated solution is in dynamic equilibrium with the undissolved solute. If we could follow the solute particles (orange spheres), we would sometimes find them in solution and sometimes back within the solid. Red, green, and blue lines represent the paths of individual solute particles. The solvent molecules are not shown.

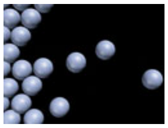

Animation 9.17

closely held "shell," Section 5.2) and pry them away from the predominately attractive forces within the crystal lattice (Fig. 9.15). Stirring and shaking speed the process because they bring more free water molecules to the surface of the solid and sweep the hydrated ions away.

If we add only a small amount—20 g, for instance—of glucose to 100 mL of water at room temperature, it all dissolves. However, if we add 200 g, some glucose remains undissolved (Fig. 9.16). A solution is said to be **saturated** when the solvent has dissolved all the solute that it can and some undissolved solute remains. At this point the concentration of solid solute in a saturated solution has reached its greatest value and no more can dissolve. The **molar solubility,** s, of a substance is its molar concentration in a saturated solution. In other words, the molar solubility of a substance represents the limit of its ability to dissolve in a given quantity of solvent.

Solubility was introduced in Section I.

In a saturated solution, any solid solute present still continues to dissolve, but the rate at which it dissolves exactly matches the rate at which the solute returns to the solid (Fig. 9.17). In a saturated solution, the dissolved and undissolved solute are in dynamic equilibrium with each other.

The molar solubility of a substance is its molar concentration in a saturated solution. A saturated solution is one in which the dissolved and undissolved solute are in dynamic equilibrium with each other.

9.9 The Like-Dissolves-Like Rule

Understanding the interplay of forces that takes place when a solute dissolves can help us answer some practical questions. Suppose, for instance, we need to remove some oil that has soiled a fabric. How can we select a good solvent for the oil? A good guide is the rule that *like dissolves like*. A polar liquid, such as water, is generally the best solvent for ionic and polar compounds. Conversely, nonpolar liquids, including hexane and tetrachloroethene, $Cl_2C{=}CCl_2$, used for dry cleaning, are often better solvents for nonpolar compounds such as hydrocarbon oils, which are held together by London forces.

We can explain the "like-dissolves-like" rule by examining the attractions between solute and solvent molecules. When a solute dissolves in a liquid solvent, the solute–solute attractions must be replaced by solute–solvent attractions, and dissolving can be expected to occur if the new interactions are similar to the original interactions (Fig. 9.18). For example, when the main cohesive forces in a solute are hydrogen

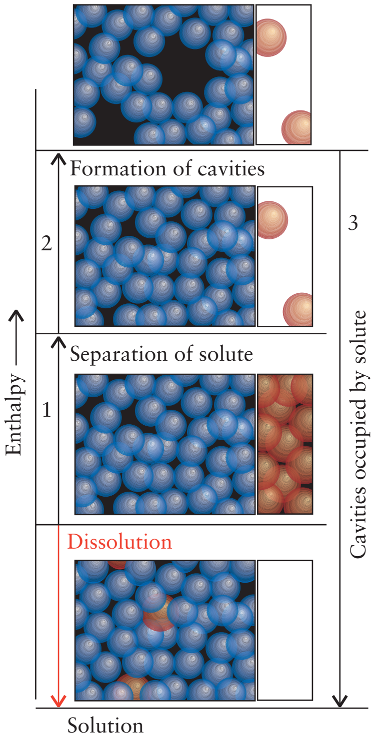

FIGURE 9.18 A representation of the changes in molecular interactions and energy associated with the formation of a dilute solution. Step 1 is the separation of solute molecules from one another. In step 2, some of the solvent molecules move apart and leave cavities in the solvent. In step 3, the solute molecules occupy the cavities in the solvent, a process that releases energy. The overall energy change for the process is the sum of the energy changes, shown by the dark red arrow. In the actual dissolving process, these steps do not occur independently.

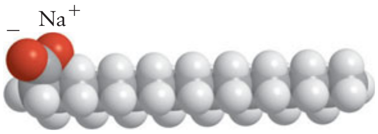
bonds, the solute is more likely to dissolve in a hydrogen-bonded solvent than in other solvents. The molecules can slip into solution only if they can replace their strong solute–solute hydrogen bonds with strong solute–solvent hydrogen bonds. Glucose, for example, has hydrogen-bond-forming —OH groups and dissolves readily in water but not in hexane.

If the principal cohesive forces between solute molecules are London forces, then the best solvent is likely to be one that can mimic those forces. For example, a good solvent for nonpolar substances is the nonpolar liquid carbon disulfide, CS_2. It is a far better solvent than water for sulfur because solid sulfur is a molecular solid of S_8 molecules held together by London forces (Fig. 9.19). The sulfur molecules cannot penetrate into the strongly hydrogen–bonded structure of water, because they cannot replace those bonds with interactions of similar strength.



3 Sodium stearate, $NaCH_3(CH_2)_{16}CO_2$

The cleaning action of soaps and detergents relies on the like-dissolves-like rule. Soaps are the sodium salts of long-chain carboxylic acids, including sodium stearate (**3**). The anions of these acids have a polar carboxylate group ($—CO_2^-$), called the *head group*, at one end of a nonpolar hydrocarbon chain. The head group is **hydrophilic,** or water attracting, whereas the nonpolar hydrocarbon tails are **hydrophobic,** or water repelling. Because the hydrophilic head group of the anion is able to dissolve in water and the hydrophobic hydrocarbon tails are able to dissolve in grease, soap is very effective at removing grease. The hydrocarbon tails sink into a blob of grease up to the head groups and the hydrophilic head groups remain on the surface of the blob. The casing of soap molecules, which is called a **micelle,** is soluble in water and so carries away the grease (Fig. 9.20).

Soaps are made by heating sodium hydroxide with a fat such as coconut oil, olive oil, or beef fat, which contain *esters* formed between glycerol and fatty acids (see Section 19.7). The sodium hydroxide attacks the esters and forms the soluble soap. In the case of beef fat, stearic acid forms the soap sodium stearate, seen in (**3**). Soaps, however, form a scum in hard water (water that contains Ca^{2+} and Mg^{2+} ions). The scum is an impure precipitate of almost insoluble calcium and magnesium stearates.

Hard water is discussed in Section 9.12.

Modern commercial detergents are mixtures. Their most important component is a **surfactant,** or *surface-active agent*, which takes the place of the soap. Surfactant

FIGURE 9.19 Sulfur, which is a solid with nonpolar molecules, does not dissolve in water (left), but it does dissolve in carbon disulfide (right), with which the S_8 molecules have favorable London interactions.

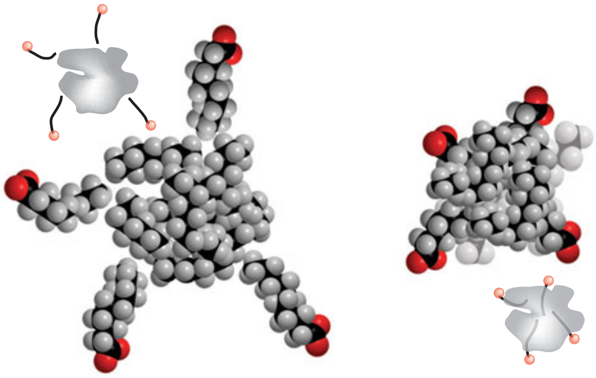


FIGURE 9.20 On the left, the hydrocarbon tails of a soap or surfactant molecule begin to dissolve in grease. (Schematic representations of the molecules, with the grease depicted as a gray blob and the polar heads of the surfactant molecules shown in red, are shown next to the space-filling models.) The water-attracting head groups remain on the surface where they can interact favorably with water (right). As more surfactant molecules dissolve in the grease, the whole blob, called a micelle, is suspended in water and is washed away.

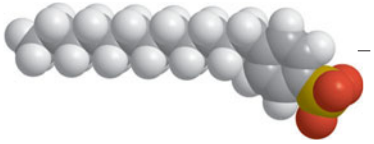
molecules are organic compounds with a structure and action similar to those of soap. A difference is that they typically contain sulfur atoms in their polar groups (**4**). Detergents are used because they do not form precipitates with the ions in hard water.



4 A typical surfactant ion

A general guide to the suitability of a solvent is the rule that like dissolves like. Soaps and detergents contain surfactant molecules that have both hydrophobic and hydrophilic regions.

9.10 Pressure and Gas Solubility: Henry's Law

Almost all aquatic organisms rely on the presence of dissolved oxygen for respiration. Although oxygen is nonpolar, it is very slightly soluble in water and the extent to which it dissolves depends on its pressure. We have already seen (in Section 4.2) that the pressure of a gas arises from the impacts of its molecules. When a gas is introduced into the same container as a liquid, the gas molecules can burrow into the liquid like meteorites plunging into the ocean. Because the rate at which the gas molecules strike the liquid increases as the pressure of a gas increases, we should expect the solubility of the gas—its molar concentration when the dissolved gas is in dynamic equilibrium with the free gas—to increase as its pressure increases. If the gas above the liquid is a mixture (like air), then the solubility of each component depends on that component's partial pressure (Fig. 9.21).

The straight lines in Fig. 9.21 show that *the solubility of a gas is directly proportional to its partial pressure, P*. This observation was first made in 1801 by the English chemist William Henry and is now known as **Henry's law.** The law is normally written

$$s = k_H P \qquad \textbf{(2)*}$$

The constant k_H, which is called **Henry's constant,** depends on the gas, the solvent, and the temperature (Table 9.5).

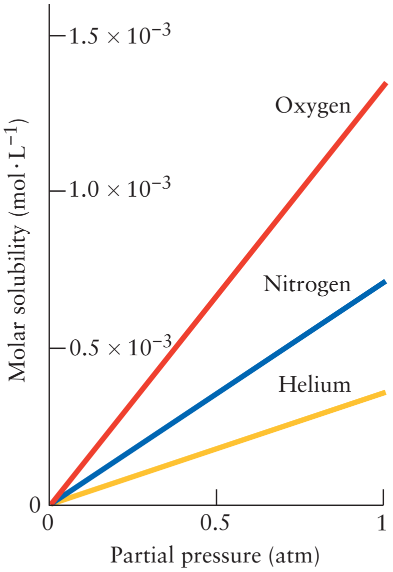


FIGURE 9.21 The variation of the molar solubilities of oxygen, nitrogen, and helium gases with partial pressure. Note that the solubility of each gas doubles when its partial pressure is doubled.

EXAMPLE 9.4 **Estimating the solubility of a gas in a liquid**

Verify that the concentration of oxygen in lake water is normally adequate to sustain aquatic life, which requires an O_2 concentration of at least 0.13 mmol·L^{-1}. The partial pressure of oxygen is 0.21 atm at sea level.

Anticipate We know that aquatic life is viable under normal circumstances, so we should expect to achieve the critical concentration, probably with a safety margin.

PLAN Use Eq. 2 to calculate the concentration of oxygen.

SOLVE

From $s = k_H P$,

$$s = (1.3 \times 10^{-3}\ \text{mol·L}^{-1}\text{·atm}^{-1}) \times (0.21\ \text{atm})$$
$$= 2.7 \times 10^{-4}\ \text{mol·L}^{-1}$$

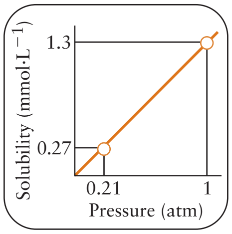

TABLE 9.5 **Henry's Constants for Gases in Water at 20°C**

Gas	k_H (mol·L^{-1}·atm^{-1})	Gas	k_H (mol·L^{-1}·atm^{-1})
air	7.9×10^{-4}	hydrogen	8.5×10^{-4}
argon	1.5×10^{-3}	neon	5.0×10^{-4}
carbon dioxide	2.3×10^{-2}	nitrogen	7.0×10^{-4}
helium	3.7×10^{-4}	oxygen	1.3×10^{-3}

Evaluate The molar concentration of O_2 is 0.27 $mmol{\cdot}L^{-1}$, which is more than adequate to sustain life, as we anticipated.

Self-Test 9.7A At the elevation, 2900 m, of Bear Lake in Rocky Mountain National Park, the partial pressure of oxygen is 0.14 atm. What is the molar solubility of oxygen in Bear Lake at 20.°C?

[***Answer:*** 0.18 $mmol{\cdot}L^{-1}$]

Self-Test 9.7B Use the information in Table 9.5 to calculate the amount (in moles) of CO_2 that will dissolve in enough water to form 900. mL of solution at 20.°C when the partial pressure of CO_2 is 1.00 atm.

The solubility of a gas is proportional to its partial pressure, because an increase in pressure corresponds to an increase in the rate at which gas molecules strike the surface of the solvent.

9.11 Temperature and Solubility

Most substances dissolve more quickly at higher temperatures than at low ones. However, that does not necessarily mean that they are more soluble—that is, reach a higher concentration of solute—at higher temperatures. In a number of cases, the solubility turns out to be lower at higher temperatures. We must always distinguish the effect of temperature on the *rate* of a process from its effect on the final outcome.

Near room temperature most gases become less soluble in water as the temperature is raised. The lower solubility of gases in warm water is responsible for the tiny bubbles that appear when cool water from the faucet is left to stand in a warm room. The bubbles consist of air that dissolved when the water was cooler; it comes out of solution as the temperature rises. In contrast, most ionic and molecular solids are more soluble in warm water than in cold (Fig. 9.22). We make use of this characteristic in the laboratory to dissolve a substance and to grow crystals by letting a saturated solution cool slowly. However, a few solids containing ions that are extensively hydrated in water, such as lithium carbonate, are less soluble at high temperatures than at low. A small number of compounds show a mixed behavior. For example, the solubility of

Exceptions to the common observation that the solubilities of gases decrease as the temperature is raised include gases that react with water, such as carbon dioxide and ammonia.

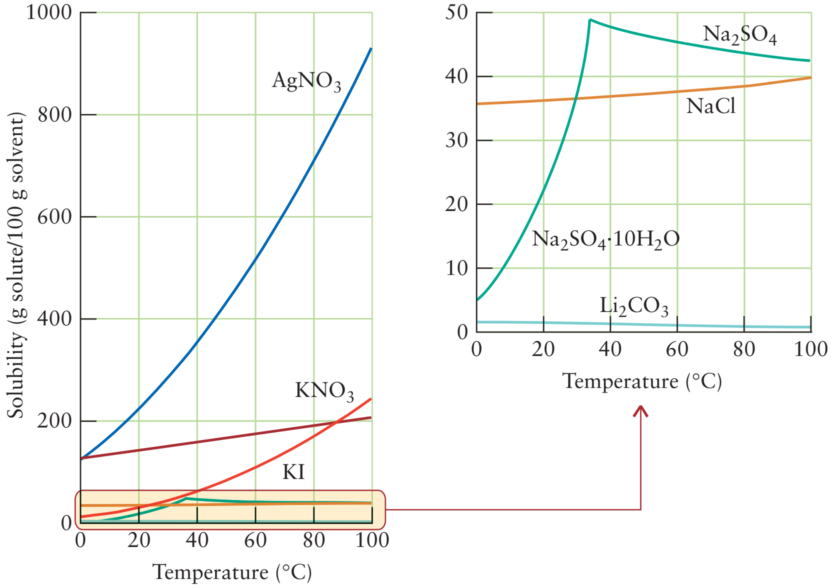

FIGURE 9.22 The variation with temperature of the solubilities of six substances in water. The graph on the right is expanded vertically to show the variation in solubilities of three ionic compounds more clearly.

TABLE 9.6 Limiting Enthalpies of Solution, ΔH_{sol}, at 25°C, in kilojoules per mole*

	Anion							
Cation	fluoride	chloride	bromide	iodide	hydroxide	carbonate	sulfate	nitrate
lithium	+4.9	−37.0	−48.8	−63.3	−23.6	−18.2	−2.7	−29.8
sodium	+1.9	+3.9	−0.6	−7.5	−44.5	−26.7	+20.4	−2.4
potassium	−17.7	+17.2	+19.9	+20.3	−57.1	−30.9	+34.9	+23.8
ammonium	−1.2	+14.8	+16.0	+13.7	—	—	+25.7	+6.6
silver	−22.5	+65.5	+84.4	+112.2	—	+41.8	+22.6	+17.8
magnesium	−12.6	−160.0	−185.6	−213.2	+2.3	−25.3	−90.9	−91.2
calcium	+11.5	−81.3	−103.1	−119.7	−16.7	−13.1	−19.2	−18.0
aluminum	−27	−329	−368	−385	—	—	—	−350

*The value for silver iodide, for example, is the entry found where the row labeled "silver" intersects the column labeled "iodide."

sodium sulfate decahydrate increases up to 32°C but then decreases as the temperature is raised further.

The rate of dissolving, but not necessarily the solubility of a substance, increases at higher temperatures. Most gases are less soluble in warm water than in cold water; solids show a more varied behavior.

9.12 The Enthalpy of Solution

The change in molar enthalpy when a substance dissolves is called the **enthalpy of solution,** ΔH_{sol}. The change can be measured calorimetrically from the heat released or absorbed when the substance dissolves at constant pressure. However, because solute molecules interact with one another as well as with the solvent, to isolate the solute–solvent interactions we focus on the **limiting enthalpy of solution,** the enthalpy change accompanying the formation of such dilute solutions that the solute–solute interactions are negligible (Table 9.6). The data show that some solids, such as lithium chloride, dissolve exothermically, with a release of heat. Others, such as ammonium nitrate, dissolve endothermically.

To gain insight into the values in Table 9.6, we can think of dissolving as a hypothetical two-step process (Fig. 9.23). In the first step, we imagine the ions separating from the solid to form a gas of ions. The change in molar enthalpy accompanying this highly endothermic step is the lattice enthalpy, ΔH_L, of the solid, which was introduced in Section 7.19 (see Table 7.6 for values). The lattice enthalpy of sodium chloride (787 $kJ \cdot mol^{-1}$), for instance, is the molar enthalpy change for the process

$$NaCl(s) \longrightarrow Na^+(g) + Cl^-(g)$$

We saw in Section 7.19 that compounds formed from small, highly charged ions (such as Mg^{2+} and O^{2-}) cohere strongly and that a lot of energy is needed to break up the lattice. Such compounds have high lattice enthalpies. Compounds formed from large ions with low charges, such as potassium iodide, typically have weak attractive forces and correspondingly low lattice enthalpies.

In the second hypothetical step, we imagine the gaseous ions plunging into water and forming the final solution. The molar enthalpy of this step is called the **enthalpy of hydration,** ΔH_{hyd}, of the compound (Table 9.7). Enthalpies of hydration are negative and comparable in value to the lattice enthalpies of the compounds. For sodium chloride, for instance, the enthalpy of hydration, the molar enthalpy change for the process

$$Na^+(g) + Cl^-(g) \longrightarrow Na^+(aq) + Cl^-(aq)$$

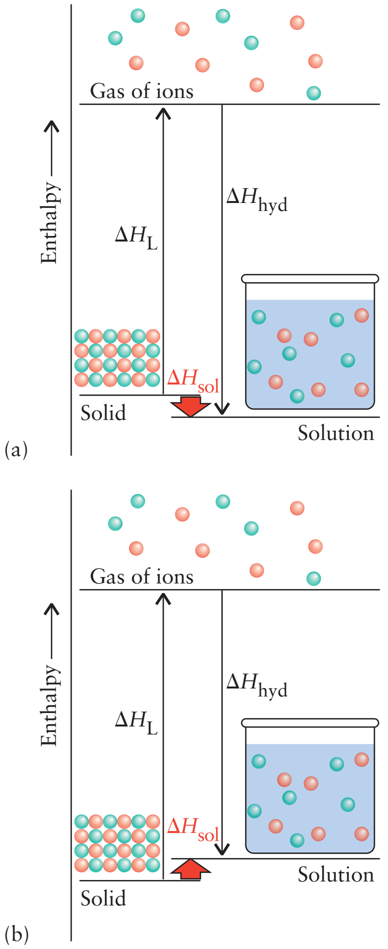

FIGURE 9.23 The enthalpy of solution, ΔH_{sol}, is the sum of the enthalpy change required to separate the molecules or ions of the solute (the lattice enthalpy, ΔH_L; step 1 in Fig. 9.18), and the enthalpy change accompanying their hydration (ΔH_{hyd}; steps 2 and 3 in Fig. 9.18). The outcome is finely balanced: (a) in some cases, it is exothermic; (b) in others, it is endothermic. For gaseous solutes, the lattice enthalpy is zero because the molecules are already widely separated.

TABLE 9.7 Enthalpies of Hydration, ΔH_{hyd}, at 25°C, of Some Halides, in kilojoules per mole*

	Anion			
Cation	F^-	Cl^-	Br^-	I^-
H^+	−1613	−1470	−1439	−1426
Li^+	−1041	−898	−867	−854
Na^+	−927	−784	−753	−740
K^+	−844	−701	−670	−657
Ag^+	−993	−850	−819	−806
Ca^{2+}	—	−2337	—	—

*The entry where the row labeled Na^+ intersects the column labeled Cl^-, for instance, is the enthalpy change, $-784\ kJ\cdot mol^{-1}$, for the process $Na^+(g) + Cl^-(g) \longrightarrow Na^+(aq) + Cl^-(aq)$; the values here apply only when the resulting solution is very dilute.

is $-784\ kJ\cdot mol^{-1}$. That is enough energy for 1 g of NaCl (as a gas of Na^+ and Cl^- ions) to raise the temperature of 100 mL of water by nearly 50°C. Hydration is always exothermic for ionic compounds because of the formation of ion–dipole attractions between the water molecules and the ions. It is also exothermic for molecules that can form hydrogen bonds with water, such as sucrose, glucose, acetone, and ethanol.

Now we bring the two steps of the dissolving process together and calculate the enthalpy change for the overall process:

$$\Delta H_{sol} = \Delta H_L + \Delta H_{hyd}$$

When we include the data, the limiting enthalpy of solution of sodium chloride, the enthalpy change for the process

$$NaCl(s) \longrightarrow Na^+(aq) + Cl^-(aq)$$

is

$$\Delta H_{sol} = \underbrace{787\ kJ\cdot mol^{-1}}_{\text{Lattice enthalpy}} - \underbrace{784\ kJ\cdot mol^{-1}}_{\text{Enthalpy of hydration}} = \underbrace{+3\ kJ\cdot mol^{-1}}_{\text{Enthalpy of solution}}$$

Because the enthalpy of solution is positive, there is a net inflow of energy as heat when the solid dissolves (recall Fig. 9.23b). Sodium chloride therefore dissolves endothermically, but only to the extent of $3\ kJ\cdot mol^{-1}$. As this example shows, the overall change in enthalpy depends on a very delicate balance between the lattice enthalpy and the enthalpy of hydration.

Thinking point: Why does sodium chloride dissolve in water spontaneously despite the fact that the dissolving is endothermic?

High charge and small ionic radius both contribute to a high enthalpy of hydration. However, the same properties also contribute to high lattice enthalpy. It is therefore very difficult to make reliable predictions about solubilities on the basis of ion charge and radius. The best we can do is to use these properties to rationalize what is observed. With that limitation in mind, we can begin to understand the behavior of some everyday substances and the properties of some minerals. For example, nitrates have big, singly charged anions and hence low lattice enthalpies. Their hydration enthalpies, though, are quite large because water can form hydrogen bonds with the nitrate anions. As a result, they are rarely found in mineral deposits because they are soluble in groundwater, the water that trickles through the ground and washes away soluble substances. Carbonate ions are about the same size as nitrate ions, but they are doubly charged. As a result, carbonates commonly have higher lattice enthalpies than do nitrates, and it is much harder to break the ions out of solids such as limestone (calcium carbonate). Hydrogen

carbonate ions (bicarbonate ions, HCO_3^-) have a single charge and their salts are more soluble than carbonates.

The difference in solubility between carbonates and hydrogen carbonates is responsible for the behavior of "hard water," which is water that contains dissolved calcium and magnesium salts. Hard water originates as rainwater, which dissolves carbon dioxide from the air and forms a very dilute solution of carbonic acid.

Although we write the reaction as leading to the formation of H_2CO_3, a high proportion of dissolved carbon dioxide remains unreacted.

$$CO_2(g) + H_2O(l) \longrightarrow H_2CO_3(aq)$$

As the water runs over and through the ground, the carbonic acid reacts with the calcium carbonate of limestone or chalk and forms the more soluble hydrogen carbonate:

$$CaCO_3(s) + H_2CO_3(aq) \longrightarrow Ca^{2+}(aq) + 2\,HCO_3^-(aq)$$

These two reactions are reversed when water containing $Ca(HCO_3)_2$ is heated in a kettle or furnace:

$$Ca^{2+}(aq) + 2\,HCO_3^-(aq) \longrightarrow CaCO_3(s) + H_2O(l) + CO_2(g)$$

The carbon dioxide is driven off and the calcium carbonate is deposited as the hard, insoluble deposit known as *scale*.

Enthalpies of solution in dilute solutions can be expressed as the sum of the lattice enthalpy and the enthalpy of hydration of the compound.

Remember that ΔG is a measure of the overall change in entropy: at constant temperature and pressure, ΔS is the change in entropy of the system and $-\Delta H/T$ is the change in entropy of the surroundings (Section 8.9).

9.13 The Gibbs Free Energy of Solution

A negative enthalpy of solution tells us that energy is released as heat when a substance dissolves. However, to judge whether dissolving is spontaneous at constant temperature and pressure, we need to consider the change in Gibbs free energy, $\Delta G = \Delta H - T\Delta S$. In other words, we have to consider changes in the entropy of the system, not just the change in enthalpy.

The disorder of a system typically increases when a solid dissolves (Fig. 9.24). Therefore, in most cases, we can expect the entropy of the system to increase when a solution forms. Because $T\Delta S$ is positive, this increase in disorder makes a negative contribution to ΔG. If ΔH is negative, we can be confident that ΔG is negative overall. Therefore, we can expect most substances with negative enthalpies of solution to be soluble.

In some cases, the entropy of the system is lowered when the solution forms because the solvent molecules form cagelike structures around the solute molecules. As a result, ΔS is negative and the term $-T\Delta S$ makes a positive contribution to ΔG. Even if ΔH is negative, ΔG might be positive. In other words, even if energy is released to the surroundings, the increase in the entropy of the surroundings may not be enough to overcome the decrease in entropy of the solution. In such a case ΔG is positive and the substance does not dissolve. For this reason, some hydrocarbons, such as heptane, are insoluble in water even though they have weakly negative enthalpies of solution.

If ΔH is positive, $\Delta G = \Delta H - T\Delta S$ can be negative only if $T\Delta S$ is positive and larger than ΔH. That is, the solubilities of substances that dissolve endothermically depend on the balance of the entropy change of the system and that of the surroundings. A substance with a strongly positive enthalpy of solution is likely to be insoluble, because the entropy of the surroundings may decrease so much as energy leaves them and enters the solution that dissolving corresponds to an overall decrease in disorder.

Understanding the contributions to the Gibbs free energy of dissolving helps us to explain the temperature dependence of solubility. The Gibbs energy becomes more

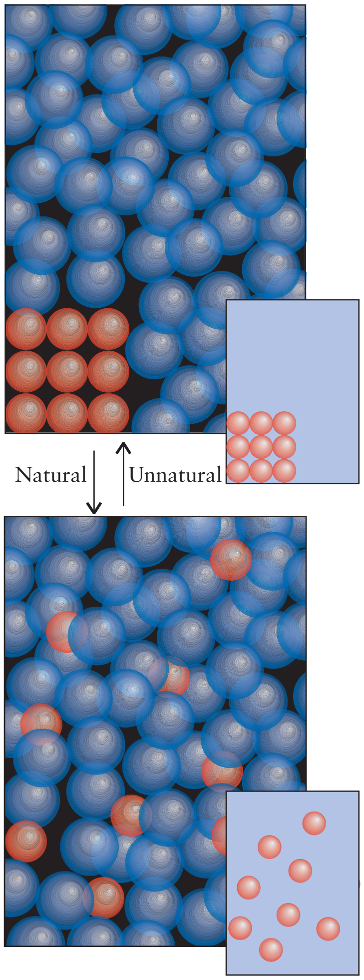

FIGURE 9.24 The dissolution of a solid is a natural process that is usually accompanied by an increase in disorder. However, to decide whether the dissolution is spontaneous, the accompanying changes in the surroundings must be considered, too. The insets show the solute particles alone.

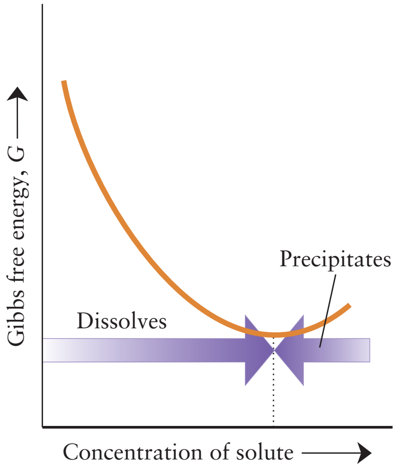

FIGURE 9.25 At low concentrations of solute, dissolving is accompanied by a decrease in Gibbs free energy of the system; so it is spontaneous. At high concentrations, dissolving is accompanied by an increase in Gibbs free energy; so the reverse process, precipitation, is spontaneous. The concentration of a saturated solution corresponds to the state of lowest Gibbs free energy at the temperature of the experiment.

The word colligative means "depending on the collection."

negative and favorable to dissolving as the temperature increases only when ΔS is positive. For most ionic substances, dissolving does indeed result in an increase in the entropy of the system and these substances are more soluble at higher temperatures (see Fig. 9.22). However, when a gas dissolves in a liquid, its molecules occupy much less space and there is a considerable reduction in the entropy of the system. In such a case $-T\Delta S$ is positive. Consequently, an increase in temperature causes ΔG to rise and dissolving is less favorable.

Because ΔG for the dissolving of a solute depends on the concentration of the solute, even if ΔG is negative at low concentrations, it may become positive at high concentrations (Fig. 9.25). A solute dissolves spontaneously only until $\Delta G = 0$. At that point, dissolved and undissolved solute are in equilibrium—the solution is saturated.

Dissolving depends on the balance between the change in entropy of the solution and the change in entropy of the surroundings.

COLLIGATIVE PROPERTIES

Some properties of a solution are essential to life. For example, *osmosis*, the tendency of a solvent to flow through a membrane into a solution, promotes the flow of nutrients through biological cell walls. When chemists started to study the physical properties of solutions quantitatively, they discovered that some properties, including osmosis, depend only on the relative amounts of solute and solvent and are independent of the chemical identity of the solute. Properties that depend on the relative numbers of solute and solvent molecules and not on the chemical identity of the solute are called **colligative properties.** The four colligative properties we shall consider are the lowering of the vapor pressure of the solvent, the raising of its boiling point, the lowering of its freezing point, and osmosis. All four properties involve an equilibrium between two phases of a solvent or (for osmosis) between two solutions with different concentrations.

9.14 Molality
